The cutting of escape wheels for watch movements requires several operations, to form the teeth accurately to their somewhat complex shape. In all except the largest watch factories, the cutting of these wheels is done on machines similar in principal to the larger automatic gear cutters used in the machine shop, excepting that a turret containing a number of spindles is used instead of the single spindle found in the larger tool. In the commercial form of automatic gear cutter, this turret is indexed by hand after each cut around the work. Some of the largest watch factories have designed machines of their own which index automatically, not stopping until the entire cutting has been accomplished. These machines, however, are not on the market. The Waltham Machine Works, Newton St., Waltham, Mass., has recently produced the machine shown in Figs. 1 and 2, which is entirely automatic in its action and is built for sale to the trade generally.

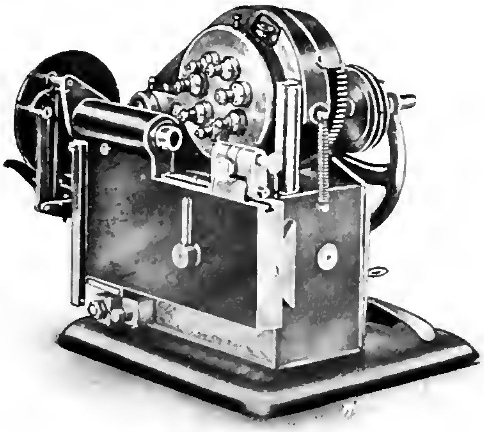

Fig. 1 Automatic Machine for Cutting Escape Wheels for Watches.

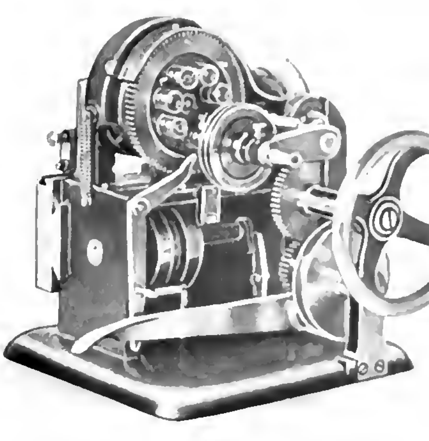

Fig. 2. View showing Mechanism within the Base

The base of the machine encloses the cam mechanism which governs its movements, as shown in the illustration Fig. 2. On the base is mounted a spindle turret, of cylindrical form, containing, in this case, seven spindles (less than seven spindles may be used in cutting shapes of wheels in which so many cuts are not required). In operation the machine takes the first cut around the wheel, indexing automatically, step by step. When the last tooth has been cut, the drive is disconnected from the cam-shaft, and engaged with the turret spindle revolving mechanism. When the turret has been indexed to a new position, the feed is again connected, when the second cut proceeds as did the first one. The last time around, at the completion of the last cut, the machine is stopped.

The spindle head swings upward about its pivot on the return stroke of the work and the indexing of the latter takes place during this movement. The periphery of the cylinder which carries the spindles, carries also a series of adjusted screws for regulating the depth of cut for each cutter. For longitudinal position, each cutter is adjusted by turning the threaded quills that serve as bearings for the spindles. Each cut is thus independently adjusted. A swing feed stop is provided for supporting the work arbor. The index mechanism is of the standard form used by this firm.

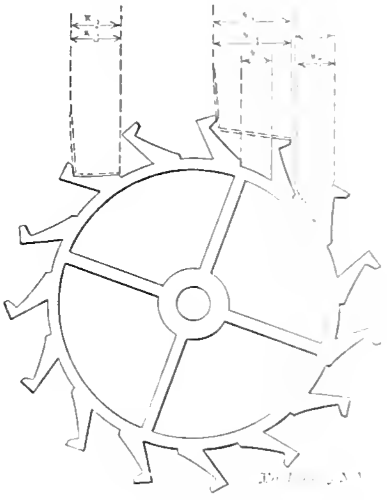

Fig. 3. Shape of the Teeth and Layout of the Cutting

Fig. 3 shows the shape of teeth produced and the layout of the cutting. It will be noted that there are in this case fifteen teeth, and that seven cuts are required to complete each tooth, making 105 cuts in all. As explained, this is done entirely automatically, and the machine stops at the completion of the 105th cut.

ARMSTRONG KNURLING TOOL.

The knurling tool shown in the accompanying illustration is made by the Armstrong Bros. Tool Co., 113 N. Francisco Ave., Chicago, Ill. Its construction is evident from a glance

at the illustration. Exclusive of the rolls and pins, it is composed of but two parts the shank, and the rocking holder for the rolls. The holder fits into a tongued and grooved circular seat in the shank, being retained in place there by a pin passing through a circular groove in the tongue formed on the shank. The holder is thus free to swivel when brought in contact with the work, so that both of the rolls bear on the metal with even pressure. This method of self-centering gives practically no lost motion, and the joint has ample bearing to resist the strains of both end and side thrust.

Armstrong Knurling Tool of Simple and Rigid Design.

This tool is furnished with either coarse, medium or fine knurls. The knurls and pins are made of hardened tool steel. The other parts are drop forged or bar steel, hardened.

NEW LINE OF POOLE BORING AND TURNING MILLS.

The J. Morton Poolé Co., Wilmington, Del., has designed a new line of boring mills for sizes from 7 to 14 feet swing. The accompanying illustrations show the general features of this new line. It is intended to meet the requirements of general shop use. The various sizes are liberal in their dimensions, and are carefully designed as to distribution of metal and weight to give the maximum efficiency at high speed. The journals and bearings are carefully scraped; bronze gears and bushings are used throughout wherever necessary. A particular point is made of ease of operation, all rapid movements being effected by power, insuring rapid production of work.

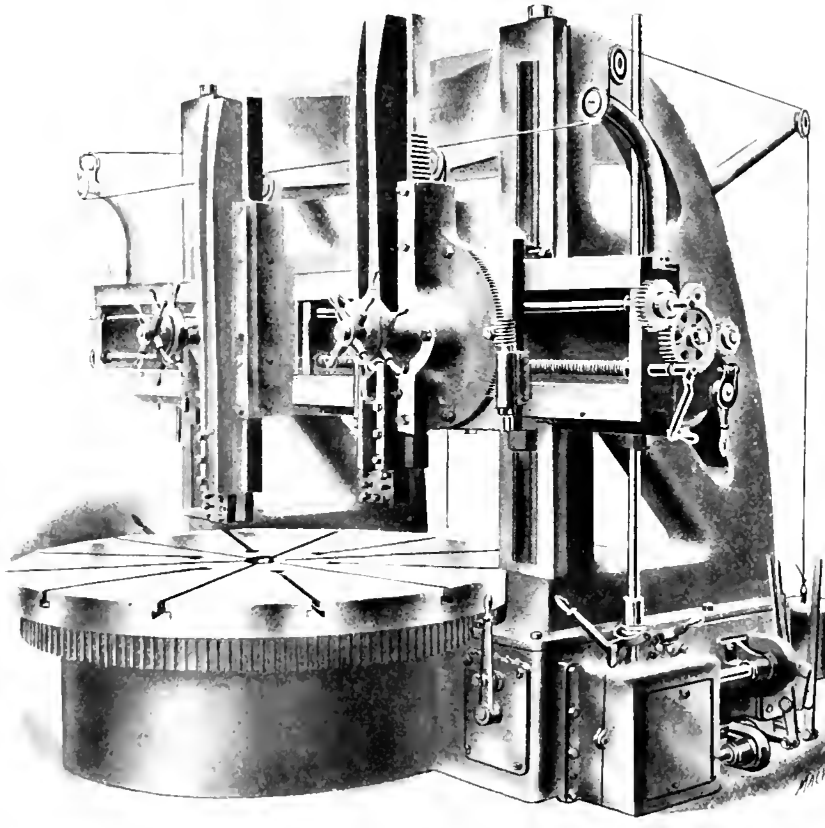

Fig. 1. Poole Boring and Turning Mill, 7 to 14 feet Swing.

A general view of one of these machines is shown in Fig. 1. It will be seen that the bed is unusually deep; it is of box construction, and is braced with internal ribs to give the required stiffness. The uprights are securely bolted to the bed, and are properly dowelled and connected by a stiff cross base. The cross rail housings and top brace can be removed from the machine, when a sweep can be attached to the table for boring large castings. Under these conditions there is no part of the machine projecting within the travel of the sweep, thus adapting it, particularly, for such work.

The drive of the machine is best seen in Fig. 2, which shows the back gearing with the cover removed. The 3-step cone shown is connected by a silent chain with the driving shaft of the back gearing. This latter, by means of positive and friction clutches, gives four changes of speed. This, with the three-step cone and two-speed counter-shaft, gives 24 table speeds in all. It will be noted that the back gear shafts are not journaled in the sides of the bed, but are set in pedestal bearings, whose caps may be removed, thus permitting the removal of the entire gearing without dismantling the mill. All the gearing at the back of the machine is well protected with a heavy gear cover, which may be easily removed. For electrical drive, the cone pulley shown is replaced with a motor, which is connected to the driving shaft in the same way by a silent chain. By using a motor having a variable speed ratio of 2 to 1, the full range of speeds given by the belt drive is obtained, but with finer gradations.

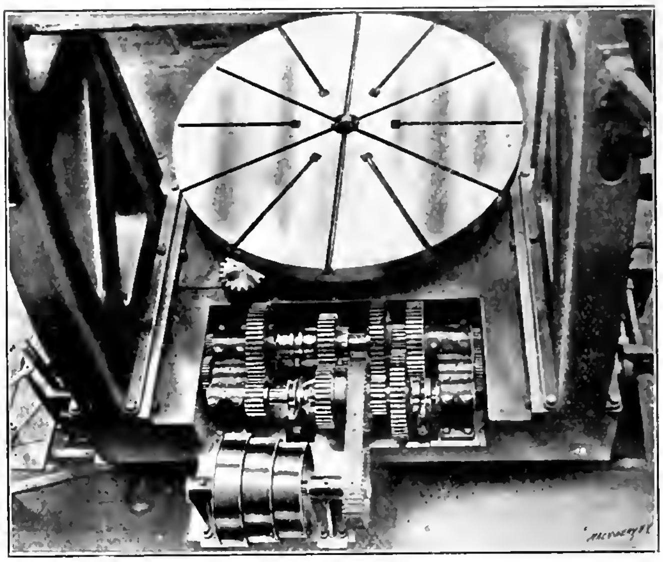

Fig. 2. Looking Down on Gear Drive from the Rear.

All the gearing is of steel, except the table gear and the driving pinion, the latter of which has 20 teeth. These are both made of a high-grade, close-grained cast iron, especially adapted for the gearing. They will be furnished with steel at an extra cost, if desired. The table is driven on a very large diameter, giving adequate power up to the full range of the machine. The table spindle is accurately finished by grinding on dead centers. It is carried in two bearings of large diameter, provided with taper bushings and adjusting screws to take up the wear. The lower bearing is supported in the bed by a heavy bonnet. Owing to the depth of the bed, the bearings can be placed far enough apart to insure stability.

The cross rail is of box girder form and of large cross section, circular in the center. It is held in position by clamps on the inside and outside edges of the uprights. It is raised and lowered by a power traverse, the mechanism of which is very simple, and is located within the bed, thus

adding to the neat appearance of the machine. The power traverse is also applied, in this machine, to the cross-heads and tool bars as well, which are handled by power in either direction, thus saving a great deal of time and labor. The rapid traverse shaft is driven by spur gearing from the intermediate back-gear shaft in both the motor- and belt-driven machines. It is impossible to throw in both the traverse and slow feed at the same time.

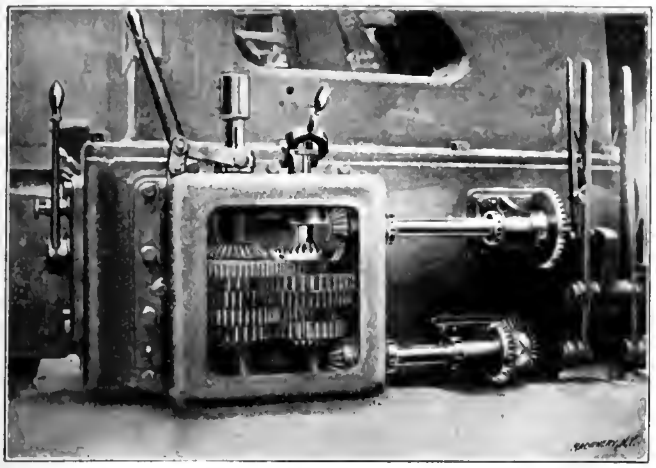

Fig. 3. Feed-box of the Poole Boring and Turning Mill.

The cross-heads are entirely independent in their movements as to direction and amount of feed; each one can be brought to the center for boring. The rams are very stiff and are separately counterbalanced by weights at each end of the rail. The counterbalance weight is connected at the rear of the frame, thus providing room for chains from overhead cranes. Each head is equipped with a forged steel square tool bar, secured by three binding screws and a set-screw. By the operation of the swivel worm, the heads can be set at any angle up to 50 degrees in either direction. Eight feeds are provided for each head, ranging from 1/40 inch to 1 inch per revolution of the table. Fig. 3 shows the feed box (there is one on each side of the table) with the cover removed. The eight changes are obtained in this box without stopping the mill. The feeds of the two heads are entirely independent. The gears are of cast iron and bronze, of coarse pitch and wide face, strong enough for the heaviest work they will ever be called on to perform.

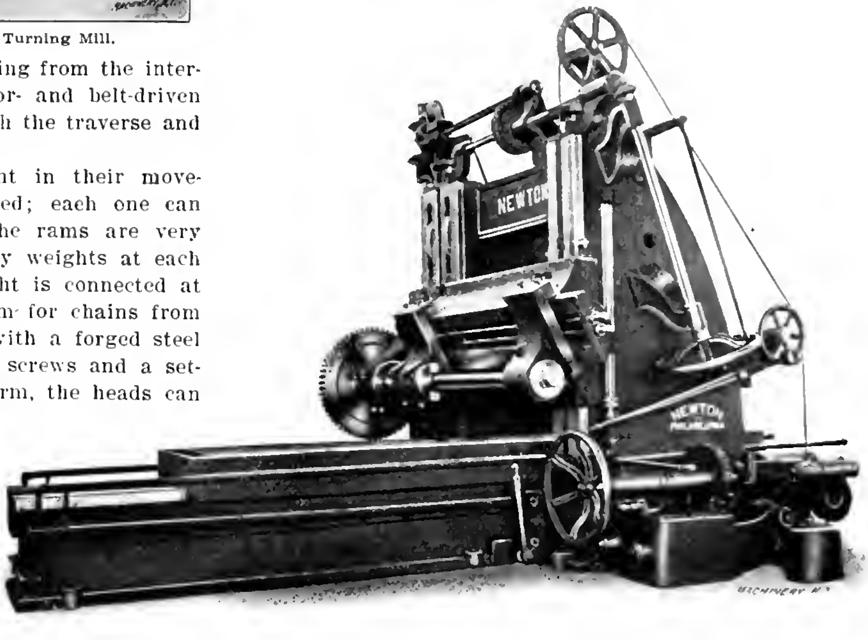

Fig. 1. Newton Horizontal Milling Machine from Operator's Side.

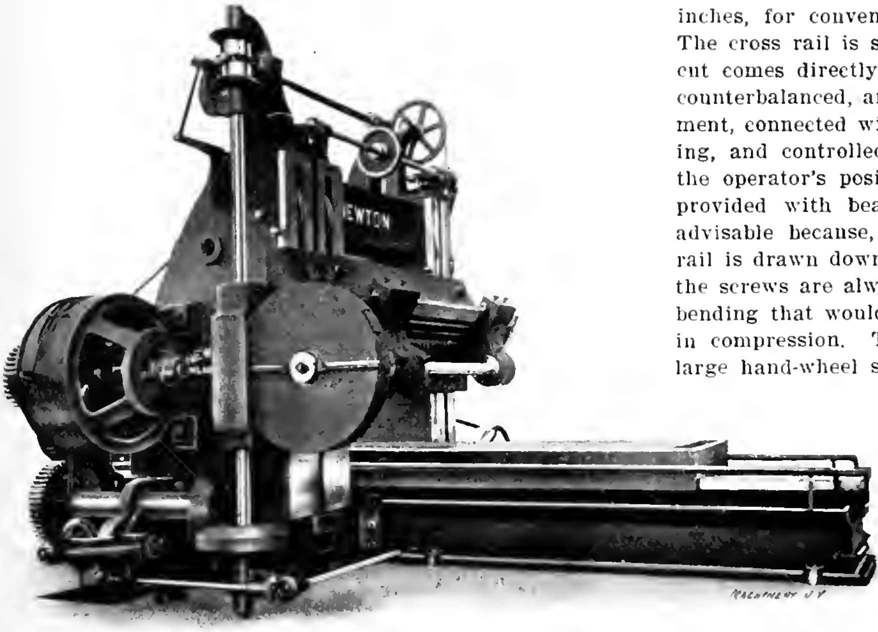

Fig. 2. Newton Horizontal Milling Machine from Motor and Worm-drive Side.

All mills of this make can be furnished with the following special attachments; threading and drum scoring, key-seating, and slotting, traveling or stationary head with revolving spindle, and special heads with various styles of tool bars for special work.

THE NEWTON NO. 7 HORIZONTAL MILLING MACHINE.

Figs. 1 and 2 illustrate the latest and heaviest designs of plain milling machines built by the Newton Machine Tool Works, Inc., Philadelphia, Pa. It is provided with the builders' latest arrangements of feed and speed control, in which all the operating handles are located on the working side of the machine, as shown in Fig. 1. The machine is intended for the heaviest kind of slab milling.

The spindle is driven, as shown in Fig. 2, by a 50 H.P. motor, which is connected by spur and bevel gears with the splined vertical shaft, mounted on the left-hand housing. This shaft drives a hardened steel worm of very steep pitch, engaging a bronze worm-wheel keyed to the spindle, and running in oil. The spindle of this machine is 8¼ inches in diameter, and has a cross adjustment along the rail of 12 inches, for convenience in setting the cutters to the work. The cross rail is set at such an angle that the thrust of the cut comes directly against the broad bearing surface. It is counterbalanced, and is provided with a rapid traverse movement, connected with the vertical shaft on the left-hand housing, and controlled by the counter-weighted lever shown at the operator's position in Fig. 1. The elevating screws are provided with bearings at both top and bottom. This is advisable because, in forcing the cutter into the work, the rail is drawn downward and by placing bearings at each end the screws are always in tension. This avoids the danger of bending that would otherwise result from having the screws in compression. The hand adjustment is by means of the large hand-wheel shown on the angular shaft in Fig. 1. At the side of the housing in this engraving will be noted a threaded rod with four adjustable collars (only two shown) for determining the vertical position of the rail for duplicating depths of cuts in manufacturing work.

The power for the feeds is taken, as shown in Fig. 2, from the horizontal driving shaft at the base of the housing, through bevel gears and a clutch by which the shaft is reversed. This clutch is controlled through the small bevel gears and rock shafts shown, by a lever on the operator's side of machine in Fig. 1. The feed shaft drive comes through to this side, where it may be connected with the feed shaft,

[illegible] a high speed ratio for the rapid movements of the table, and through the feed change box shown, which gives nine rates of feed by the manipulation of the two handles provided. This change from rapid traverse to power feed is effected by a lever conveniently placed, which also serves to lock the table in position when set centrally, with the feed thrown out. This locking is convenient when cutting down into the work. The table is fed through a spiral gear and rack. Hand adjustment is obtained by the large hand-wheel shown on the horizontal shaft in Fig. 1.

The work table of this machine is 42 inches wide, and will [illegible] 8 feet in length. The distance between the uprights, and the distance from the center of the floor to the top of the work table is 50 inches. The approximate net weight of the machine is 96,000 pounds.

NEWTON HORIZONTAL BORING, DRILLING AND MILLING MACHINE.

Figs. 1 and 2 show two views of a horizontal boring, drilling and milling machine built by the Newton Machine Tool Co., Inc., Philadelphia, Pa., for the Japanese government. These machines are interesting because of their range of capacity and the completeness of the speed, feed and rapid traverse movements incorporated. Particular attention has also been paid to bringing the various controlling handles within reach of the operator.

The machine is driven by a 7½ H.P. motor, with a speed ratio of 3 to 1. This motor is mounted on the left of the machine, and is best seen in Fig. 1. The power is transmitted from this through raw hide and steel spur gears, splined shafts and bevel gearing, to a driving shaft in the head, parallel with and above the spindle. This connection is made through a bevel gear reversing device, seen in Fig. 1, operated by a handle near the front end of the spindle, within convenient reach of the operator. The driving shaft may be set to drive the face-plate directly through the internal gear, or, for high speeds, by a longitudinal shifting of the driving shaft; the spur gear keyed to it may be engaged with a similar gear keyed to the spindle. For the face-plate drive, the pinion is cut from the solid metal of the shaft. The speed range is from 10.44 to 31.44 revolutions per minute for the face-plate drive, and from 33.75 to 101.25 revolutions per minute for the high-speed connection.

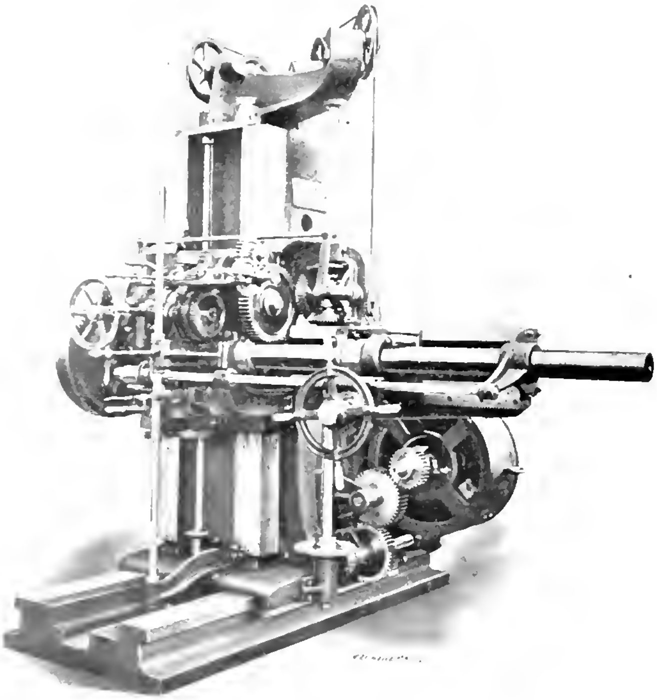

Fig. 1. Newton Horizontal Boring, Drilling and Milling Machine.

The feeds are taken from the driving shaft, through the train of gears shown. The feed operates through a bevel gear [illegible] mechanism which applies to all the feed movements in the machine. The hand-wheel on the heads gives a fine adjustment for all the machine settings. At this station the manipulation of suitable levers applies the feed either to the longitudinal traverse of the bar, the vertical traverse of the head, or the horizontal traverse of the column on the bed. The traverse of the column on the bed is effected by a spiral rack and pinion movement. In this case, the handles for throwing in the rapid movement and the power feed, interlock with each other, so that the simultaneous application of both is impossible. All the rapid movements are derived from the horizontal shaft shown below the motor in Fig. 1. The rapid movement of the spindle is by hand, through the wheel shown in the extreme right of Fig. 2. With the construction of spindle feed slide provided, the length of the bar and the length of its traverse can be increased to any amount required by the work of the purchaser.

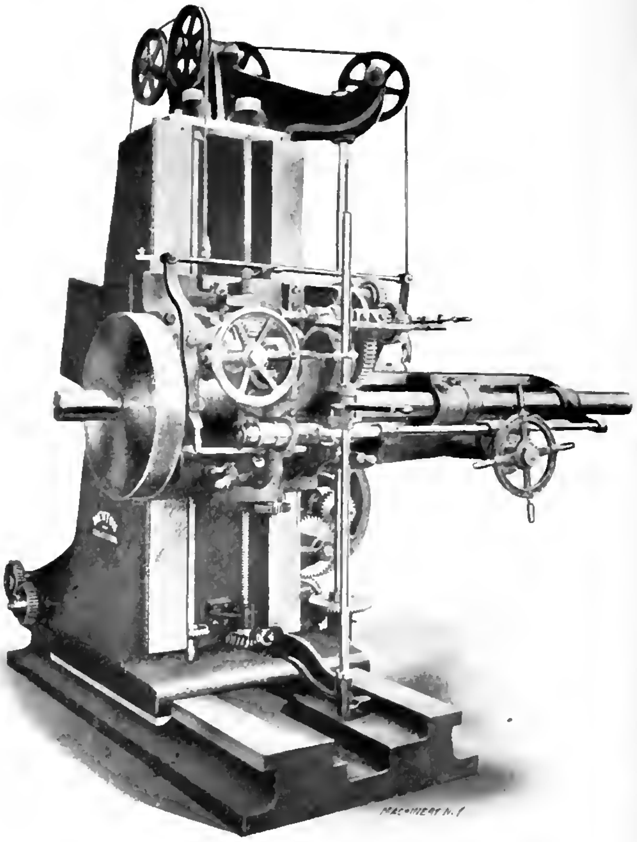

Fig. 2. Newton Horizontal Boring, Drilling and Milling Machine.

The spindle of this machine can be adjusted from 20 inches to 60 inches above the floor plate. The upright in this particular case has a horizontal movement of 4 feet, although this can be increased if desired. The face-plate of the machine is 28 inches in diameter over all. The spindle is 4½ inches in diameter and has a continuous power feed 32 inches in length; it is provided with a No. 6 Morse taper.

THE NEW BRITAIN MACHINE CO.'S POLISHING FRAME.

The polishing frame shown herewith is built by the New Britain Machine Co., New Britain, Conn., for those who prefer the form in which the spindles run in conical bearings in maple blocks. The frame is a large section, with a suitable amount of overhang, allowing tubes, cylinders, hollow ware and irregular shapes to be finished without the interference met with where straight frames are used. The weight is sufficient to avoid trouble from vibration. The base, while giving a large supporting area, is narrow and does not obstruct the work of cleaning up or sweeping the floor.

The frames are bored to take wood blocks two inches in diameter. The adjustment of these blocks is locked by set-screws, which do not, however, bear directly on the wood. Each of these set-screws is provided with a swiveling, drop

forged handle, which is always in place and may be swung out of the way so as to not interfere with the work. The belt may be led from an overhead or a rear countershaft, as desired.

The height of this machine from the center of the spindle to the floor is 32 inches; the length of arbor used is about 12 inches; and the shipping weight is 250 pounds. The arbor is not regularly furnished, but any form suitable to the customer's work will be supplied at extra cost.

A Polishing Frame for Wood-centered Spindles.

SLOCOMB REFERENCE DISKS.

The J. T. Slocomb Co. of Providence, R. I., is now furnishing reference disks similar to those used for testing micrometers, but arranged in sets for general use. The set shown in the illustration ranges by sixteenths from one-quarter inch to two inches. The disks are provided with handles for convenience in using; the quarter inch and five-sixteenths sizes are made in one piece with their handles, while those for the other sizes are detachable.

Set of Slocomb Reference Disks for General Use.

These disks are made of a good quality of tool steel, hardened very hard, and properly seasoned before finishing. This finishing is done with a high degree of accuracy. They are also made with considerable thickness to give them durability. Each of them is marked with the common fraction and decimal equivalent for the size, in such a manner that the dimensions are plainly see when the cone is open. The plugs on which they are placed are also numbered to correspond. The whole outfit regularly comes, as shown, in a serviceable morocco case, though the disks will be furnished singly, if desired.

WILLIAMS, BROWN & EARLE BLUE-PRINT DRYING FRAME.

The accompanying illustration shows an arrangement for drying blue-prints, made by Williams, Brown & Earle, 918 Chestnut St., Philadelphia, Pa. The difficulty of obtaining the blue-prints quickly is one that is of common occurence, and has been met by all draftsmen. Where a print is required for immediate use, it is almost impossible to dry it quickly in the old-fashioned way, by hanging it on a line and allowing it to drip onto the floor or into a sink, especially if the air of the room is saturated with water. This device saves half the time in drying, and gives the further advantage of drying the prints flat, leaving them in the best possible condition for use.

As may be seen, the apparatus consists of an inclined tray, with a draining trough at the bottom. The blue-print is spread on the back of this tray, where the extra water is removed by the rubber scraper, as shown, which also flattens it against the back of the frame. The tray at the bottom can be connected with a drain pipe, or the water can be drained off into a bucket, thus keeping the floor perfectly dry. The arrangement shown has a drying box equipped with a heater for either artificial or natural gas. It can also be furnished without the heater, and with any desired size of tray.

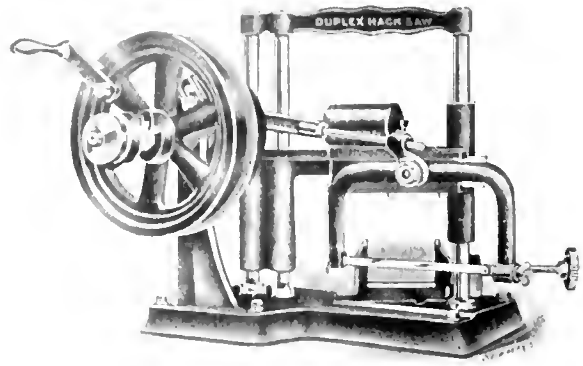
Frame for Drying Blue-prints quickly.

BUFFALO SPECIALTY CO.'S DUPLEX HACK-SAW.

The hack-saw shown herewith is built by the Buffalo Specialty Co., Buffalo, N. Y. It is unusual in that it is designed to be used either by hand or by power. It may be placed on the work bench, where it will take up no more room than the ordinary bench vise. It is thus adapted for use in garages, stock-rooms, tool-rooms, steamship engine-rooms, round-houses, and bicycle and other repair shops.

As a hand machine, it is much easier to operate than a hand hack-saw, owing to the fact that the momentum of the fly-wheel tends to steady the movement, and owing to the fact also that the hand does not have to guide the hack-saw frame. The slide bearing on which the arm operates is made

of such proportions as to insure accurate alignment and durability, thus reducing the breaking of saw blades. This bearing is adjustable to allow wear to be easily and quickly taken up. The connecting rod is adjustable, permitting saw blades to be used their entire length; the stroke is also adjustable to permit the sawing of large work, it being possible to set it

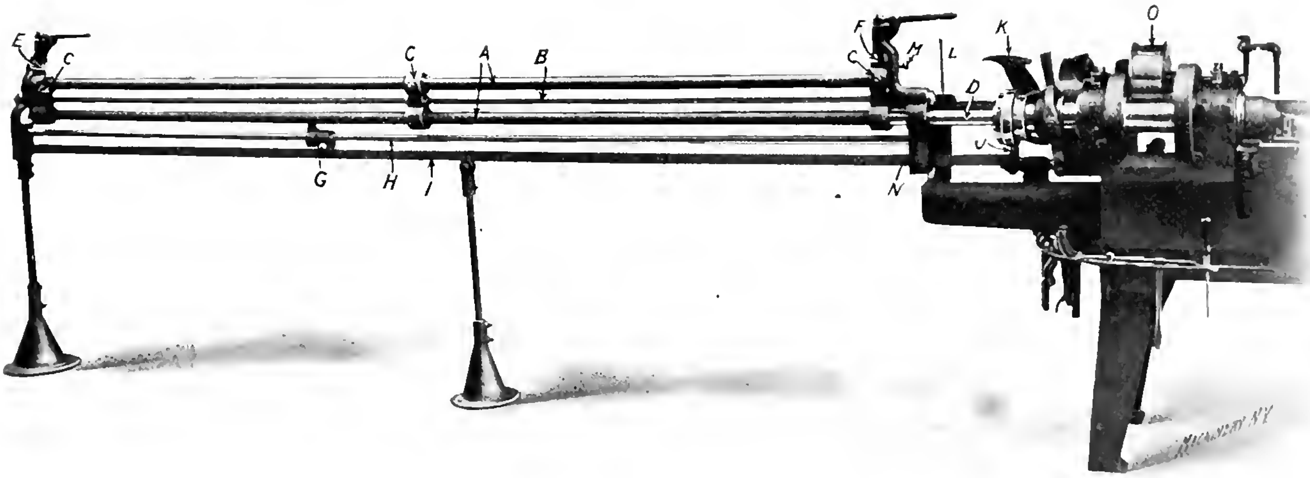


A Small Hack-saw adapted to either Hand or Power Drive.

for any stroke between 3 and 5 inches. The capacity of the machine is for stock up to 4 inches square. The length of the saw blade used is 9 inches. The speed, when power-driven, should be from 85 to 100 revolutions per minute. The net weight of the machine is 80 pounds.

MAGAZINE ATTACHMENT FOR CLEVELAND AUTOMATIC SCREW MACHINE.

The Cleveland Automatic Machine Co., Cleveland, Ohio, has recently designed a magazine attachment for use with its automatic screw machines, which is adapted to using material that hitherto could only be used at a considerable loss of time. That is to say, it may be employed for feeding, automatically, to the machine irregular lengths of stock, such as short ends of bars, tubing, pipe, etc. The machine will work these up into screw machine parts, cutting them off to exact length and discarding all that will not finish out. It handles, also, anything that is nearly parallel, such as castings and drop forgings. It is made double, so that one of the holding tubes can be filled while the other is in operation, thus involving no loss of time in stopping the machine. Another important feature is the fact that it can be attached to any of the builder's plain machines without requiring it to be rebuilt.



Automatic Screw Machine fitted up for Using Short Bars of Stock, Castings, etc.

The magazine consists of a revolving barrel composed of two steel tubes *A*, mounted on a shaft *B*, by means of three castings *C*. The lower tube is in line with the spindle of the machine and meets a tube *D* of similar size which extends through the spindle and reaches to the rear of the chuck jaws. These two tubes *A* may be revolved about the bearings in the extensions of shaft *B*, so as to bring one or the other of them in line with the spindle, when they may be locked in position by means of the two plungers *E* and *F*, seen at each end of the tubes in the photograph. These plungers may be drawn out by means of the horizontal handles shown above them. Underneath the lower tube *A* is a carrier *G*, which is free to slide on the fixed shaft *H*. Directly underneath this carrier will be seen the rack *I* which has saw-shaped teeth milled the full length of the upper edge. This rack is reciprocated by the feed lever *J* to which it is attached, this lever being operated by the regular stock feed cam which is a part of the machine. The ratchet teeth of this rack, as it is reciprocated, engage a pawl in carrier *G* and move it forward step by step, pushing the short bars of stock or individual castings through the tube and the spindle and into the chuck, one after another, as fast as the work is done. The rod *L* is an automatic stop for the machine, which is actuated by carrier *G* when this has reached its extreme forward position.

A special spindle drive is used on the particular machine illustrated, the particular features of which are a wide belt and a powerful drive through differential gearing enclosed in driving pulley *O*, which drive is thrown into action for the threading operation. When the machine is on the cutting operation, the rear train of spindle gears is used, giving a fast speed for cutting off. This change is controlled by a sliding gear arrangement operated by a lever at the rear of the spindle head.

Time Recorder, made by E. Howard Time Recorder Co. This recorder is driven by a Howard clock movement, in which the record is made on a flat sheet by stamps controlled by an arm swinging around a numbered dial.

A Loose Pulley Oil Cup, made by the Lawson Mfg. Co., Buffalo, N. Y., employs the novel plan of using the centrifugal effect of a loose piston in the oil cup to force the oil into the journal of the pulley.

A Sheet Metal Punch for general shop use on light work has been brought out by the Queen City Punch & Shear Co., Cincinnati, Ohio. This is a quick-acting punch with a narrow jaw, to permit handling light work.

An Automatic Wire Cutter which will handle brass, iron or steel wire up to 7/16 inch in diameter, is built by the Narragansett Machine Co., Providence, R. I. It will cut off lengths of wire up to 2 feet at the rate of 260 per minute.

A New Pressure Blower has been placed on the market by the Natural Power Co. of St. Louis. The particular feature of this blower is the design of the runner, which gives, it is claimed, a high-pressure with a very low rotative speed.

An Alternating Current Motor Brake has been developed by the Westinghouse Electric & Mfg. Co., Pittsburg, Pa. This

brake is held open by an electro-magnet and is closed by springs, though the braking force is increased by the rotation of the brake drum itself.

A Portable Milling Machine for truing up the pedestal bearings of car truck frames is built by H. B. Underwood & Co. (Flanders Machine Works), 1024 Hamilton St., Philadelphia, Pa. While adapted to this special work, it is also applicable to general portable milling.

A Multiple Hand Punch, for piercing a number of holes at once, is made by the Lansing Machine Co., Lansing, Mich. This tool will easily pierce 24 holes in No. 16 gage sheet steel. The surface of the die is so shaped that only four of the punches are working at once.

A Motor-Driven Speed Lathe, made by the American Wood Working Machinery Co., Rochester, N. Y., has a General Electric motor mounted directly on the spindle as a part of the head-stock. The carriage is provided with a rack feed on the bed, and has a cross slide and compound rest.

The "G. M." Screw-Cutting Engine Lathe has been placed on the market by the G. M. Lathe Co., Lennox Bldg., Cleveland, Ohio. It is intended to fill the demand for a low-priced lathe for automobile garages, jobbing machine shops, etc. It is driven by a five-step cone pulley, and swings 16¼ inches over the shears.

A Power Hack-saw Machine built by Henry G. Thompson & Son Co., New Haven, Conn., introduces the feature of a positive lift and a quick return on the back stroke. The machine is intended for use on 10-, 11-, or 12-inch blades, and will operate on stock up to 5 inches in diameter. An automatic stop is provided.

A Cam-Cutting Machine has been brought out by the Garvin Machine Co., Spring and Varick Sts., New York City. It has a large capacity, being able to cut cams up to 36 inches in diameter of face, edge, disk, or cylinder types. It resembles in its construction a profiling machine, provided with special appliances for holding the work and the master cam.

A Heavy Drilling Vise is made by the Titus Machine Works of Marion, Ohio. It is similar to that built by the same firm and described in the department of "New Machinery and Tools" in the July, 1907, issue of Machinery, but is made much heavier, so that it is useful for milling machine and planer work as well as for the drill press.

An Emery Wheel Stand with a Skeleton Frame, built of castings and steel rods, is made by George E. Soper, Kankakee, Ill. The spindle is arranged to be belted directly with the line shaft, the spindle being started or stopped by raising or lowering the head on which it is mounted in a manner somewhat similar to that followed in some designs of buffing wheel stands.

A line of Shaft Turning, Straightening and Polishing Machinery of the continuous type has recently been brought out by the Brightman Mfg. Co., Shelby, Ohio. Material as short as 8 feet in length can be machined. The apparatus consists of two machines, the first of which turns the stationary shafting, while in the second it is finished by being passed between straightening and polishing rolls.

The Magnetic Chuck, built by O. S. Walker & Co., Worcester, Mass., has recently been adapted to holding very small work. This has been done by cutting the serrated pole faces of the magnet with finer teeth, thus giving a greater number of magnetic gaps in the length of the face. Special templets may be employed for centering the work over the gap in the pole faces.

An Electric Operation Recorder is made by the Bristol Co. of Waterbury, Conn., for recording the occurrence and duration of different operations such as the starting and stopping of machines, opening and closing of valves, the passing of trains, etc. Each instrument may be furnished with as many as twelve recording pens. The paper dial used gives a complete record for twenty-four hours.

The "Stuyvesant" Turret Lathe is the name given to a new product of the J. G. Blount Co., Everett, Mass. This lathe is intended for the general run of chucking and turret lathe work in the machine shop. The ways are of the flat type; another noticeable feature of the design is the fact that the cone is reversed from the usual position, having a small step in the front.

A Double-Spindle Drilling Machine, built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., employs a cross-rail with two complete spindle-heads adjustable on it. This cross-rail is mounted on two housings which, in turn, support a work table 20 inches wide by 6 feet 5 inches long. There are four belt speeds. The back gears double this number for each spindle.

The Carr Tool Holder, built by Carr Bros. of Syracuse, N. Y., and described in the new tools department of the November, 1907, issue of Machinery, has recently been improved by the provision of arrangement for adjusting the height of the tool post without losing any of the rigidity that characterizes the older form. It has also been adapted to the use of turning and boring tools, as well as side tools.

An Automatic Nut Tapping Machine of the type in which the tap floats freely, and is centered and held from revolving by the stream of nuts passing over its shank, has been designed by Mr. W. M. McKenzie, 39 Park Place, New Rochelle, N. Y. With this style of nut machine the process of tapping is a continuous one, it not being necessary to remove the tap to empty the nuts from the shank.

A Direct Process for Copying Blueprints is being introduced in the United States by Williams, Brown & Earle, 918 Chestnut St., Philadelphia, Pa. This, which is known as the "Duplico" process, consists in brushing a solution over the blueprint, washing it, dipping it in a second solution, again washing, and, after drying, making it translucent by a third solution. This gives a negative from which prints can be made on any kind of sensitized paper.

A Hot Pressed Nut Machine, built by the Acme Machinery Co., Cleveland, Ohio, has been specially designed for the most severe working conditions and for the utmost durability and freedom from repairs. The bed is a single steel casting. The gearing is of steel, as are all the working parts, the bearing surfaces being of hardened tool steel and phosphor bronze, with cast iron lining strips, plates and bushings. Radical improvements in the mechanism have been introduced also.

A Tool-Holder for Turning Locomotive Tires has been brought out by the G. R. Lang Co., Meadville, Pa. The blade is of the straight, forming tool variety, and is held in a dovetail seat in the holder, which grasps it firmly on the sides. Notches cut in the back of the blade engage the clamping bolt in such a way as to give a positive backing for the thrust of the cut. The holder is of course useful for holding tools of other shapes, besides those employed in railroad shops.

A Thermo-Electric Pyrometer, made by the Wilson-Maeulen Co., 1 East 42d St., New York, has been equipped by its builders with an electrical alarm attachment which rings the bell when the temperature indicated passes the prescribed maximum and minimum limits. It can be quickly adjusted for any desired limits. Another device brought out by the makers provides for shifting the connections automatically to give an indication from different furnaces successively, at intervals of a few minutes apart.

A Grinding Attachment, known as the "Marvel," built by Armstrong Blum Mfg. Co., 113 N. Francisco Ave., Chicago, Ill., is arranged to be attached to the lathe or planer without

requiring any change in the over-head works. The drum for driving the grinding wheel on the carriage of the lathe or the slide of the planer, is carried by removable supports attached to the machine itself. In the case of the lathe, this drum counter-shaft is driven from the large step of the cone pulley.

A New Line of Tool Holders has been brought out by the Clifford Tool Co., Concord, N. H. The holders are made entirely of tool steel, so that they are not injured by the severest clamping strains to which they may be subjected. They are made in both straight and off-set styles. A valuable feature of their construction is the fact that the blades can be used until they have been ground very short, thus making the holders very economical in the use of costly high-speed steel.

A Combination Wheel and Disk Grinder, built by the Garvin Machine Co., Spring and Varick Sts., New York, is made along novel lines. The frame is of the milling machine type. The work table is oscillated by a worm-driven crank in the countershaft. The rear end of the spindle carries an emery-wheel for general purpose grinding. The emery disks furnished are provided with a gummed solution spread on them, which merely has to be moistened before application to the plate, no press being necessary.

A Horizontal Bulldozer is made by Logemann Bros., Milwaukee, Wis., which may be converted into a horizontal crank riveter. When so arranged, it is provided with a hydraulic holder-on, operated by an accumulator provided with the machine, which holds the work against the die with a certain definite pressure, but still allows the holder to recede when the stock is thick, or the rivet large; it allows it to advance in the case of opposite conditions. The builders also make a plain bulldozer of the same general construction, but without the gap required by the riveting machine.

An Automatic Double Slide Press, built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., involves the novel construction of employing what is practically a series of eight subpresses, through which the strip of stock is passed by a roll and ratchet feed. As the press is double acting, the variety of operations it is possible to perform is almost limitless. At 180 strokes per minute, the regular working rate, it completes that number of parts per minute, performing in the same time 1,440 operations, all of which are completed without any re-handling.

Portable Oxy-Acetylene Outfit. This outfit consists of an acetylene generator and carbon generator, mounted on a truck so that it can be taken from place to place as required by the work to be done. The acetylene is produced by lump carbide, and the oxygen by the heating of a mixture of black oxide of manganese and chlorate of potash, the heating being done by Bunsen burners fed from the acetylene tank. This apparatus has been designed to meet all fire insurance requirements, and provides for the doing of autogenous welding in a very simple and satisfactory way. The builder of the apparatus is F. C. Sanford Mfg. Co., Bridgeport, Conn.

Machine for Bending Rods or Bars. This machine, which is made by the Wallace Supply Co. of Chicago, Ill., was particularly designed for bending rods for reinforced concrete work. It is applicable, however, to all operations of this sort within its range, which is for work up to 1 inch in diameter or $\frac{1}{2}$ x 4 inches, in soft stock, cold. This great power is obtained, while still making rapid handling possible on smaller work, by providing two means of operating the bending dies. For small work, the bending is done directly by hand. For heavier work, a gear and pinion connection is operated by a ratchet lever, thus giving increased power.

A New 8-Inch Bench Lathe has been brought out by the Waltham Machine Works, Waltham, Mass. It involves a number of improvements in its construction, differing from the usual design of this type of lathe. One of the most noticeable of these differences is the placing of the large end of the cone pulley at the front end of the bearing, and the provision of unusually large chuck and spindle capacity. The removal of the pulley screw is all that is required to withdraw the spindle out through the front bearing. Convenient forms of slide rests are provided, together with chasing, screw cutting, grinding, milling, and other attachments.

A Hand Threading Machine, made by the Threading Machine Co., Sandusky, Ohio, has the novel feature of a positive lead screw for the chasers. The apparatus also includes a conical ring which automatically closes the chasers with the proper taper for the standard Briggs thread. An automatic throw-out is also provided which removes the chasers from contact with the pipe when the thread has been cut to the proper distance. The smaller sizes of this tool are operated by handles in a way similar to the ordinary threading die stock. The larger sizes are mounted on tripods or benches, and are geared to work by hand cranks.

A Large Portable Boring Machine, built by the Beaman & Smith Co. of Providence, R. I., is notable for its compactness and neatness of design, and for the way in which all the controlling handles have been brought within easy reach of the operator's platform. It consists of a traveling column mounted on a base-plate, and carrying a 10 H.P. variable speed motor for driving the spindle. The spindle has a power feed longitudinally, a vertical feed for the saddle on the column, and a horizontal feed for the column on the bed. Quick traverse is also provided for these movements. The column travel is 6 feet, and the vertical movement of the saddle, 4 feet 6 inches. The boring spindle is 5 inches in diameter and has eighteen speed changes.

An Enclosed Pinion Type Drill Chuck has been put on the market by the T. R. Almond Mfg. Co., Ashburnham, Mass. This is the well-known Almond type of chuck, altered to permit the use of a pinion and square end key for tightening. The body of the chuck is recessed to receive the pinion, which meshes with teeth cut in the front of the geared nut. As the pressure on the nut is at the back, the same wearing surface is preserved as in the former chuck of this make. A cap covers the pinion and provides a support for the outer end while the inner end has a bearing in the body of the chuck. Both pinion and nut are made of a special grade of tool steel, tempered. The knurled sleeve can be used for quick adjustment, as formerly, while the key is used for final tightening.

* * *

The growing scarcity of lumber in the United States makes the use of concrete for building and general construction work imperative wherever it can be employed, but a great drawback to the use of concrete in monolithic construction—the most desirable form—is the necessary use of a large amount of lumber for the forms to support the concrete during the setting period. An ingenious plan for avoiding a large part of the lumber expense and at the same time securing a superior concrete structure was employed at Camp Perry, Ohio, last summer, for the construction of a two-story mess hall. The sides of the building were molded in reinforced concrete flat on the ground. The reinforcement was steel rods interlaced into the structure in approved form so as to strengthen it around the windows and other openings. When the concrete had hardened the sides were raised to a perpendicular position and the corners were united by twisting the ends of the reinforcement rods together, and were filled out by pouring liquid cement around them. Obviously a much better concrete structure is obtained when molded flat, the material being more readily rammed into position. The labor is much reduced both as regards ramming and elevating into position. A drawback to the extensive use of this plan of erecting concrete structures is that it cannot be readily employed where buildings are close together, there being insufficient room for the side walls in horizontal position unless the buildings are separated by a distance equal to the height of the walls.

ANNUAL MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The twenty-ninth annual meeting of the American Society of Mechanical Engineers will be held in the Engineering Societies Building, 29 W. Thirty-ninth St., New York, December 1 to 4. Six professional sessions will be held, two of them simultaneously with other sessions. The opening session will take place at 8:45 P. M. December 1, when the president will address the society on the Conservation Idea as Applied to the American Society of Mechanical Engineers. After the reading of the president's address, a social gathering will follow. During the three following days professional sessions will be held, at which a great number of papers will be presented, these papers being briefly reviewed below. On the evening of December 2, Lieutenant Frank P. Lahm, of the Signal Corps of the United States Army, will deliver an illustrated lecture on aeronautics. On the evening of December 3 there will be a reception in the Engineering Societies Building, when the president and president-elect will receive members and guests in the auditorium.

REVIEW OF THE PAPERS.

The Engineer and the People, by Mr. M. L. Cooke.

This paper contains a general discussion on the duties of the engineer, as a member of his profession, toward the public. Throughout the paper various ways in which the engineer can fulfill these duties are pointed out, and special attention is given to the lines along which engineers could be particularly active in the public interest. The paper lays down a general plan for a larger measure of cooperation between engineering societies and the general public.

Aeronautics, by Major G. O. Squier.

This paper is the first presentation of the subject of aeronautics before a national engineering society in America. The author is connected with the Signal Service of the United States Army, and has, consequently, had an opportunity to observe at close range the construction, equipment and principles of operation of heavier-than-air machines, and dirigible balloons. The paper contains much valuable information, due to the fact that the material upon aviation on file in the War Department has been placed at the disposal of the author for the preparation of his paper.

A Method of Obtaining Ratios of Specific Heats of Vapors, by Mr. A. R. Dodge.

A method of obtaining ratios of specific heats which does not involve the use of available steam tables conceded to be inaccurate for such investigations, is given in this paper. The method is based upon the expansion of fluid initially superheated in a throttling calorimeter, and tables are included giving data for calculations.

The Total Heat of Saturated Steam, by Dr. H. N. Davis.

This paper contains the results of another investigation along the same lines as that outlined in the paper by Mr. A. R. Dodge, referred to above. The author reviews various experiments made, and compares the formulas by means of which the total heat of saturated steam can be determined. A new formula which differs somewhat from the classic Regnault's formula, is given, together with diagrams showing the deviation between the results obtained by the two formulas.

Fuel Economy Tests, by Mr. C. R. Weymouth.

Results of tests made at the 15,000 K. W. power plant of the Pacific Light and Power Company, Redondo, Cal., are here presented. The power plant has steam engine prime movers, crude oil being used for fuel. The results of the tests indicate a remarkable economy for all conditions, and of special interest is the almost uniform fuel economy for the plant, for all fractional loads from about one-half load up to the maximum capacity.

Unnecessary Losses in Firing Fuel Oil and an Automatic System for Eliminating Them, by Mr. C. R. Weymouth.

The author presents as a solution to the problem of automatic firing of steam boilers in plants using liquid fuel, an automatic system of regulation. The development and details of this system are explained, as well as results obtained by its practical application.

Efficiency Tests of Milling Machines and Milling Cutters, by Mr. A. L. De Leeuw.

Machine tool designers and machine tool builders, as well as mechanics in general, will be particularly interested in this paper, which has direct bearing on the performance of one of the most important machines in the modern machine shop Besides giving interesting data regarding tests performed on milling machines and cutters, the paper gives a general outline of the logical principles followed by the machine designer in developing what might be called a scientificially designed machine. An abstract of this paper will be found elsewhere in this issue, engineering edition.

Metal-cutting Tools without Clearance, by Mr. J. Hartness.

The objects of the tool described in this paper are: the reduction of the stresses existing at the cutting point; the provision for support of the cutting point by a bearing of the face of the tool against the surface of the metal just cut, with a view of eliminating lateral vibration; and the balancing of the side pressure upon the cutter. The cutter is supported in a holder which allows it to swivel about an axis coincident with the cutting edge, thus permitting the tool to follow the cut. A cutter with an acute point is used, which produces a continuous chip, and a chip breaker is a part of the design.

Development of a High-speed Milling Cutter with Inserted Blades, by Messrs. Wilfred Lewis and W. H. Taylor.

This paper contains a review of prevailing methods of making inserted blade milling cutters, and then outlines the reasoning which led up to the design of the milling cutter described. The paper is amply illustrated, showing the details of the design; and results of experiments carried out for testing the efficiency of the cutter in actual work, are presented. One of the most prominent features of the new milling cutter is that the blade is bent to form a helix, thus permitting a definite slope and lip angle throughout the entire length of the blade, a condition which is not possible with the ordinary inserted blade milling cutter having straight blades inserted at an angle with the axis of the cutter body.

Interchangeable Involute Gear Tooth Systems, by Mr. Ralph E. Flanders.

This paper discusses the effect of changing the addendum and pressure angle of interchangeable involute gearing, from the standpoints of interference, number of teeth in continuous action, strength, efficiency, durability, smoothness of action, etc. The comparisons of various typical involute systems in regard to these points seem to the author to justify the adoption of a new or alternative standard of smaller addendum and greater pressure angle, for use in large, heavy work, and for smaller high-speed gearing as well, if experience shows that it can be used on that work without losing smoothness of action.

Spur Gearing on Heavy Railway Motor Equipments, by Mr. N. Litchfield.

This paper deals with the breakage of gearing in heavy electric railway service. A resumé is given of the methods employed to overcome the breakage, and the strains in the teeth as calculated by the Lewis formula are shown. Attention is called to the fact that this formula is not entirely applicable on account of the difficulty in maintaining alignment of gear and pinion.

Articulated Compound Locomotives, by Mr. C. J. Mellin.

The articulated compound locomotive as met with in present American locomotive practice for heavy freight service, is described, and the object and advantages of this design are briefly referred to. By means of this construction the tractive power can be doubled over that of the ordinary engine for a given weight of rail, and, at the same time, a substantial saving in fuel is obtained.

Liquid Tachometers, by Mr. A. Trowbridge.

This paper contains an illustrated description of the operation, construction and methods of testing liquid tachometers. The principle on which the liquid tachometer acts is that the pressure developed by the centrifugal force of the liquid when the instrument is running at a certain speed, is a definite quantity. Among the many applications for which liquid tachometers have been adapted the first has been for labora-

tory service in testing dynamos and engines and other machines with revolving members. Another use for these instruments has been as a speed indicator for automobile and locomotive service

Training Workmen in Habits of Industry and Cooperation, by Mr. H. L. Gantt.

This paper deals with the old and new methods of training workmen, and maintains that if the training is based on scientific investigation, the efficiency of the workmen can be greatly increased, and employers can, as a consequence, afford to compensate those who show increased efficiency far in excess of the compensation usually paid for similar work.

Salt Manufacture, by Mr. G. E. Willcox.

This paper contains a description of the mechanical methods and engineering features of large salt plants, and reviews from the mechanical engineer's point of view, a few of the more recent developments in this manufacture. Reference is made solely to plants operated by what is known as the steam grainer system, as distinguished from the vacuum pan system and the solar or open-air system. The paper is illustrated with line diagrams and half-tone engravings and contains much of general interest.

Industrial Photography, by Mr. S. Ashton Hand.

The importance of photography in the machine industry should not be underestimated, because photography is one of the most important aids of the selling department of a machine-manufacturing plant, the photographs themselves, or, in the majority of cases, half-tones made from the photographs, being an important part of all advertising mediums. In the present paper the author describes in detail the apparatus employed and the principles considered in making photographs of industrial objects. It deals with the preparation of the subject to be photographed, the lighting and position, the focusing, the exposure, and the copying and enlarging of negatives.

Reminiscences of a Gas Engine Designer, by Mr. L. H. Nash.

In this paper the author reviews some of the steps of progress in the development of the gas engine, which have come within his personal observation. He describes different types of engines, including the two-cycle engine, and several devices of general interest invented by himself. One of these is a sewing machine motor which failed of commercial success because of the lack of mechanical appreciation of the feminine operator of this machine.

Some Possibilities of the Gasoline Turbine, by Mr. F. C. Wagner.

In considering the possibilities of a gas turbine, it is commonly assumed that the gas should be burned with something near the theoretical quantity of air required for complete combustion, the same as is done in the expansion gas engine of the ordinary type. The temperatures produced by the combustion of the gas, however, are so high that the strength of the metal wheel is seriously diminished. It is the purpose of the present paper to compare different methods for reducing the temperature of the gases, and especially to consider how such a reduction affects the efficiency of the turbine and air compressor. The paper contains considerable data which will interest gas and gasoline engine designers.

Physical Properties of Carbonic Acid and Conditions of its Economic Storage for Transportation, by Prof. Reid T. Stewart.

A number of tables and charts accompanying this paper show, in condensed form, the results of recent investigations made regarding the physical properties of carbonic acid. The value of these investigations is that they furnish the data necessary in investigating the strength and safety of existing carbonic acid cylinders, and in the designing of new cylinders on a safe and economic basis. The methods employed in carrying out the scientific investigations are reviewed, and the latter part of the paper refers directly to the design of carbonic acid cylinders, giving formulas relating to their calculation and proportioning.

The Slipping Point of Rolled Boiler Tube Joints, by Prof. O. P. Hood and Prof. G. L. Christensen.

The object of this paper is to supply data regarding the behavior of joints made by the familiar method of rolling boiler tubes into containing holes. Diagrams are presented showing the loads required to pull tubes from their seats, and results of tests with cold drawn boiler tubes rolled into various forms of tube openings, are given. The method of applying the load and measuring the slip is also illustrated and described.

Tests of Friction Clutches for Power Transmission, by Prof. R. G. Dukes.

This paper gives the results of tests on friction clutch couplings for determining their maximum capacity. Five examples of the best-known types of clutches were purchased in the open market, and all were tested under similar conditions. Each clutch was subjected to a series of cone pressures, gradually increasing in amount, the maximum load which the clutches would pick up and carry being determined for each cone pressure.

An Averaging Instrument for Polar Diagrams, by Mr. W. F. Durand.

This paper has been prepared with the intention of describing an instrument for obtaining averages for diagrams, plotted in polar coordinate. While this paper is chiefly of theoretical interest, engineers interested in dial-recording gage instruments which trace diagrams in polar coordinates, but with a curvilinear path of the tracing arm, will undoubtedly find the instrument described, of interest.

* * *

The matter of supplying machines with lubricating fluid may be decided either in favor of a distributing system of pipes supplied from a common reservoir by one pump, or by making each machine a unit in itself, having its own reservoir and pump. Both systems have certain advantages and disadvantages. If a central distributing system is installed, it is the same as "putting all your eggs in one basket"; if anything goes wrong with the piping or pump, a whole department is held up until the trouble is remedied. Again, there is the difficulty of carrying the supply and return pipes through the shop to every machine, without causing obstructions and a generally hideous mess. If the shop construction is such that the supply for one floor can be distributed underneath the floor and up to each machine through the floor beneath it, there is little objection to the distribution plan, but this plan is not always feasible. Serious troubles frequently arise from clogging of the pipes by deposits adhering until a pipe is completely filled. These difficulties are avoided by the unit system in which each machine has its own supply system. The individual system means a reservoir and pump for each machine, and instead of one pump occasionally giving trouble you may have a hundred in the course of a year. The individual reservoirs may add to the floor space required, and keeping up the supply means carrying in fresh lubricant in pails. These features are somewhat objectionable, but balancing one system against the other, Mr. McGregor, of the Union Twist Drill Co., Athol, Mass., found from personal experience that the individual system is incomparably better, and it was adopted for the twist drill fluting machines in the drill department of his company. The installation is satisfactory in all respects. The general appearance of a department fitted thus is superior to that of one having the common distributing system. The secret of success is getting pumps that are reliable, and providing strainers that strain.

* * *

The paper "High Powered Rifle and Its Ammunition" presented by Mr. Franklin Phillips at the monthly meeting of the American Society of Mechanical Engineers, November 10, was attended by a good audience of interested members. The paper was illustrated with numerous lantern slides, and many technical points in regard to the construction and use of military rifles were brought out. Captain Phillips is an expert rifle shot and spoke with much enthusiasm on the need of teaching the art of rifle shooting to young men. Captain Casey of the U. S. Army followed with a few remarks in regard to the development of the Spitzer bullet, and spoke of the change from 150-grain bullets to 180-grain bullets, made necessary by the irregularities due to windage with the lighter bullet. He was followed by Captain Waldron of the Ross Rifle Co., Mon-

treal, Canada. Captain Waldron illustrated on the screen a new cartridge developed for the Ross rifle, which gives the extraordinary initial velocity of 3,000 to 3,100 feet per second. A piece of steel plate ⅝ inch thick, 40 carbon steel, was exhibited which had been penetrated at a distance of 40 to 50 yards. Some one remarked, after the meeting, that with such guns "Mother's Bible" would not be of much service in protecting her son from the bullets of the enemy.

* * *

In the description of the handy center indicating tool by W. W. Cowles in the November issue it is stated that the ball in which the point is mounted is hardened. This is not necessary and, in fact, the ball is preferably left in the annealed condition necessary for drilling the hole. It was also intimated that the spindle of the machine must be stopped in order to use the tool. This is unnecessary as the indicator can be used without stopping the machine by simply guiding the pointer to the prick-punch mark with the finger and then withdrawing the work. The pointer will then run "out" if the center mark is not dead in line with the spindle.

* * *

PERSONAL.

William E. Keily has resigned his position as managing editor of the *Western Electrician*, and will act as a general writer on technical and commercial subjects.

Walter B. Snow, publicity engineer, Boston, Mass., has been appointed by Governor Guild, a member of the Massachusetts Commission for the Blind.

Hugh A. Brown has resigned his position in the Chicago office of the Crocker-Wheeler Co. to become sales manager for the Rockaway Coaster Co., Cincinnati, Ohio.

James A. Pratt who for the past two years has held a position as instructor in machine work at Pratt Institute, Brooklyn, N. Y., has been appointed to a similar position at Williamson Free School of Trades, Delaware County, Pa.

J. R. Gordon has been appointed manager of power apparatus sales for the Western Electric Co. in its Southern territory. Mr. Gordon is well known throughout the country as a pioneer in the electrical field, having been associated with those who organized and operated the first Edison plants. His headquarters will be in Atlanta, Ga.

F. W. A. Joly, president of the Association of German Manufacturers of Fire-brick (Wirtschaftliche Vereinigung Deutscher Chamotte Fabrikanten), is on a visit to America to study American conditions with a view of drawing therefrom applications for the fire-brick industry in Germany. The association of which he is president has established standards of quality and shape, reducing the number of shapes materially; it has studied the requirements of customers with reference to tensile strength, refractory qualities and uniformity of product. American fire-brick makers may obtain valuable suggestions from the experiences of German makers. Mr. Joly is making the Hotel Astor, New York, his headquarters.

* * *

OBITUARY.

Prof. William Edward Ayrton, a noted electrical engineer and inventor, died in London, November 8, aged sixty-one.

Cyrus C. Currier, of Cyrus Currier & Sons, Newark, N. J., died October 30 at his home in South Orange, N. J., aged sixty-one.

General John E. Mulford, founder and for thirty-one years president of the Prentiss Vise Co., died at his home in Montour Falls, New York, October 18, aged seventy-nine years.

Herbert D. Hale, architect of the Engineering Societies Building, New York, died at his home in New York, November 10, aged forty-two years.

Frank B. Kleinhans, chief draftsman of the United Engineering Co., Pittsburg, Pa., died in Easton, Pa., aged 34. Mr. Kleinhans was the author of the book "Boiler Construction," and a contributor to MACHINERY and other trade journals.

Alfred Marsh, a geologist and chemist, and inventor of the gas meter in common use, died November 17 at Kalamazoo, Mich., aged ninety years. Mr. Marsh was born in England and for many years was employed by the Manhattan Gas Co., New York.

William Eddy Ripley, one of the oldest and most esteemed employes of the Brown & Sharpe Mfg. Co., Providence, R. I., died November 10 at his home in that city, aged sixty-five years. Mr. Ripley was connected with the Brown & Sharpe Co. for almost all his active business life, having entered the employ of the company in 1861. Up to 1902 he was timekeeper in charge of the cost-keeping department, and since has filled the responsible position of confidential secretary. Mr. Ripley was a member of the local societies, clubs and lodges, and is survived by a widow and a son and daughter.

Samuel D. V. Burr died at his home in Plainfield, N. J., October 28, aged fifty-three. He was born in New York and moved to Plainfield when a boy, where he graduated from the Plainfield High School in 1870. Later he graduated from Rutgers College, and became a writer on engineering and scientific subjects. Mr. Burr was on the staff of the *Scientific American* for six years, the *Engineering News* for three years, and the *Iron Age* for sixteen years. He was the author of "Bicycle Repairs," "Tunneling Under the Hudson," "Rapid Transit in New York and Other Great Cities." He is survived by his wife, son and daughter.

George A. Fairfield, secretary of the Hartford Board of Trade and one of the best known business men of the city, died suddenly November 9, aged seventy-four. He was apprenticed at seventeen in the machine shop of Lucius and Ira Dimmock, Northampton, Mass., makers of silk machinery. Following his apprenticeship, he worked for several concerns, and at the breaking out of the Crimean War, was with Robins & Lawrence, Windsor, Vt., who had contracts for making guns for Great Britain. When this work was completed he went with the American Machine Works at Springfield, Mass., where he designed most of the labor-saving machinery in the U. S. Government Armory in that city. In 1857 he was employed by Colt's Patent Fire-arms Mfg. Co. of Hartford, where he worked on a contract with the Russian Government to furnish it with machinery for manufacturing fire-arms. Mr. Fairfield opened the first purely mechanical drawing school in Hartford in 1858. In 1865 he entered the employ of the Weed Sewing Machine Co. and built it up into a great enterprise. Later he was associated with Colonel Albert Pope in the manufacture of bicycles and was influential in bringing the great industry to Hartford. Mr. Christopher M. Spencer interested Mr. Fairfield in the manufacture of the Spencer repeating rifle, and it was for some time manufactured in the Weed Sewing Machine factory. Mr. Fairfield was director in a number of the important industrial and commercial concerns in Hartford.

Elmer G. Eberhardt of Newark, N. J., vice-president of the Newark Gear Cutting Machine Co., died November 21, 1908, of tuberculosis, after an illness of less than a year. He was born in Newark, 1881, and attended the public schools there. He was graduated from the Newark High School in 1896 at the age of fifteen years, and from there entered Stevens Institute at Hoboken, N. J. He was soon at the head of his class, but decided, in his second year, to take up the practical work of machine tool designing and construction, and therefore discontinued his course to engage in work with his father, Henry E. Eberhardt. After several years of this work, during which he made a number of improvements and inventions, especially relating to automatic gear-cutting machines and crank shapers, he decided to finish his technical education. He accordingly entered Sibley College of Cornell University in the middle of the school year of 1900-1901, and graduated in 1904 with the degree of mechanical engineer.

While at Cornell he acquired the nickname of the "General" because of his acknowledged leadership in the classes of mathematics, mechanics, and engineering. He was elected president of the Cornell Institute of Electrical Engineers and

Elmer G. Eberhardt.

vice-president of the Cornell Society of Mechanical Engineers. At the close of his course he was awarded the honorary key of the Sigma Xi for high scholarship in the engineering studies. Besides his studies, he was actively interested in athletics.

Upon graduation, Mr. Eberhardt entered into the machine tool manufacturing business, forming with his father and three brothers, the Eberhardt Brothers Machine Company, which is now the Newark Gear Cutting Machine Company. He was made the vice-president, and from the beginning of the business, until his illness necessitated his leaving the work which he loved, he was active in the designing and construction of the gear-cutting machines and crank-shapers made by the firm. He took out a number of patents upon inventions covering many branches of the machine field.

Mr. Eberhardt had been a contributor to MACHINERY ever since its beginning, and he many times expressed himself as much interested in the problems which appeared from time to time in its columns. He had a wide reputation as a consulting engineer upon matters especially relating to gears and gear-cutting, and engaged in original investigations along this line. He was an associate member of the American Institute of Electrical Engineers and of the American Society of Mechanical Engineers.

Mr. Eberhardt is survived by his parents, one sister and four brothers, three of whom are engaged in the business. He was beloved by all who knew him, and especially in the factory was he liked, by the apprentices and others who looked up to him as a teacher with experience.

* * *

COMING EVENTS.

December 1-4.—Annual convention of the American Society of Mechanical Engineers, Engineering Societies Building, 29 West 39th St., New York City. C. W. Rice, 29 West 39th St., New York, secretary.

December 7-10.—Annual convention of the National Commercial Gas Association, First Regiment Armory, Michigan Ave. and 16th St., Chicago, Ill. Coincident with the meeting, and throughout the week, the association will hold its annual exhibition of gas appliances. John C. D. Clark, 157 Michigan Ave., Chicago, chairman of the committee of arrangements.

December 9.—Mr. M. A. Loeb, secretary and treasurer of the Rock Island Battery Co., Rock Island, Ill., has issued a call to the manufacturers and dealers of gas and gasoline engines, and dealers and manufacturers of accessories thereto, to attend a preliminary meeting at the Auditorium Hotel, Chicago, December 9, 1908, 10 A. M., with a view of discussing and formulating plans for the formation of an association. Officers are to be elected and a committee appointed for the purpose of arranging for a national convention to be held at some time and place decided upon by the executive committee.

December 11.—Meeting of the American Institute of Electrical Engineers at 33 West 39th St., New York City, 8 P. M. R. W. Pope, secretary.

December 31-January 7.—Ninth annual show of the American Motor Car Manufacturers' Association at Grand Central Palace, New York City.

January 16-23.—Ninth annual show of the Association of Licensed Automobile Manufacturers at Madison Square Garden, New York.

NEW BOOKS AND PAMPHLETS.

THE LUMBER CUT OF THE UNITED STATES, 1907. 53 pages, 6 x 9 inches. Published by the Department of Commerce and Labor, Washington, D. C.

Charities and the Commons is a weekly journal of philanthropy and social advance issued by the Charity Organization Society of the City of New York, publication office 105 East 22d St., which will be found of value to all interested in social welfare work. The price is $2.00 per year, single copies 25 cents.

THE TEMPERATURE-ENTROPY DIAGRAM. By Charles W. Berry. 299 pages, 5 x 7¼ inches. 109 figures. Published by John Wiley & Sons, New York. Price $2.00.

This is the second edition of a volume first brought out in 1905, and intended especially for the use of students of thermodynamics. The present edition is considerably enlarged, it being more than doubled in size. A more extended application of the principles of the $T\phi$-analysis to advanced problems of thermo-dynamics has been made, the chapter on the Flow of Fluids has been entirely re-written, and various other phases of the subject in hand have been more thoroughly discussed.

THE MECHANICAL WORLD ELECTRICAL POCKET BOOK FOR 1909. 208 pages, 4 x 6 inches. Published by Emmott & Co., Ltd., Manchester, England. Price 6d. net.

This convenient and useful handbook contains considerable matter of value to electricians and others interested in the electrical industries, dynamos, and motors. Some of the different sections are headed: Electrical Units, Electrolysis, Magnets, Electric Bells, Power Transmission, Dynamos and Motors, Alternate Current Systems, Rotary Converters, Care of Dynamos and Motors, Line Wires and Conductors. Many useful tables are included, and blank pages for diary and memoranda conclude the book.

AUDEL'S GAS ENGINE MANUAL. 469 pages, 5¼ x 8¼ inches. Published by Theo. Audel & Co., New York. Price $2.00.

This book is a practical treatise relating to the theory and operation of gas, gasoline, and oil engines, and includes chapters on producer gas plants, marine motors, and automobile engines. It contains a great deal of useful information relating to the care of combustion engines. Some of the most interesting chapters are: Theoretical Working Principles; Indicator Diagrams of Engine Cycles; Fuels and Explosive Mixtures; Gas Producer Systems; Compression, Ignition and Combustion; Governing and Governors; Ignition and Igniters; Installation and Operation; Oil Engines; Testing; Nature and Uses of Lubricants.

PATENTS AS A FACTOR IN MANUFACTURING. By E. J. Prindle. 134 pages, 5 x 7½ inches. Published by The Engineering Magazine, New York. Price $2.00.

The purpose of this volume, according to the author, is not to make the inventor and manufacturer his own patent lawyer, but it is intended to convey general ideas regarding the nature of patents, the protection they may afford, the relation of employers and employees to patents and the general rules by which the courts will proceed in upholding a patent and in thwarting attempted infringement. It is intended especially to lay down fundamental principles, in order to enable the inventor or manufacturer to take the early steps which are usually taken before the advice of counsel is secured.

THE MECHANICAL ENGINEERING OF STEAM POWER PLANTS. By F. R. Hutton. 825 pages, 6 x 9 inches. 700 figures. Published by John Wiley & Sons, New York. Price $5.00.

This is the third, re-written, edition of Professor Hutton's well-known work on steam power plants. The new treatments in the present edition which are specially noteworthy are those of the analysis of the power plant, and the distinction between the simple and the complex phases of this problem; the treatment of the steam pipe as an element of co-ordinate importance with the boiler and engine; the chapters on auxiliaries; the chapter on steam turbines; and on the engine mechanism. These new sections add considerably to the value of the book, and will prove interesting to power-plant engineers and others concerned with the subject, in its engineering aspect.

MACHINE SHOP CALCULATIONS. By Fred H. Colvin. 174 pages, 4½ x 7 inches. Published by the Hill Publishing Co., New York. Price $1.00.

In the preface of this book the author states that while the treatment of the subject may be considered too elementary by some, he has tried to make every point so clear that anyone can comprehend it, and to show how the methods apply to every-day shop work. The different chapters in the book are headed as follows: Common Fractions; Decimal Fractions; Cancellation; Ratio or Proportion; Percentage; Speed of Pulleys; Speed of Gearing; Gearing a Lathe to Cut Any Thread; Screw Thread Calculations; Drilling for Taps; Taper Work; Speed of Lathes, Planers and Shapers; Square and Cube Root; Measuring Surfaces; Contents or Volume of Solid Bodies; Measuring Angles; Making and Using Formulas; The Vernier and Micrometer; Regular Polygons and Their Properties; The Uses of Shop Trigonometry; Trigonometry Tables.

RAILROAD ENGINEERING. By W. L. Webb. 296 pages, 6½ x 9½ inches. 161 figures, 23 tables. Published by the American School of Correspondence, Chicago, Ill. Price $3.00.

This book is divided into three sections, each dealing with a different phase of railroad engineering. The first section is devoted to railroad surveys, dealing with surveying methods and instruments and railroad location. The second, and by far the largest, section is devoted to construction, operation, and maintenance, and the third to the economics of railroad management; this latter part, of course, deals with this subject from the engineer's point of view. The volume is especially adapted for purposes of self-instruction and home study, and care has been taken to keep the treatment of each subject within the range of the student's understanding, so that the work appeals not only to the technically trained expert, but also to the self-taught practical man who wishes to keep abreast of modern progress. Of course elementary mathematical foundation is required in order to be able to follow the developments of the formulas and the methods explained.

CATALOGUES AND CIRCULARS.

PATTERSON TOOL & SUPPLY CO., Dayton, Ohio. Leaflets of the Owen milling machines built in three sizes.

PRATT & WHITNEY CO., Hartford, Conn. Miniature catalogue of Pratt & Whitney turret lathes, which are built in five sizes.

WEBER GAS ENGINE CO., Kansas City, Mo. Catalogue of Weber gas engines and gas producers.

SKINNER CHUCK CO., 94 N. Stanley St., New Britain, Conn. Circular of the 1904 pattern independent Skinner lathe chuck.

S. OBERMAYER CO. Cincinnati, Ohio. Catalogue No. 40 containing 369 pages devoted to foundry supplies and information for the foundryman.

NATIONAL SEPARATOR & MACHINE CO., Boston, Mass. Circulars descriptive of cylinder turret drill presses, and combined oil separator and filter.

REEVES ENGINEERING CO., Mt. Vernon, Ohio. Catalogue of Reeves vertical internal combustion engines for gas, gasoline and distillate fuels.

AMERICAN SPIRAL PIPE WORKS, P. O. Box 485, Chicago, Ill. Catalogue of spiral riveted pipe, forged steel pipe flanges, hydraulic and exhaust steam supplies.

VICTOR R. BROWNING & CO., Cleveland, Ohio. Bulletins Nos. 2 and 3, illustrating overhead electric traveling cranes and Armington electric hoists, which are made in several styles.

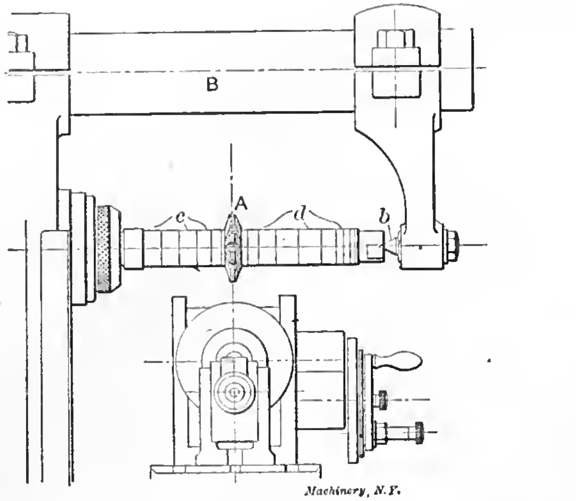
BRASS FOUNDERS SUPPLY CO., Newark, N. J. Catalogue No. 14 of flasks and other equipment and supplies for modern brass, bronze aluminum and iron and steel foundries.

Supplement to MACHINERY, January, 1909.

Operations for the Article in this number entitled "Machine Shop Practice—Gashing and Hobbing a Worm-Wheel."

SHOP OPERATION SHEET NO. 85.

John Edgar. MACHINERY, January, 1909.



Preparing the Milling Machine to Gash a Worm-wheel Blank.

Note.—This work is to be done on a universal milling machine.

1. Place the dividing head and tail-stock in place on the machine table. Since the gear connection is not needed for this work, the head may be placed in any convenient position along the table—preferably near the center.

2. Place a cutter arbor in the spindle, and select a gear cutter *A* of the proper number and pitch, corresponding to the number and pitch of the teeth to be cut in the blank.

3. The cutter should be placed on the arbor after a sufficient number of collars *c*, to bring the cutter approximately over the center of the table, have been put on. Insert the key which drives the cutter, and, after the collars *d* have been placed on the arbor, bind the cutter securely in place with the arbor nut.

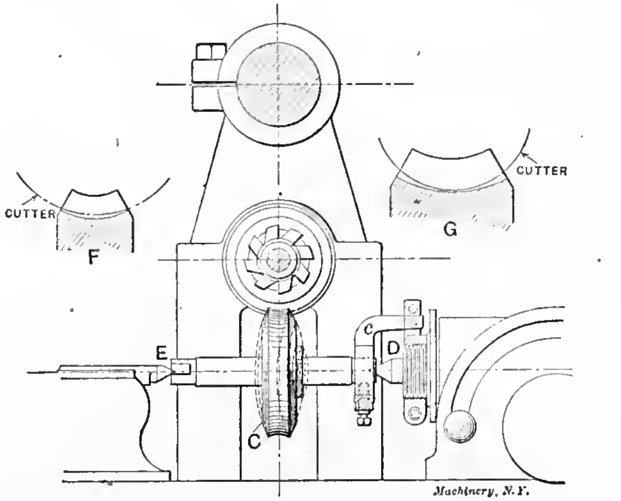
4. Adjust the arbor support center *b* to the center of the arbor, and clamp the overhanging arm *B*.

5. Move the carriage in or out, as the case may require, until the center of the dividing head spindle is directly under the center of the cutter. If a standard gear cutter is used, the center in the head may be set to coincide with a center line on the cutter which is placed there by the makers to facilitate setting the cutter central with the work spindle. If a plain cutter is used (which will be without the center line), a convenient method of setting it is to place an arbor on the head and tail centers; then with the blade of a centering square projecting upward, adjust the carriage until the side of the cutter has a full contact with the central edge of the blade. A second adjustment of the carriage, equal to one-half the thickness of the cutter, will locate the latter central with the dividing head.

6. Clamp the carriage to the knee slide.

SHOP OPERATION SHEET NO. 86.

John Edgar. MACHINERY, January, 1909.



Gashing a Worm-wheel Blank.

Note.—It is assumed that the table is set laterally as previously described.

1. After pressing the previously turned blank *C* on an arbor, place the arbor, with a dog *c* for driving attached, between the head and tail centers *D* and *E*, and clamp the dog.

2. Shift the table until the center of the blank is directly under the center of the arbor, as shown in the illustration. If care is used, the setting may be gaged by observing the light between the cutter and the curved throat of the blank.

3. Swivel the table until the cutter and the axis of the blank are at the proper angle with each other, and clamp the table. This angle should be indicated on the drawing. The way of determining it, however, is explained in the Machine Shop Practice article in this issue of Machinery.

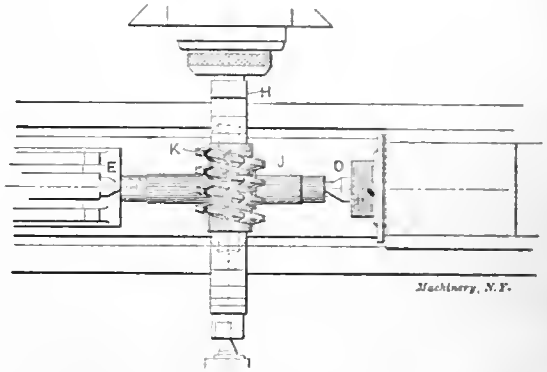
4. The cutter is next sunk into the blank to the proper depth. Unless the diameter of the cutter is equal to that of the hob, care must be taken not to gash too deep. When the diameter of the cutter is greater than that of the hob, we have the condition shown at *F*; the depth to which the gashing cutter should be set is limited by the depth of the cut at the side of the blank. Should the diameter of the cutter be smaller than that of the hob, the condition shown at *G* is encountered; here the depth to which the cutter should be set is shown to be on the center line.

5. Bring the cutter into contact with the throat of the blank and then set the dial on the elevating screw to zero. Start the machine, and raise the blank an amount equal to the desired depth of cut which should be slightly less than the whole depth of the tooth.

6. Drop the knee so that the blank clears the cutter and index for the next tooth. Continue gashing and indexing until the required number of gashes have been cut.

SHOP OPERATION SHEET NO. 87.

John Edgar. MACHINERY, January, 1909.



Hobbing a Worm-wheel.

Note.—The blank is assumed to have been previously turned to the correct diameter, within narrow limits, and gashed.

1. Insert a true-running arbor *H* in the machine spindle, after thoroughly cleaning both the spindle hole and arbor shank. After pressing the blank on a true arbor *J*, place the latter between the centers *D* and *E*, without a driving dog attached.

2. Steady the outer end of the arbor by fixing the center of the arbor support into it.

3. Adjust the table longitudinally until the center of the blank is directly under the center of the arbor *H*. The blank may be set quite accurately by bringing it into contact with the arbor and adjusting the work until the arbor rests centrally in the throat of the blank.

4. With the arbor still in contact with the periphery of the blank, at its throat, set the dial of the elevating screw at zero. Measure the diameter of the arbor with a micrometer, and divide this dimension by 2, obtaining the radius. Measure the diameter of the hob *K*, and also ascertain its radius. Subtract the radius of the arbor from the radius of the hob, lower the knee of the machine an amount equal to this result, and again set the dial at zero. The knee may now be lowered a small amount in order that the blank may clear the hob when the latter is being placed on the arbor.

5. Tighten the hob on its arbor, and then raise the knee until the hob is in mesh with the gashes in the blank. It will be observed that the whole tooth depth has not been reached when the hob bottoms in the gashes. The machine is now set in motion and as the hob revolves, the blank rotates with it. The hob is now fed into the blank, by raising the knee, until the dial indicates the correct depth. If the hob is properly made, and the wheel blank accurately sized, the teeth will be cut to the correct depth when the inner diameter of the hob grazes the blank at its throat diameter. The hob and blank should now rotate several times to eliminate any spring and to produce smooth teeth. This rotation should not, however, continue too long as the tendency is to produce thin teeth.

These tables are based on {
Maximum Fiber Stress 80,000 to 150,000 Lbs. Per Square Inch,
Torsional Modulus of Elasticity 10,500,000.

For no vibration multiply actual load by 1.5
For moderate vibration multiply actual load by 2 } *and select resultant pressure in table.*
For incessant vibration multiply actual load by 3

In calculating deflection consider 2 coils as ineffective.

For helical springs of square steel multiply load by 1.2 and deflection by 0.59.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—1.*

R. B. BROWN.

THE introduction and development of the electric motor, which has revolutionized so many of the methods of manufacture and transportation, has, perhaps, influenced the design of no other single auxiliary apparatus in the productive industries more than that of cranes and hoists. The present series of articles, therefore, has been written with the intention of placing on record the present practice in the design of overhead cranes, electrically operated, and of presenting such data as will aid the designer of such apparatus to properly calculate and proportion the various details, and supervise their construction.

Overhead Travelers.

The overhead traveler in its various forms is probably in greater demand than any other type of electric crane on the market, a fact which has induced many firms to specialize in this particular branch of crane building. As a result of the continued and growing demand for these cranes, many attempts have been made, with more or less success, to standardize, as far as possible, the various details of construction.

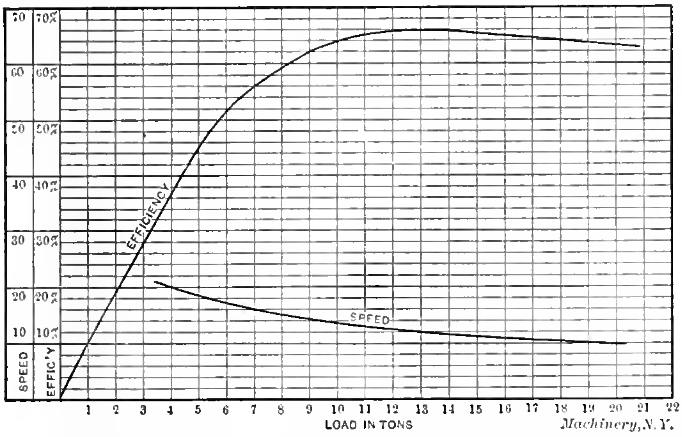

Fig. 1. Lifting Diagram for 20-ton Crane; Full Load Speed 10 feet per minute.

Electric travelers represent a type of crane which under ordinary conditions is in almost continual service, and, as with other constant working machines, it is essential that rapidity of operation, together with economy in current consumption, be preeminent factors to the purchaser and manufacturer alike. The requirements of the former should be based on the results of general experience gained during the past few years, while these results depend entirely on the skill of the designer, and the workmanship.

The three types of ordinary travelers in use are the one-motor, three-motor, and four-motor cranes. The three-motor, and for medium and heavy cranes, the four-motor types, have been found to be by far the most efficient, and are, practically speaking, the only types now used for modern workshops, warehouses, and similar localities. Until quite recently, the single motor type was considered preferable, on account of its cheapness, for engine rooms and similar places where a crane is only required occasionally. The present price of motors and their connections, and the fact that single motor cranes require more gearing than the three-motor type, is in favor of the universal adoption of the latter, more especially since several makers manufacture the crabs of this type in quantities and keep them in stock, and can therefore give a quicker delivery.

One of the principal obstacles that has been placed in the way of standardizing electric cranes, is the widely varying opinions of engineers on the question of speeds. Except for travelers which are required for work of a special nature, there is no reason why all cranes of this type should not be worked at practically the same speeds. In order to consider the conditions affecting the speed of each motion, they must be dealt with separately.

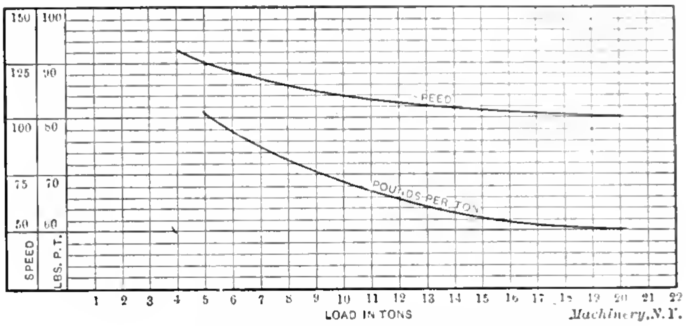

Fig. 2. Travereing Diegrem for 20-ton Crane; Full Load Speed 100 feet per minute.

When inquiring for a crane of any type, it is usual to state the speed at which the maximum load has to be lifted; and in selecting this speed the fact should not be overlooked that, excepting the case of small powered cranes and those required for special service, the normal load is seldom more than about 20 per cent of the full capacity of the crane. It is better, therefore, to consider what is the highest and safest speed at which this normal load can be worked, and then select a full load speed which will give the same foot-tonnage of work done. By the use of crane-rated series wound motors, a variation above the rated speed of about 50 per cent, increasing in proportion to the load, can be obtained, and this fact makes the use of change gears on the main lift unnecessary. If, however, a crane is to be used in a shop where a great deal of small material has to be constantly handled, but where a full load only occurs occasionally, as for instance, in a fitting shop, it is more economical to have an auxiliary barrel fitted onto cranes of from ten to twenty tons capacity, and worked by the main lift motor. When a light lift is required, it should be one-fifth of the full capacity of the crane, and the speed specified should be such as will give the same foot-tonnage as the main lift. Auxiliary barrels are generally placed on the main barrel pinion shaft, and so arranged that either the main pinion or the auxiliary barrel may be driven from this shaft by means of a clutch.

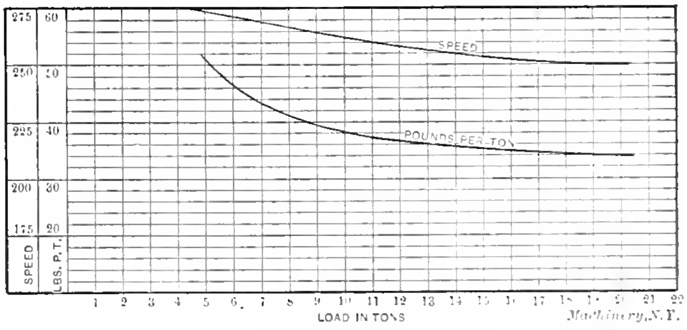

Fig. 3. Traveling Diegram for 20-ton Crene; Full Load Speed 250 feet per minute.

---

*For previous articles on cranes, crane design, and efficiency of crane mechanism, see History of Crane Design, June, 1908; Design of Light Structural Jib Cranes, by W. H. Butz, December, 1907; Power Required for Cranes and Hoists, by Ulrich Peters, November, 1907; Formulas for Force Required to Move Crane Trolleys, by John S. Myers, October, 1907; Calculations for Shaft Gear and Bearings of Crane Motors, by George J. Leire, July, 1905; Notes on Band Brake Design, by C. F. Blake, March, 1905, and January, 1901.

For cranes of twenty-five tons and upwards, that are to be in constant use, the best practice now demands an independent motor for the auxiliary barrel, the capacity of which is generally five or six tons, and the speed from twenty to thirty feet per minute.

The conditions concerning the acceleration of speed under lighter loads apply in a similar manner to traversing and traveling, and it is never worth while having a change of gear applied to these motions. The traveling speeds are a somewhat variable quantity, and cases often occur where small-powered cranes have to travel at a very high speed, as, for example, where cranes are used over pig casting beds or stock yards; when engaged in such work they may travel at a speed of 500 feet per minute, or more. For ordinary shop and similar practice the various speeds given in Table I are deduced from the modern requirements and represent an average of the speeds which have been standardized by leading makers.

In connection with the speeds in Table I., it will be necessary to explain how the horse-power required in each case has been arrived at. The horse-power of the lifting motor depends purely on the work done on the load, and the power absorbed in the resulting friction of the gearing, journals, and pulleys. This quantity varies to some extent with the number of reductions and the type of gearing. The efficiency of a crane is generally lowest at the test, improving somewhat as the journals and teeth get bedded down. The efficiency of the first or motor reduction with well-made machine cut spur gears running in an oil bath, has been found by trial to reach as much as 97 per cent, and may be taken at 95 per cent under ordinary practical conditions.

120	5	60	32	60	20	...	80	95	150	....	45	50
150	5	75	38	40	20	....	90	105	150	....	55	60

The average efficiency of one reduction of cut spur gears, running dry, is 92 or 93 per cent, and of cast spur gears running dry, 90 per cent. The loss due to journal friction is generally about 2 per cent for each axle when properly lubricated. The only other loss in efficiency of any importance is in the snatch block, if there is one fitted to the crane. This quantity is always reduced by using large pulleys and, preferably, small hardened pins, the pulleys being bushed with gun-metal, under which condition the efficiency works out to about 97 per cent.

From the above results a very fair idea of the over-all mechanical efficiency of a crane can be determined, if the number of reductions and the other particulars are known. It will be found that small high speed cranes have a higher efficiency than the larger ones, owing to there being less gearing; thus, in the case of a crab lifting three tons on a single rope and having two reductions of machine cut gearing, the first of which runs in oil, the overall efficiency will be about

$$\frac{95 \times 92 \times 98 \times 98}{100} = 84 \text{ per cent.}$$

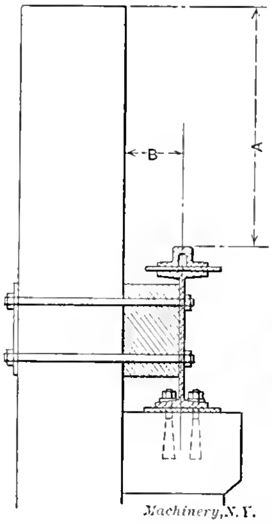
For a contrary example take a 50-ton crab having four reductions, the first three of which are machine cut, the motor reduction running in oil. Then the overall efficiency will be about

$$\frac{95 \times 93 \times 93 \times 90 \times 98^4 \times 97}{100} = 66 \text{ per cent.}$$

A very common rule in practice is to allow ten foot-tons of work done at the hook per brake horse-power, this factor being equivalent to a mechanical efficiency of about 66 per cent. This constant is practically correct for medium and large cranes, but for small sizes it allows for a slightly larger motor than is really necessary, which is perhaps a good fault, since small cranes are generally in constant use. The above calculations are not, generally speaking, necessary in practice, but have been made in order to show how and where the power due to friction is principally absorbed, and it will be seen that the results agree very closely with the diagrams shown in Fig. 1, which are made from trials taken from overhead cranes, representing the best class of design and workmanship. It is usual and more instructive to speak of the gross efficiency of a crane, that is the combined electrical efficiency of motor and wiring, and the mechanical efficiency of the gearing, or in other words, the ratio between current consumed at the switchboard and work done at the hook. This is the efficiency as shown by the diagrams.

The electrical efficiency of a lifting motor may generally be taken at 80 per cent, covering motor and wiring, so that in the case of the 3-ton crane exemplified above, the gross efficiency would be about $\frac{84 \times 80}{100} = 67$ per cent. Similarly, the 50-ton crab would give a gross efficiency of $\frac{66 \times 80}{100} = 53$ per cent. Both of these quantities agree with actual results.

The horse-power, or current required for each motion, as given in Table I. is the calculated power based on the above described coefficients; for practical purposes, however, the nearest manufactured size of motor would be used. The power required for traversing and traveling must be sufficient to overcome the rolling and axle friction, and the friction of the intermediate driving gear. The horse-power of these motors is generally based upon a certain tractive resistance, usually expressed in so many pounds per ton of rolling load. This is a very variable quantity, even the results of tests showing a remarkable latitude. Although it is best to work with data obtained from experiments, it will be well to show the calculations which most nearly agree with actual results.



Machinery,N.Y.

TABLE II. CLEARANCE SPACE REQUIRED FOR OVERHEAD CRANES.

Size of Crane.	A		B
Tons.	Ft.	Ins.	Inches.
3	5	0	7
5	5	6	7
7½	5	6	7
10	5	9	7½
15	6	0	7½
20	6	0	8
25	6	6	8
30	7	0	9
40	8	0	9
50	8	6	10
60	9	0	10
75	9	6	10
100	10	0	12
120	12	0	12
150	12	0	12

The axle friction μ depends to some extent on the lubricating arrangements, but in the calculations it is assumed that these conditions are well provided for, both in traversing and traveling. The power required is figured from the formula

$$P = (\mu r) \frac{W}{R}$$

where W = load in pounds,
R = radius of wheel in inches,
r = radius of axle in inches,
μ = coefficient of friction = 0.10.

The rolling friction of metal wheels on steel rails is considered to be equal to $0.002 \frac{W}{R}$. This quantity may, therefore, be combined with the above quantity and the result obtained direct, thus

$$(\mu r + 0.002) \frac{W}{R}.$$

Take for example a 30-ton crab weighing six tons, having runners 18 inches in diameter, and axles 4½ inches in diameter. The combined axle and rolling friction will be

$$(0.1 \times 2.25 + 0.002) \times \frac{36 \times 2{,}240}{9} = 2{,}034 \text{ pounds.}$$

The efficiency of the driving gear can be found in the same manner as described for the lifting gear, when the number of reductions are known. In the present example there would be three reductions of machine cut gears, all running dry, the total efficiency of which would be about

$$\frac{92 \times 92 \times 92 \times 98 \times 98}{100} = 75 \text{ per cent.}$$

Taking the full load speed at 60 feet per minute, it will be found that the brake horse-power required will be

$$\frac{2{,}034 \times 60 \times 100}{33{,}000 \times 75} = 5 \text{ B. H. P.}$$

The axle friction of the traveling gear will always be found to be considerably less than that of the traversing motion, due to the fact that the crab axle diameter is often larger than the main axle, while the runners are usually only half as large, and the resistance varies in proportion to the ratio of these quantities, as will be seen from the above formula. When assuming the efficiency of the driving gear for the traveling motion, some special allowance should be made for the loss of power due to the cross shaft. This shaft is carried by several bearings, and it is probably the deflection of the girders, and the consequent slight bending of the shaft, that causes the drive to be rather inefficient.

No direct results concerning this shaft are available, but its efficiency will probably be about 90 per cent for cranes of moderate span. Allowing for two reductions of machine cut gears running dry, the efficiency of this drive will, therefore, be about $\frac{92 \times 92 \times 90}{100} = 76$ per cent. Suppose for example, that a 30-ton crane traveler weighs 25 tons, and runs upon wheels 30 inches in diameter having 4-inch axles; then the combined rolling and axle friction will be, as in the case of the crab.

$$(0.1 \times 2 + 0.002) \times \frac{55 \times 2{,}240}{15} = 1{,}659 \text{ pounds.}$$

Taking the traveling speed at 150 feet per minute, and neglecting acceleration which may, for ordinary speeds, be assumed as taken care of by the coefficient of friction and the overload of the motor permissible, the brake horse-power required will be

$$\frac{1{,}659 \times 150 \times 100}{33{,}000 \times 76} = 10 \text{ B. H. P.}$$

The resistance to traction, as nominally referred to, which this power covers will be

$$\frac{10 \times 33{,}000}{150 \times 55} = 40 \text{ pounds per ton.}$$

Similarly the 5 B. H. P. motor for traversing allows for 76 pounds per ton. For practical purposes 40 to 50 and 60 to 70 pounds per ton have been allowed for the best class of travelers having large diameter wheels and machine cut gears. Some tests have shown that a higher factor than 70 pounds per ton is required for traversing, such results possibly being due to the fact that the lubrication was inefficient; the travelling wheels also are often too small. The diagrams in Figs. 2 and 3 show actual results obtained in the traversing and traveling motions of cranes.

Before concluding this installment on preliminary considerations, it is advisable to call the architect's attention to the importance of allowing an adequate working space for travelers when designing shops, etc. Due to overlooking this fact, the first cost is often considerably increased, while the crane is generally of inefficient design and unsightly appearance. The dimensions given in Table II have been taken from actual practice, and will be a guide to those designing new buildings. The headroom given in this table is the least possible with an ordinary type of crab, some designs requiring rather more space. Table II shows a simple form of attachment for track girders, which has been found to answer very well for cranes up to 30 tons, and possesses the merits of being easily adjusted and inexpensive.

* * *

PRODUCING BLACK NICKEL COATINGS ON METAL SURFACES.

The following solution for depositing a black nickel coating on metal surfaces is given by the *Brass World*. The solution consists of the following constituents: water, one gallon; double nickel salts, 8 ounces; ammonium sulphocyanate, 2 ounces; zinc sulphate, 1 ounce. If the zinc sulphate is not in the form of white crystals, but is white and dry, then only one-half ounce should be used. The double nickel salts are dissolved in the water, and then the ammonium sulphocyanate is added. After this has been done, the zinc sulphate is introduced. The solution is used at its ordinary temperature, but in winter should not be allowed to get colder than 60 degrees F., and works best at about 80 degrees F. Ordinary nickel anodes are employed, with a surface several times that of the work to be plated. The work is cleaned carefully, preparatory to the plating. The black nickel deposit may be put directly on steel, brass, copper, German silver, or bronze, but it is preferable to first flash the work in a hot copper solution, then in a white nickel solution, and finally deposit the black nickel. For cheap work, the copper and white nickel deposits may be dispensed with, but the black nickel is less apt to peel off if put on the white nickel. The black nickel is deposited with a weak current. Best results are obtained with a current from ½ to ¾ of a volt.

The deposition should be allowed to stand for an hour or more if a heavy deposit is desired. When the article comes from the black nickel solution, it will be found that it is of a gray or brown shade. While this disappears to a considerable extent when lacquered, the color is not a dead black. By using a dip consisting of one gallon of water, twelve ounces of iron perchloride, and one ounce of muriatic acid, a dead black color is produced. All nickel deposits should be lacquered after dipping.

The following causes of difficulties should be guarded against: If the black nickel deposit has spear-shaped markings on it and is partly white, too high a voltage has been used. If the deposit flakes off after standing for some time, too strong a current has been used, or the work has not been clean. If the deposit is too heavy, it is also apt to flake off. If the deposit is still brown or gray after it comes from the dip, the dip is old, or the article has not remained in the dip long enough. If, although the voltage is right (less than one volt), the deposit is streaked, the bath has become acid; add carbonate of nickel (plastic) to neutralize the acid. Use plenty of anode surface and old nickel anodes if possible. If the edges of the deposit are removed in the dip, the dip is too hot, or the black nickel was not deposited a sufficiently long time. If the surface is iridescent after lacquering, the lacquer is too thin.

* * *

Statistics dealing with the iron industry of the world show that, during 1907, the United States produced about 43 per cent of the total pig-iron and 45 per cent of the total amount of steel produced in the world. Germany takes second place with, respectively, 22 and 24 per cent. Great Britain comes in the third place with 17 and 12 per cent, respectively.

INDUSTRIAL PHOTOGRAPHY.*

The first aim of the photographer of machines and industrial subjects, in general, intended for half-tone reproduction in catalogues and trade journals, should be to produce prints that will require the least retouching when used for making half-tones, and this for two reasons: First, the retouching of prints for half-tone work is quite expensive; and second, the print that requires the least retouching gives much the best results in the finished half-tone. The photographs from which the half tones in this article have been reproduced were not retouched at all.

Nearly all industrial establishments are equipped with a photographic outfit of some kind, and in some instances an experienced photographer is in charge; but in the majority of cases one of the draftsmen must take care of all the photographic work of the establishment, and it is in the hope of aiding some of the latter that the author prepared the paper abstracted.

Apparatus.

The camera should be a strong and serviceable one having a long bellows with very little cone. In fact, one with a perfectly straight bellows is best, as it allows greater adjustment of the lens board without danger of the bellows folds cutting off any of the object. The vertical and side swings should be ample. The camera need not be larger than 6½ by 8½ inches, and should not be larger than 8 by 10 inches, as anything over this size is cumbersome to handle, and requires a very expensive lens and a great deal of skill to operate. If large prints are wanted, bromide enlargements can be made up to any reasonable size, and if for any reason large direct or contact prints are wanted, a slightly enlarged positive can be made from the negative, and a negative as large as wanted can be made from the positive. This procedure has its advantages, as it is often possible to correct in a great measure any errors in exposure or development, and many errors in lighting and position.

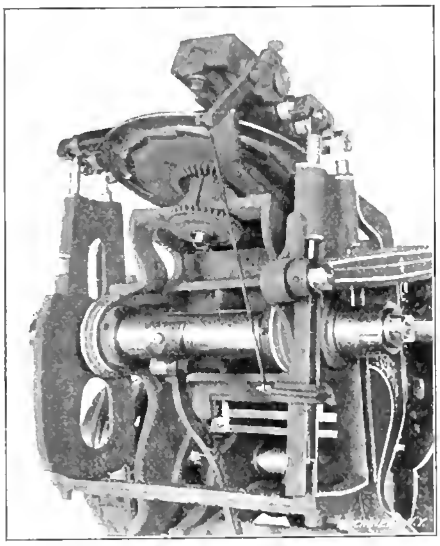


Fig. 1. Details Brought Out, and Deep Shadows Avoided by Preparation of Machine Parts before Photographing—No Retouching made on Photograph.

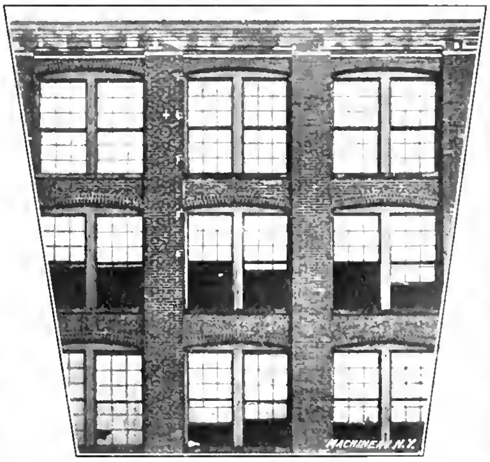

Fig. 2. Distorted View in Fig. 3 corrected in Reproduction.

Fig. 3. Distorted View caused by Pointing Camera upwards.

The tripod should be solid and stiff with the fewest possible joints. The lens should be the best obtainable, and too great emphasis cannot be placed on its being of long focus. Never under any circumstances should its focus be shorter than the diagonal of the largest plate with which it is to be used. It should be capable of rendering sharp definition from corner to corner of the plate when using a comparatively large diaphragm. The plates should not be the most rapid made, as the emulsion with which these are coated is not generally rich enough in silver to give printing density for anything but portrait work, and also because the timing of the exposure must be very exact. Plates of medium speed are the best and should be of the kind known as "double coated" or "non-halation."

If interior views are to be made where windows and other openings to the light have to be faced, then the plates should be coated on the back with a compound known as "backing." This "backing" should be washed off with a damp sponge before development.

Proparation of the Subject.

If a machine is to be photographed, it should be painted with a finishing coat of drab paint, which may be designated as "mouse color," and the paint should be so mixed as to dry absolutely "flat," that is, without any gloss whatever. If parts underneath the machine or in shadow are wanted to be shown, they should be painted a lighter shade than the more prominent parts, and the deeper they are in shadow the lighter they should be painted, in extreme cases even blending the color gradually into a white. All brightly polished parts should be daubed or rubbed over with a handful of soft putty to dull the brightness. Unless these precautions are taken, the parts in shadow will show very dark in the photograph, and if very close together will be seen only as one shapeless mass, and the bright spots will show chalky white with very black lines and little or no detail. If letters or figures cast on any part of the machine are wanted to be shown, daub them with white paint from the end of a finger. Rubbing with chalk will give them a very rough appearance.

It must be borne in mind that all high lights and shadows are greatly intensified in photography, and that a sensitive plate that will register all the gradation of tone as seen by the human eye has yet to be made. Fig. 1 is an illustration of a machine that was properly prepared for being photographed. If possible it is best to photograph a machine before it has been run, otherwise oil from the bearings will seep out on the paint and leave dark and glossy spots which will look bad in the photograph. If the machine is to be run before being photographed, then it should not have its finishing coat until after the run or test is over. Before the finishing coat is put on, all the bearings should be thoroughly flushed with gasoline and the whole exterior cleaned with the same stuff to remove all oil.

Lighting and Position.

Machinery should never be photographed out-of-doors or under a skylight, as there is too strong a top light, which causes deep shadows. The light should preferably come from the north, and should fall on the machine at a downward angle of about 20 degrees from the horizontal. Cross lights from other windows should be avoided by pulling down the shades or tacking up heavy paper. Cross lights make a confusion of shadows and obliterate certain lines, giving the machine anything but a natural appearance. If necessary to photograph the machine by other than northern lighting, then make the exposure when the sun is overhead. If the exposure must be made when the sun is shining through the windows at any considerable slant, tack cheese cloth over the windows to diffuse the light.

---

*Abstract of paper by Mr. S. Ashton Hand, read before the American Society of Mechanical Engineers, December, 1908.

A machine should never be photographed directly from the front, which will make it appear too flat. For depth, the camera should be placed enough out of center to show a little of one side of the machine and high enough to show a little of the top. A background of heavy drilling, either white or very light in color, should be hung not less than 6 feet back of the machine. It should be of ample size—large enough so that the camera can be moved where wanted and still show the background behind every part of the machine. If there are folds or wrinkles in the background, have a man at each side take hold of the edges and shake the curtain slowly and gently during the whole time of the exposure. This will prevent the folds or wrinkles from showing in the photograph.

Fig. 4. Camera and Negative Holder arranged so as to correct Distortion shown in Fig. 3.

Shop floors are dark in color, and if a machine is photographed directly on the floor it is often puzzling to know where the lower part of the machine ends and the floor begins. Therefore a floor cloth of the same color and width as the background should be used. It should be deep enough to extend from 4 to 6 feet in front of the machine and under it and to the background. Instead of a floor cloth, sheets or strips of light colored paper can be used, but be sure there is no pronounced red or yellow, as such colors are non-actinic and will show black in the photograph.

Focusing.

Never focus on the center of the ground glass, as this will give you the point of sharpest focus of the lens, and what is wanted is the average focus; therefore focus at a position midway between the center and the edges of the ground glass. Get the nearest parts of the machine in focus. Small diaphragms will sharpen up the distant parts. Sometimes a better effect can be obtained by pointing the camera slightly downward, but if at any time the camera is used in any other than a level position, the ground glass should be brought to a vertical position, otherwise the result will be distorted lines. Fig. 3 shows a distorted view of a part of the side of a building, made by pointing the camera upward. If the photograph of a machine shows such distortion, and for any reason it cannot be photographed again, a negative can be reproduced eliminating the distortion, by placing the negative in a frame tilted at such an angle that the narrowest lines are nearest the lens, and making a positive in the camera, tilting the ground glass at an equal angle, but in the opposite direction. A negative can be made from this positive, as shown in Fig. 2, which was actually made from a negative reproduced in the above manner from that used for Fig. 3. Notice how much the top of the negative had to be enlarged to bring the lines parallel. Fig. 4 shows a camera and negative holder in the proper position for this operation.

Fig. 5. Photograph taken without Special Precautions against Strong Light in the Background.

If the machine to be photographed is a long one, requiring a raking view, use the horizontal swing to bring that part of the ground glass on which the image of the farthest part of the macine appears, farthest away from the lens. This will even up the focus and make it possible to use a larger diaphragm, shortening the time of exposure, and also extend the vanishing point to a greater distance, giving it a more normal perspective. If there are perceptible vibrations to the floor on which the photographing is done, get three pieces of harness felt ½ inch thick, and two or three inches square. Place one of these on the floor under each leg of the tripod, and they will absorb all ordinary vibrations and keep the camera steady.

Fig. 6. Same Interior as in Fig. 5, but taken with Strong Light in Foreground.

Exposure.

Exposures should always be ample, as an under-exposed plate can never be made to show that which the light has not impressed upon it (although it can be greatly helped by skillful development), but a moderately over-exposed plate can easily be treated in development, or even afterwards, so as to yield a first-class print. If in doubt as to the correct time of expcsure, make a guess as near as possible. Suppose your guess to be four minutes, then put a loaded plate holder in the camera and draw the slide so as to expose two inches of the plate and make an exposure of two minutes; cap the lens, draw the slide out two inches more, and make another exposure of two minutes. Repeat this, drawing the slide two inches at a time, until the whole plate has been exposed. If the plate is 8 by 10 inches, there will be five parts, having respective exposures of 10, 8, 6, 4, and 2 minutes each. Develop this plate, and it will be easy to tell which part has had the proper exposure, and from the position of this part the time can readily be found.

Interiors.

In photographing interiors, avoid pointing the camera towards windows if possible, but if this cannot be avoided, then cover the windows with heavy drilling or thick wrapping paper, fastening it well around the edges, so that no bright margins of light are visible. After the exposure has been made, the window coverings can be removed and an additional exposure of a fraction of a second can be given. This will give the windows a natural appearance and will often show objects on the outside. Interiors can be photographed without these precautions, but skillful work will be required to make good negatives.

Figs. 5 and 6 were made on a very bright day when snow was on the ground, and the light coming in the windows was intensely white. As the negatives were wanted in a hurry, no precautions were taken to soften or keep out the light at the windows. The far end of Fig. 5 was a southern exposure, and the sun heat was streaming in at the windows. Fig. 6 is a view in the same room taken from the south end, where the light was so intense that the milling machine in the foreground appears light in color, although it was painted a dark steel color.

Copying.

In copying drawings or other subjects in black and white, it is necessary to use a very slow plate, give the shortest possible exposure, and use a concentrated and well-restrained developer. If a copy is to be made from a blue print, it will be necessary to bleach the print in a weak solution of ammonia and water, and after a thorough washing, to immerse it in a weak solution of tannic acid. The part that was formerly blue will now be a rich purplish brown.

Enlarging Negatives.

A negative can be reproduced in a larger size by first making a positive in the copying camera, and then making a large negative from the positive by the use of the same instrument. If a negative is enlarged to many times its original size, a granular effect will be noticed. This is caused by magnification of the emulsion structure which is made up of countless thousands of hills and valleys. This granular effect can be eliminated by slightly over-exposing and greatly over-developing the original negative, and then reducing it to the proper density. The positive should have the same treatment.

Reduction does three things: (*a.*) It reduces or clears the shadows faster than the high lights. Therefore over-exposure is resorted to in order to increase the density of the shadows in proportion to the high lights, so that they shall bear proper relation to each other after reduction. (*b.*) It thins the density of the negative or positive. Therefore over-developing is resorted to in order to have resulting density after reduction. (*c.*) It cuts down the hills to the level of the valleys, so that very little if any granular effect is noticeable when the emulsion is magnified.

In reproducing negatives either in the original or a larger size, there is a splendid chance for what may be termed "jockeying." A brilliant negative may be made from a very flat one, and *vice versa;* errors in perspective can be corrected by the method illustrated in Fig. 4; and unequal lighting can be corrected by judicious shading during exposure, etc.

X-Ray or Ghost Photographs.

When an illustration is wanted to show clearly some hidden interior part of a machine in relation to and more distinctly than other parts, the usual procedure is to have a wash drawing made in India ink, from which the half-tone is produced. This method is always expensive, and the results are often very unsatisfactory.

In a power-driven machine for cutting paper, the power is transmitted through worm gearing and a positive clutch, all of which is enclosed in an oil-tight case, as shown in Fig. 8. An illustration showing the worm and worm-wheel in mesh was wanted.

The case and its contents were removed from the machine and mounted on a box. The upper part of the case was taken off, leaving the worm-wheel and the clutch collar exposed to view. The worm and shaft were removed from the upper part of the case and placed in their proper position in relation to the worm-wheel, as shown in Fig. 7. A dark background was placed in the rear and an exposure was made. After the exposure the cap was put on the lens, the worm and shaft taken away, and the upper part of the case put in position as in Fig. 8. A light background was substituted for the dark one, and another exposure made on the same plate, the result of which is shown in Fig. 9.

Development.

Of the art of development much has been written, and more has been said, but the fact remains that the only adequate teacher is experience. After many years of experience, the author of the paper abstracted hesitates to attempt to tell in writing how to handle a sensitive plate in development. A few hints, however, concerning the behavior of certain mixtures of developer, may be of service.

Too weak a developer makes a flat thin negative.

Too concentrated a developer makes a negative with too much contrast.

Under-developing makes a negative lacking in printing density.

Over-developing makes a thick dense negative requiring a very long time to print.

An under-exposure should be developed with a diluted developer.

An over-exposure should be developed with a concentrated developer well restrained with bromide of potash.

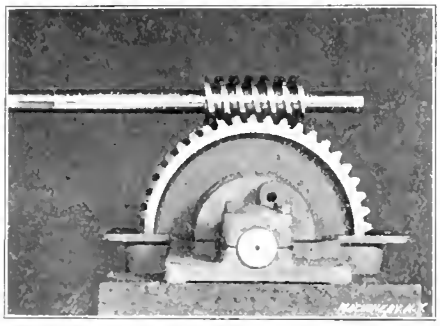

Fig. 7. Photograph of Worm and Gear with Upper Part of Case Removed.

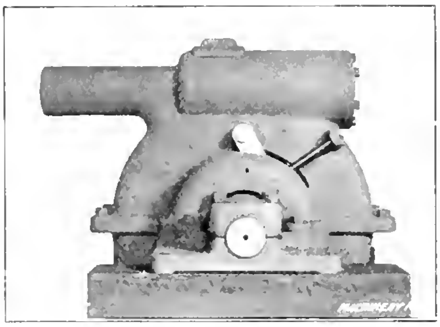

Fig. 8. Exterior of Case to be Photographed on Same Plate as Worm and Gear in Fig. 7.

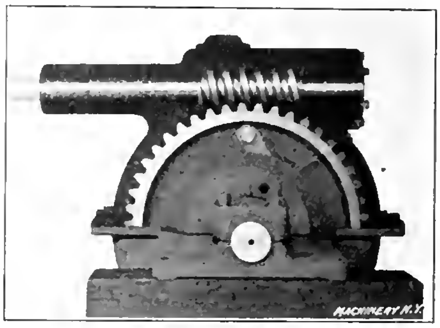

Fig. 9. Result of Exposures of Figs. 7 and 8 on Same Plate.

Developers, like artists' colors, should be mixed with brains.

Better choose a moderately slow developer, learn how to use it, and don't let any one persuade you to change it.

The actual printing can, as a rule, be done better by a professional photographer than by an amateur, and as a rule it will be found cheaper to have the prints thus made.

* * *

An ingenious method of regulating the speed of mechanism so as to be absolutely synchronous and to have a known velocity, has been used, which is very simple and worth noting because of the principle. Say that we are given the case of operating a mechanism for autographically recording the pressures of succeeding explosions in a closed receptacle using an apparatus similar to a steam engine indicator, and that it is essential that the speed of the recording apparatus be the same for each test. The method used by Mr. Frederick Grover in his well-known gas explosion tests was to mount a stop watch (that is, one having the second hand in the center) in the mechanism train so as to rotate in a direction opposite to the movement of the second hand and at the same speed. The hand then stood still in space when the mechanism was correctly timed. Any deviation forward or backward showed that the mechanism was running too fast or too slow. A suitable speed-varying device enabled the observer to speed up or slow down the train and thus keep the second hand standing perfectly still. The device is a perfect check on numbers of rotations per minute and the regularity of action.

* * *

According to an English patent specification, celluloid may be made non-inflammable by the addition of chloride of aluminum and nitrate of aluminum.

DESIGN AND CONSTRUCTION OF METAL-WORKING SHOPS—5.

SPECIFICATIONS, ESTIMATES AND CONTRACTS IN ENGINEERING PRACTICE.

WILLIAM P. SARGENT.*

According to Schopenhauer, words and signs simply serve the purpose of fixing conceptions in the mind. The words and signs of engineering are the drawings and specifications, and the contractor will execute his work according to how well these convey to him the conceptions and requirements of the planning engineer. In the specifications, the exact character of the work should be fully and explicitly stated, and the wording should be definite, so as to convey the precise meaning.

Specifications are made up of general clauses covering the general conditions, responsibility of the two parties, etc., and specific clauses covering the details of design and construction, From an analysis of a number of specifications the following points are selected as indicating a consensus of opinion concerning many of the essential features of specifications.

General Clauses in Specifications.

1.—A concise and comprehensive statement descriptive of the work to be done in accordance with the drawings and specifications.

Example.—The work to be done under this contract comprises the furnishing and erection, on foundations provided by the owners, of two (2) water tube boilers, ready for smoke, steam, and water connections, in strict accordance with these specifications and drawings, Nos. 1 and 2, dated October 10, 1908.

2.—A complete list of the drawings, with the drawing dates, accompanying and forming a part of the specifications.

3.—The drawings and specifications together are to govern the work, and everything called for either on the drawings or in the specifications, or in both, is to be furnished or executed.

4.—Definition of the words "engineer," "owners" and "contractor," as used in the specifications.

5.—The engineer shall explain any obscurity in drawings or specifications, shall decide as to the purpose and intent of drawings and specifications, or of the kind and quality of work or material required thereby, and his decision shall be conclusive.

6.—The contractor shall keep a foreman constantly on the site, the charge of the work being his sole duty.

7.—The engineer shall give lines and levels.

8.—For dimensions governed by conditions already existing the contractor must be governed by measurements taken by himself, scale or figured dimensions notwithstanding, but no deviation shall be made without authorization of the engineer.

9.—The contractor is responsible for the full understanding of the existing condition of the site, and all work or material necessary to change the site to the condition provided for in the specifications, is included in the contract.

10.—Materials and workmanship to be subject to inspection and approval of the engineer who shall have authority to reject any material or work not in conformity with the specifications.

11.—Owners reserve the right to make alterations while work is in progress; additions to, or deductions from, the amount of the contract on account of alterations to be made according to a schedule approved by the engineer.

12.—Owners reserve the right to put other parties at work while the contract is being executed, with the understanding that there shall be no interference with the progress of work under this contract.

13.—Rubbish must be cleared away during the progress of the work at any time the engineer may direct and at the completion of the contract.

14.—All material in the buildings torn down shall be the property of the contractor and any old material may be used in the new work if approved by the engineer.

15.—Contractor must comply with municipal or state ordinances, and shall do all work necessary to so comply whether called for specifically herein, and shall not make any extra charge on this account.

16.—Contractor must pay for all permits or other municipal charges.

17.—Contractor shall carry builders' insurance to cover the amounts paid from time to time by the owners and assign the policies to the owners.

18.—Contractor shall indemnify and save harmless the owners from all suits or actions of any kind for, or on account of, use of patented articles or rights, and any damages or injuries received or sustained by any party or parties by or from the contractor or his agents or servants in the performance of the work.

Many of the above clauses in the specifications examined differ widely in the intent and are often worded so as to tend to envelop and conceal the meaning rather than to explain it. There is often repetition after repetition of seemingly identical thoughts.

The third clause seems to often cause difficulties, and every engineer or architect has more or less trouble in so wording it that he does not occasionally meet with a contractor who either innocently or wilfully misconstrues the clause in a manner to relieve himself from some work intended.

The fourth, fifth, sixth, and seventh clauses are seldom misunderstood but should be worded very clearly.

The eighth clause is found with a wide variation in intent and wording. Often it is used to throw the responsibility for the architects' or engineers' work onto the contractor. This is palpably unfair. Where would one find, for instance, a designer or draftsman who would send drawings into the shop and expect the machinist to assume the responsibility for the accuracy of the dimensions? Generally a contractor will ignore any clause which makes him responsible for the dimensions, trusting that the specifications will not be strictly held to. Of course there are cases where measurements can not be obtained, except during some period of the work or wrecking, or where existing structures have been used as basing lines, or are not as they seem, and it is perfectly fair to have the contractor verify such dimensions in question, as he is the best fitted to do so. It is better to specifically state such dimensions than to write a general clause that is unfair or that will be tacitly ignored; but it is proper to have the contractor call attention to any real or apparent error, thus affording a chance for investigation and rectification before any loss is entailed.

Clauses Found at Times in Specifications and at Times in Contracts.

There are a number of clauses affecting the following points, that are not always found in the specifications but if not, they will be in the contract: time of completion, violation of contract, payments, ownership of work and materials, liquidated damages, bond.

As to the time of completion, it is well that it be stated in the specifications if possible, as the fact that the work should be finished at a definite date appeals to the sporting instinct of the foremen and workmen when they know that it is "up to them." Generally, however, the contractor names the date of completion, and it gets into the contract, but not into the specifications.

Clauses dealing with the monetary part of the transaction seem more properly to belong to the contract. This leaves the specifications entirely an instrument for guidance in accomplishing the material results desired. Very few contractors would care to have the terms of payment or matters of a like nature open to their foremen or workmen as would be the case if such clauses were included in the specifications.

In a paper read by a contractor before an engineering society, some of the shortcomings of specifications were discussed from a contractor's point of view. One statement was: "A contractor should not be held responsible for the stability of a structure, provided the work is constructed as required by the specifications." Another contractor stated that there is positively nothing which raises a bid price like asking a contractor to assume uncertainties.

Specifications are not very interesting reading unless one has some actual work to be performed, but as the general

---

* Address: 315 South First St., Rockford, Ill.

figures of cost given previously would not hold good without limitation, the writer will epitomize the specific clauses covering the details of design and construction. Utility, permanency, and low cost are the desiderata governing the same, and buildings erected on these lines should be equal in quality and appearance to the one illustrated in Fig. 30 (see December issue).

Excavation.—Depths and widths: per drawing. Specified depth insufficient: notify engineer. Bottoms: level, undisturbed. Material excavated: placed on premises or carted away at engineer's option. Shoring: if necessary; to remain if withdrawing endangers adjacent structures.

Back-filling.—As soon as practicable. Puddled and tamped.

Grading.—Inside buildings: wet and tamp, per drawings. Immediately around buildings: per drawings.

Cement, Mortar, Concrete.—Cement: Portland, to comply with and subject to tests; per specifications recommended by The A. S. C. E.; cement submitted to engineer at least twelve days before using.

Sand.—Clean, sharp, and coarse.

Stone.—Clean, hard, durable—to pass 2-inch ring in any direction.

Gravel—Clean, hard, free from other matter except sand; proportion of sand such that all voids will be filled.

Cinders.—Clean anthracite.

Lime.—Thoroughly burned, freshly slaked, clean.

Cement mortar.—1 part cement, 2 parts sand.

Lime mortar.—1 part lime, 4 parts sand.

Gaged mortar.—1 part cement mortar, 1 part lime mortar.

Concrete.—1 part cement, 2 parts sand, 5 parts broken stone; 1 part cement, 7 parts gravel; 1 part cement, 5 parts cinders, 2 parts sharp fine gravel.

Structural Steel.—Medium steel: 60,000 to 70,000 pounds tensile strength; elastic limit not less than one-half the tensile strength, manganese less than 1.0 per cent. Contractor to furnish all members shown on drawings and all other metal work necessary to the stability of structure; bolts must fit; shop connections riveted; abutted surfaces machined; field connections bolted, except column splices and column connections. Contractor to make his own working drawings, must verify drawings furnished him, and be responsible for accuracy of his drawings in all details; drawings subject to approval of engineer. Painting: one shop coat, two coats on all surfaces inaccessible after erection; finish field work so that all exposed surfaces shall have two coats; paint approved by engineer. Inspection: work and material subject to inspection by inspector appointed and paid by owners; final inspection and acceptance at building.

Brickwork.—Brick: straight, hard, sound; face brick selected of uniform color. Every seventh course headers; joints not to exceed ½ inch; laid to line, shoved joints; masons to set anchors, etc.; openings next to steel work slushed with mortar; walls left clean and neat, using acid solution if directed by engineer.

Woodwork.—Kinds and grades specified according to local conditions and practice. Soundness and freedom from structural defects of more importance than appearance.

Roofing and Sheet-metal Work.—Slag or gravel roof according to "Barret's Specification" with a guarantee for ten years; flashed up against parapet walls to 12 inches above low point of gutter; counterflashing built into walls, of Taylor's IX Old Style tin; down-spouts with copper intake and copper wire strainer 8 inches high.

Sky-lights.—Wired glass at least ¼ inch thick, in copper bars; design approved by engineer.

Glazing.—Windows factory ribbed in upper sash. Lower sash and doors D. S. A. quality clear glass.

Painting.—All metal work to have two coats, and all woodwork to have three coats when finished; each coat different color.

Hardware.—Plain, extra-heavy. Sliding doors on approved hangers and tracks.

Plumbing.—According to local ordinances.

Estimating on Shop Construction Work.

That the best way to learn to do a thing is by doing it holds true with estimating. The only aid that the writer can offer is of a general nature, as the variable conditions of locality and trade activity affect prices greatly. Unless an engineer has been engaged in contracting, his estimate will generally be lower than a contractor's bid, but his estimates of quantities should not vary materially from those of the contractor.

The following example will show variations in bids from experienced contractors on a factory building, designed by the architects to cost $160,000. The extreme range of sixteen bids was from $172,000 to $230,000. The three lowest bids were within $1,000; the next three were about $3,000 higher but within a range of $1,000. This was close bidding. When estimating on construction work the engineer should try to put himself in the contractor's place and figure as though responsible for obtaining the contract for the work in competition with others, and at the same time securing a reasonable profit.

"Unit cost," in the following paragraphs, means the basing cost to the contractor, excluding expense items. "Total cost" includes the expense items. "Price" is the amount (including profit) received by the contractor. These prices, obviously, are the costs from the view-point of the owner.

The total cost of material should be estimated as comprising: *a.* The cost F. O. B., shipping, freight, unloading, hauling, storing. *b.* 5 per cent for contingencies. *c.* 1½ per cent for interest on funds up to the time of payments (partial) by the owner. *d.* 1/5 per cent for bond (of contract). *e.* 2/5 per cent for builders' insurance. These percentages will vary from those stated for specific instances. To this total cost add a percentage for profit.

The total cost of labor comprises: *a.* Wages of skilled and common labor, or pay-roll; *b.* 5 per cent for superintendence. *c.* 4 per cent for general expenses. *d.* 1 per cent for insurance of workmen and public. *e.* 10 per cent for contingencies. *f.* 1½ per cent for interest on money. *g.* 1/5 per cent for bond. *h.* 1/5 per cent for builders' insurance. To this total cost add a percentage for profit.

To make up the total cost of a project to the owners, 5 per cent of the grand summation should be added to cover the cost of engineering.

Basing Costs and Prices for Estimating.

The unit prices given below are based either on cost records or on the most reliable authorities in print, and it is believed that estimates incorporating them will be close to fair contract prices if care is taken to add the proper expense and profit percentages that rule in any particular section. The contract prices quoted are not in all cases the lowest, but are selected as being bid by the contractor that would render the best service for the price paid.

First Section—Buildings.

Excavation.—Cost of labor, in cents per cubic yard in place, based on 15 cents per hour; loosened with pick and thrown on bank: *a.* Loam and gravel, 5 feet deep, 15 cents. *b.* 6 to 10 feet deep, 30 cents. *c.* in loam and clay, 5 feet deep, 20 cents. *d.* 6 to 10 feet, 45 cents. Backfilling: *e.* Loose earth, 5 cents. *f.* Tough earth, 7 cents. Tamping: *g.* 6 cents. Carting: *h.* At rate of 30 cents per mile. In winter, add 50 per cent to *a, b, c, d, e, f, g.* Contract prices: Ohio, 1906-07 (*a*) summer, 25c.; winter, 50c.; Connecticut, 1906 (*c*) 65c.; carting, ½-mile haul, 10 cents; excavation, 15 feet deep in clay, and carting (hoisting engine already on ground), $1.00 per cubic yard; driving tunnel in clay, depth 30 feet, excavation, shoring, and carting, $3 per cubic yard. See "Gillete's Cost Data" for additional costs on excavation and allied subjects.

Concrete.—Cement should be purchased in the winter months to get the lowest price. A fair average cost of cement at the mixer, allowing for waste and lost sacks, is $1.50. Broken stone, $1.25. Sand, $1.00. Gravel, $0.75 per cubic yard. Cost of materials per cubic yard of concrete in place: 1—2—5 mixture broken stone, $3.75; 1 to 7 gravel concrete, $2.25.—Labor: For foundation work, mixing and placing by hand, 60 cents per yard; mixing by machine and placing by hand, 45 cents per yard.—Forms: Labor and material, 40 cents per yard.—Contract prices: Without forms, Ohio, 1907, gravel, $4 per yard; with forms, $5 per yard. Connecticut, 1906, broken stone, 1—2—5, without forms, $6; with forms, $6.50. These prices are for building foundations. Machine foundations including setting of bolts, pockets, etc.: Ohio, gravel concrete, $4.75; forms 7½ cents per square foot additional. Connecticut, broken stone concrete including forms, $7.—Concrete for ground floors including the setting of sleepers: Ohio, gravel concrete, 18 cents per cubic foot. Connecticut, stone concrete, 22 cents per cubic foot.—Roof slab: Connecticut, cinder concrete, 4 inches thick, 10-foot span, 21 cents per square foot. Ohio, 10-foot span, stone, 25 cents per square foot.—Gallery floors: 250-pound live load, 5-foot spans, cinder concrete, 26 cents per square foot. For 600-pound load, 5-foot span, 35 cents per square foot.—Reinforced concrete tunnels driven in clay 30 feet below surface, 4 x 10 feet inside, $35 per lineal foot: concrete with forms, $14 per cubic yard additional. Tunnel: 6 x 8 feet inside with industrial track, turn-table, 12-inch and 15-inch cast-iron pipes in floor, tapped sockets in walls for pipe hangers, $41 per lineal foot complete. Length about 330 feet, part driven and part open cut.

Cut Stone.—For sills, Ohio, 1907, tool planed, $1.25 per cubic foot. Connecticut, 1906, $2 per cubic foot; rock faced, $1.65 per cubic foot. Labor: setting, 25 cents per cubic foot.

Brickwork.—Cleaning old brick, $1 per 1,000. Unloading, 30 cents per 1,000. Cost of brickwork is governed by local prices and wages. Generally one helper is required to each mason. With cement at $1.50, sand $1, lime 63 cents per barrel, lime mortar will cost $1.25 per 1,000 kiln count, gaged mortar will cost $2.47 per 1,000. One to three cement mortar, $2.80 per 1,000. One to two cement mortar, $3.70.—Average price of brick at the yards in 1906: Illinois, $4.79; Michigan, $5.70; Ohio, $5.90; New York, $6; New England, $7 per 1,000.—Contract prices: Wall measure (22½ per cubic foot), Ohio, 1906, $11; 1907, $11.50. Connecticut, 1906, $13.30; Illinois, 1908, $10 per 1,000. Kiln count, or actual brick required will run about 17 per cubic foot of wall.

Terra-cotta.—Tile coping for 9-inch wall, 14 cents per lineal foot; corners, 36 cents. For 13-inch wall, 20 cents per foot; corners, 55 cents. Labor setting, 6 cents per foot.

Windows.—Plank frames, S. S. glass primed at mill, 15 cents per square foot of wall opening; box frames, D.S.A. glass, primed, 20 cents per square fcot; add 1½ cents for hardware; 4 cents for painting two coats; 10 cents for setting per square foot. For factory-ribbed glass add 2½ cents per square foot. Metal frames and sash with ribbed wire-glass, $1.60; with polished plate glass, $2.35 per square foot.—Metal window shutters, 50 cents per square foot. Window guards, No. 15 galvanized wire, ½ inch diamond mesh, in place, less than 15 square feet to one guard, 20 cents per square foot; 25 to 35 square feet, 17½ cents; 40 to 60 square feet, 15 cents per square foot.

Doors.—Wooden sliding doors, in place: 35 cents per square foot; steel rolling doors, 70 cents per square foot.

Skylights.—Copper bars, ¼ inch ribbed glass, 60 cents per square foot in place; if wire glass, add 10 cents per square foot.

Roofing.—Tar and gravel or tar and slag, $4.00 per square (100 square feet). Copper strainers with intakes, $1.50, in place. Down spouts, 5-inch galvanized, 25 cents per lineal foot, in place; 6-inch, 30 cents. Flashing, galvanized No. 24, 14 inch, 7 cents per lineal foot; in place, 14 cents; 20-inch, 13 cents and 20 cents. Counterflashing, material, 10 cents; in place, 25 cents.

Floors.—Cost complete, 6 inches gravel concrete, 4x4-inch cedar sleepers, 2-inch centers, tar and sand, 2x6-inch T. & G. Y. P. planking, ⅞x4-inch square edged No. 1 Maple top floor, 18 cents per square foot. Contract price, Ohio, 22¼ cents per square foot.—Cement floors: 6 inches cinders, 3 inches concrete, 1 inch cement top, 10 cents per square foot. Contract price, Connecticut, 1906, for 5 inches concrete, 1 inch cement top, 20 cents; 6 inches concrete, ½ inch cement binder, 1 inch asphalt, 24 cents.

Structural Steel.—Pittsburg, Nov., 1908: Beams and channels, 15 inch and under, $1.60; over 15 inch, $1.70; angles 6 inch and under, $1.60; plates, $1.60. Following prices should cover the cost to owner of the material erected and painted at any point where freight rate is not more than 15 cents a hundred. Trusses, 1,500 pounds and under, $65.00 per ton; 3,000 pounds and over, $60.00 per ton. Single I-beam columns, $55.00. Plate and angle columns, $65.00 to $70.00. Lattice columns, $72.00 to $78.00. Plate girders, $58.00 to $60.00. Beams, $50.00 to $52.00.

Carpenter Labor.—This is the most difficult class of construction work as regards estimating, as the "personal equation" enters largely and records of labor cost vary under seemingly like conditions. The following figures should be checked according to local conditions before using, as the quantities run up into big figures. All figures are for board measure, and in estimating allowance should be made for waste if standard lengths cannot be used (multiples of 2 feet), and for the difference between actual dimensions and "strip count" or nominal size. For instance 2x6-inch tongued and grooved material is cnly 5¼ inch face, and 1⅝-inch thick. Therefore it will require 11.7 per cent more lumber, board measure, than if the material were up to size. 1x4-inch maple is only 13/16x3¼-inch when matched. Hence the economy of square edge material, as but ¼ inch to 5/16 inch is required to dress the width. Unloading, from car to wagon or car to pile, 900 feet per hour per man. Purlins: Squaring to length, boring, raising and bolting to trusses, 61 feet per man per hour. Roof sheathing: Raising to roof level, 160 to 200 feet per hour per man. Laying: 55 to 60 feet per hour. Flooring: Gallery; under planking, raising 200 feet per man; laying, 60 feet; maple top flooring, 26 feet per man per hour. Ground floor: planking, 100 to 120 feet per man; maple top floor, 30 feet per man per hour. Nails: For roof sheathing allow 60 cents per 1,000 feet; floor planking, $1.25; maple top floor, ⅞ inch, 55 cents; 1⅛ inch, 75 cents. Fences: Ordinary board, 60 cents per lineal foot; swinging or sliding wagon gates, $50.

Sewers.—Tile salt glazed pipe F.O.B. site per lineal foot.

	6 in	8 in.	10 in.	12 in.	15 in.	20 in.	30 in.
Pipe	$0.09	$0.15	$0.225	$0.29	$0.42	$0.75	$2.83

Labor Excavating, laying and backfilling standard pipe, 125 per cent of cost of material; for lidded pipe, 150 per cent. Electrical tile ducts, 3¼ cents per duct foot or 13 cents per lineal foot of 4 duct conduit. Add 125 per cent for labor.

Percentage tables of cost of buildings are often given in books on estimating, but they are based on the complete cost of the building and some items are given in one table and not in others. This makes such tables almost useless. Table XII. is compiled from the best of these, but is based on the cost of the structural steel which cost does not vary so much as many of the other items. The prices of steel work of different classes previously given includes all expense and profit. Therefore, in making up the total sum for use as a basis for using the table, make allowance only for contingences of 5 to 10 per cent according to the thoroughness with which the quantities are estimated. It should be noted that the cost of skylights is about 15 times as much as gravel roof per square foot. When using the table, the per cent and cost should be increased to the basis of 4 cents per square foot for the roofing when there are no skylights and galleries.

TABLE XIII. POWER PLANT—EFFICIENCY AND COST.

Based on units of 500 Horse-power.

(MACHINERY, February, 1905; Sibley Journal; Author's personal records.)

Cost per K.W. hour of current consumed, 1.4 cent }

TABLE XIV. RECENT BIDS ON VARIOUS SIZES OF ENGINES, GENERATORS AND TURBO-GENERATORS, PER HORSE-POWER.

Nominal Engine Capacity. .... Nominal Generator Capacity...	300 H P. 200 K W	450 H.P. 300 K W.	750 H P. 500 K.W.	Two 750 H.P. 500 K.W.	Foundation.	Condenser.	Piping.	Switch Board.	Total per H.P. for 1500 H.P.
Engine..................	$21.20	18.80	14.45	14.45	2.50	4.50	3.39	3.69	$36.38
Generator.	14.78	10.85	7.85	7.85					
Turbo-generator..........	....	....	23.30	23.30	1.25	4.50	3.39	3.45	35.89

When using this table for "snap" estimates, add to the total sum, which represents the cost of the buildings alone, the cost of all items necessary to bring the buildings and equipment to an operative basis. The moving of the equipment from the old shops, and the repairing of old machines, should not be forgotten. The hints given in the previous installments of this series will aid in making a complete estimate. It is doubtful if there has ever been an estimate made on the cost of shop improvements that has not been exceeded by the actual costs, as invariably the tendency is towards adding equipment, or making some things better than intended.

Description of Shops in Table XII.

Shop No. 1. Machine shop, four story, high-class, 100,000 square feet floor space; steel frame; concrete floors. Live loads: second floor, 250 pounds per square foot; third and fourth floors, 200 pounds each. Roof: 2 x 6-inch plank, slag and tar, load 50 pounds per square foot. Ground floor: concrete with sleepers and 1⅛-inch maple top floor; upper floors 1⅛-inch maple. Windows, 65 per cent of wall surface. Two stair towers; two elevator shafts; one closet tower outside of main floor space

Shop No. 2. Machine shop, 150 x 400 feet, with 37 feet gallery, 40 feet to eaves. Heavy work.

Shop No. 3. Machine shop, 150 x 300 feet, 40 feet to eaves, no gallery; heavy wood floors.

Shop No. 4. Foundry, 31,000 square feet floor space. Sand floor, 30 x 220 feet; main floor, molding sand, 115 x 220 feet; wash room, 31 x 75 feet, cement floor.

Shop No. 5. Foundry, 130,000 square feet. Sand floor, 30 x 450 feet. Brick curtain walls. Office. Wash room, 32 x 120 feet. Yard crane runway included.

Shop No. 6. Forge shop, 13,000 square feet, 25 feet to eaves. Dirt floor. Trolley hoist runway inside of building and over storage yard outside.

Second Section—Power Plant Equipment.

Boilers.—Horizontal water tube, highest grade; units of 260 or 300 boiler horse-power, F.O.B. site, $10.00 per horse-power. Foundations, $1.00 per horse-power. Boiler setting with No. 1 fire-brick in first two passes, $2.25 per horse-power. Boiler room piping, $2.50 per horse-power. Breeching, $0.75. Stokers, $3.80; setting, $0.15, but deduct $0.60 for grates and fronts not used. Stacks: Steel stacks, guyed, one stack to each unit, $1.80 per horse-power. Self-supporting, one stack to 2 units, $2.50 per horse-power erected. Radial brick stacks, one for complete plant, 150 feet high with fire-brick core 50 feet high, $3.90 per horse-power. Balanced draft, $5.00 per horse-power (reduces the cost of the stack 50 per cent). Feed water heaters, $0.50 per horse-power. Water softening apparatus for 1,000 horse-power, $2.80 per horse-power (non-condensing plants or where jet condensers are used). Vertical water tube boilers, with stack on foundations, ready for steam and water connections, $13.00 per horse-power. Engine room equipment is given in Table XIII. Coal-handling apparatus: Track hopper and bucket conveyor to pockets, capacity 20 tons per hour, erected, $7,650.00. Coal pockets, roofed, with chutes and measuring gages to stokers, capacity 300 tons, erected, $6,050.

Third Section—Miscellaneous.

Conveyors.—Belt, 18-inch erected on steel supports, $11.50 per lineal foot of conveyor; 24-inch, $15.00 per lineal foot. If on wooden supports, $1.00 less for each size. Vertical bucket conveyors, $20.00 per foot of lift. Track hoppers, unloading from drop bottom cars, $250.00 erected.

Locomotive Cranes.—15 ton capacity and with power and speed sufficient for use in switching, with cab enclosed, and

double drum arranged for handling two line grab bucket, complete with ballast ready for use, $6,500.00.

Grab buckets.—Single line, 25 cubic feet capacity, $1,100.00; 45 cubic feet, $1,300.00. Two line buckets, $350 and $500.

Cranes.—Traveling, erected, 15 ton, 50 feet span, $3,700, with auxiliary hoist, $550 additional; 10 ton, 50 feet span, $3,500; 5 ton, 50 feet span, $3,000; 25 feet span, $2,000; 3 ton, 25 feet span, $1,500; 3 ton trolley hoist, $1,250.

Elevators.—Belt driven freight elevators, erected, 3 ton, 40 feet per minute, $900; direct driven electric, 3 ton, 75 feet per minute, $2,500; 30 feet per minute, $1,700; hydraulic, 25 feet lift, 75 feet per minute, $2,000; 50 feet per minute, $1,200.

Contracting and Purchasing.

In every case the engineer must ask for bids. The various building contractors should be considered on the following points: Commercial integrity and general reputation; capabilities for handling contract in connection with other contracts on hand; organization and speed of execution of large contracts of the class of construction required; quality of workmanship; freedom from labor troubles. It will be found that the number of desirable bidders, when critically examined, is not large in any particular locality, still a list can be made, not neglecting those who can handle small contracts well, and rated according to the size of contract that each can handle.

General contractors will generally use the lowest bids from sub-contractors in making up their bid. The engineer should require that a list of sub-bidders should be furnished and approved by him, as often the best contractors on parts of the work will not put in bids to the general contractor, but will bid direct. It is well to encourage the smaller bidders in this practice, as the engineer can study their efficiency and reliability. The advantage to the engineer lies in obtaining accurate data of cost of various parts of the work and being able to guard against combinations and unbalanced bids.

Classes of Contracts.

Competitive bidding and a lump sum contract (at the present time) is probably the most satisfactory to the owner, and will enable the total cost to be known in advance of the commencement of work. The cost-plus-a-percentage-plan is greatly in the contractor's favor, as the greater the cost the greater the contractor's profit and there is no incentive to rush the work. The cost-plus-a-fixed-sum-plan is the best if operations must be commenced before thorough plans and specifications can be prepared.

It eliminates the element of risk to the contractor, but throws a great deal of work and worry onto the owners that would be assumed by the contractor under a lump sum contract. As to speed, that depends entirely on the organization of the contractor's forces and his desire to make a reputation for rapid execution of contracts. His pecuniary interest is no greater if the work progresses rapidly than if it lags. With a lump sum, the rapidity of construction almost always tends to larger profit to the contractor without any addition to the amount that the owner has reconciled himself to pay.

Form of Contract.

Without going into the legal points of engineering contracts, the more important particulars are: Definiteness of statement regarding the work included in the contract and that the drawings and specifications are a part of the contract and equally binding with the clauses of the contract proper; the terms of partial and complete payments and the conditions of acceptance of the work prior to such payments; provision for completing the work in the event of the contractor failing in the performance of the work or otherwise violating the terms of the contract; liquidated damages for non-completion of contract in the prescribed time; provision for the extension of the time in which the contract is to be completed according to changes and causes beyond the contractor's control. The "uniform contract" recommended by the American Institute of Architects is in the main satisfactory to both owner and contractor.

Regarding mechanics' and other liens, the engineer should investigate the State laws and protect his principals from a double payment in the event of the contractor failing and leaving material and work unpaid for.

Purchasing Equipment.

The conditions governing the purchasing of equipment are of a different nature from those pertaining to the building trades, but where specifications are drawn by the engineer for equipment, the same care should be exercised in stating definitely what is wanted

Generally the only specifications that need be drawn by the engineer are: that the apparatus shall perform a given amount of work in a given time; that this amount shall be guaranteed under actual working conditions; that in the installation the maker shall instruct in the operation; that the apparatus shall be erected and operated and tested to fulfil the guarantee; that repairs during a year caused by defects and workmanship shall be charged to the maker; that the efficiency or cost of operation shall be stated as a part of the guarantee.

GUARD FOR EMERY WHEELS.

The half-tone below illustrates a simple but effective guard for emery wheels, brought out by the Vereinigten Schmirgel- und Maschinenfabriken, Hanover-Hainholz, Germany, and illustrated in the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, Nov. 25, 1908. A particular feature of this guard, outside of its adjustability to different sizes of emery wheels, is also the elastic construction which provides for absolute safety in case the wheel should burst. In case of ordinary cast iron guards, it often happens that the emery wheel, bursting when running at high speed, breaks the guard also and scatters pieces of the guard around the room. The severity of injuries is, of course, lessened by the resistance of the guard, but damage is not entirely eliminated. In the guard shown in the illustration herewith, however, the parts of the wheels strike against a corrugated band, composed of several laminations of sheet steel. On account of the corrugated construction, the guard possesses an elasticity which aids in preventing breakage of the steel laminations in case of accident. Experiments have been undertaken by the manufacturers to ascertain the ability of the guard to withstand the bursting of wheels, and these experiments have been highly successful.

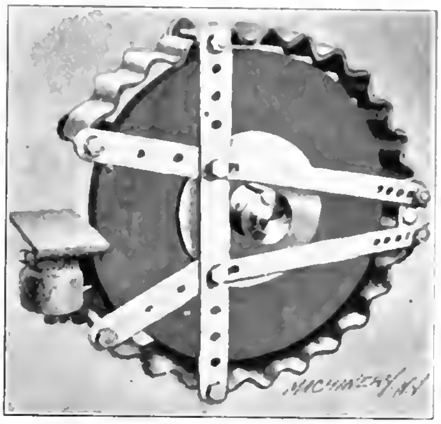

Fig. 1. Elastic Emery Wheel Guard which is able to withstand Severe Shocks.

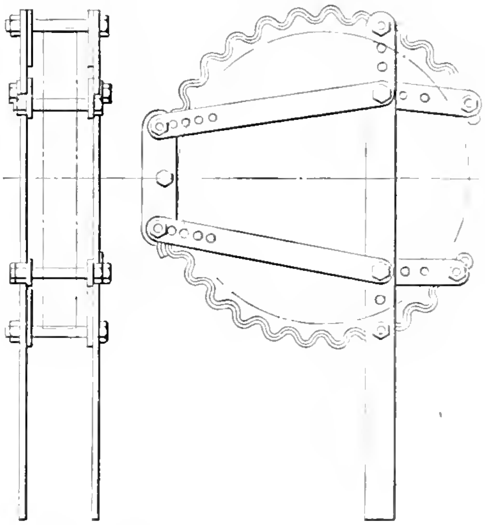

Fig. 2. Elevations of the Corrugated Guard.

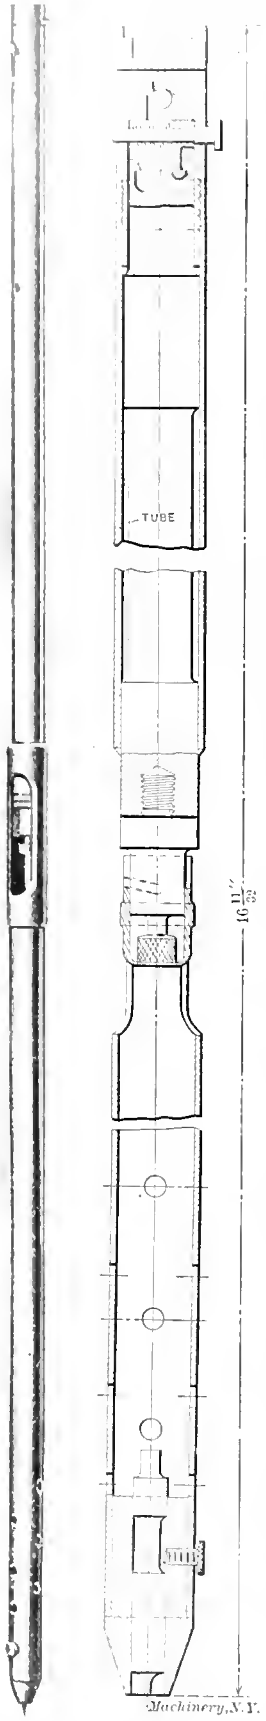
The largest concrete arch bridge in the world was recently completed in Switzerland. It comprises a central arch of 259¼ feet and six 33-foot arches in the approaches.

BALLENTINE HARDNESS TESTING DEVICE.*

In the September issue of MACHINERY, the Brinell method of testing the hardness of metals was described in an extended article. The principle involved in testing the hardness of metals by this method is based on the fact that the hardness of metals may be compared by recording the resistance of the metal to indentation. If indentations are made in various substances by the same force transmitted through the same medium, the relative hardness of different materials can be measured by determining the dimensions of the indentations. This is, in principle, the system employed by the Brinell apparatus.



Figs 1 and 2. General View and Section of Ballentine's Hardness Testing Device.

The fact should not be overlooked, however, that the measuring of the dimensions of such indentation is more or less difficult to accomplish accurately, and the method requires special instruments for obtaining the indentation, and for measuring the amount of depression in the metal tested. In order to overcome this difficulty, a means known as the Ballentine method and apparatus for quickly and accurately determining the resistance to indentation of a material has been devised and constructed.

The method employed by Mr. Ballentine consists in allowing a hammer of specified weight to fall through a specified height on an anvil to which is connected a pin which rests on the specimen to be tested. An indentation in the material is obtained, but the resistance encountered, instead of the dimensions of the indentation, is measured. This resistance is measured by the blow of the hammer being transmitted to the test pin through a soft metal recording disk located at the lower end of the hammer. This disk affords a constant resistance to deformation, and will be indented to a depth varying in proportion to the resistance the pin encounters in indenting the material tested. The recording disk is usually made from lead.

The accompanying half-tone and line engraving show the general appearance and a sectional view of the apparatus, which consists of a guide tube encasing the drop hammer which at the lower end is provided with a small anvil to which is clamped a lead disk. At the upper end the hammer is held at the top of the tube by a spring latch. At the lower end of the tube a test pin holder is located, in which are inserted the test pins for testing the various materials. The upper end of the test pin holder is provided with an anvil of the same diameter as the one on the lower end of the hammer. A small spirit level is inserted in the top of the tube for leveling the apparatus, and two small slots are cut in the guide tube for inserting and removing the recording disks. The apparatus can be used to test all materials which can be ordinarily machined by steel cutting tools, but cannot be used for hardened steel and similar materials which are too hard to be indented in this manner. Two test pins are provided, one for soft materials such as lead and babbitt metals, and another for harder materials such as iron and steel. The pin for hard material is very short and small in diameter while the pin for soft material is longer and larger in diameter.

The testing can be made either on small test specimens or directly on large parts in process of manufacture, the great advantage of this hardness tester being that it is entirely self-contained and well adapted for either laboratory or general shop use. To make a test it is only necessary to smooth off a surface on the specimen to be tested, and clamp it firmly to some rigid body.

Fig. 3. Lead Recording Disk, Before and After Test.

In Fig. 3 is shown a lead recording disk before and after the test. These disks are made within 0.0015 inch of nominal size from a material as nearly of uniform density and hardness as obtainable. The disk is measured with a micrometer before being placed on the drop hammer. When the test has been made, the thickness of the metal between the two recording anvils is again measured, and the difference between the two dimensions will indicate the resistance to indentation or the hardness of the material tested. If, for instance, the disk measured 0.300 before the test, and 0.156 after the test, the difference, 0.144 inch, indicates the hardness of the material, and this hardness would be known as No. 144. The device is manufactured by Tinius Olsen & Co., 500 N. 12th St., Philadelphia, Pa.

REMARKABLE RESULT OF COMBINING ALLEGED MACHINE EFFICIENCIES.

The following ingenious invention of a combustion motor for automobiles is described in *Svensk Motortidning.* A promising young inventor was grappling with the problem of bringing out an economical 20-horse-power combustion engine, and in doing so he studied a great many trade catalogues of accessories for engines of this kind. His investigations led him to the conclusion that by judicious selection of integral parts of the machine he would be able to bring out an engine which would come very close to becoming a perpetual motion machine. He obtained guarantees from various firms manufacturing the smaller details as to the amount each would save in fuel, and constructed an engine provided with a special carbureter, saving 30 per cent, and provided with bearings of special metal saving 12 per cent of the fuel. A governing apparatus saving 18 per cent was applied to the engine, and besides a muffler saving 10 per cent, an automatic lubrication system saving 15 per cent, a patented valve arrangement saving 11 per cent, and finally a system of ignition guaranteed to save 5 per cent; adding up his percentages of saving the inventor found that he had saved exactly 101 per cent of the fuel required. Allowing the superfluous one per cent for frictional and undetermined losses, he thus found that by the combination of the above inventions he had obtained an engine which would work without any fuel whatever, and he naturally made application for a patent on the combination of these wonderful apparatus. The principle is so simple that it is almost irritating that one did not think of it oneself. The invention reminds us of the planer salesman who, among other things claimed for his planer, said that while it took a great deal of power to start it, when once started, it ran so easily that it actually at times would drive the engine.

HOW MANY GASHES SHOULD A HOB HAVE?

RALPH E. FLANDERS *

The question of how many gashes to cut in a worm hob, particularly if the hob is multiple-threaded, has always been a puzzling one for most mechanics, including in that number the writer of this article. Until recently he had supposed that the only requirement that had to be met in this matter was that discovered by Mr. Beale, of the Brown & Sharpe Mfg. Co., at the time the writer was employed by that firm. This requirement is that the number of gashes must have no common factor with the number of threads in the worm. That is to say, if the worm is quadruple threaded, the number of gashes should be 9 or 7 rather than 8. If the work is sextuple threaded, the number of gashes should be 7 or 11 rather than 8, 9 or 10. This is one requirement, but there seem to be other factors that enter into the decision as well. These were brought to the attention of the writer by Mr. N. B. Chace, superintendent of the Cincinnati Shaper Co., in his attempt to get a hob that would cut smooth, regular teeth for the worm-wheel of the spindle drive in a machine he was building.

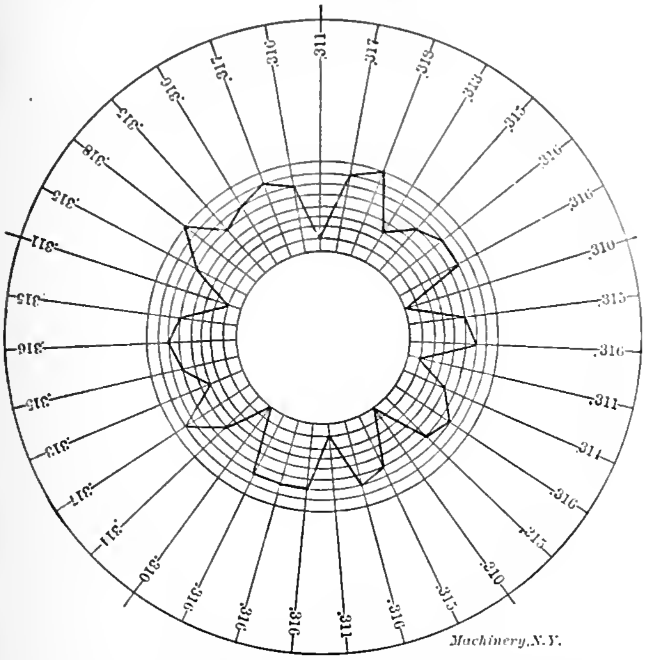

Fig. 1. Thick and Thin Teeth, produced by Incomplete Generating Action on the Part of the Hob.

The worm-wheel of this drive had 35 teeth. The worm had 7 threads and a lead of 5 inches. The number of flutes or gashes in the hob was 9. These gashes were milled spirally so that they were at right angles to the thread. The hob was made by a well-known firm which makes a specialty of such work; it was proved by subsequent tests to be accurately and finely made, and altogether a very creditable piece of work. Do what he could, however, Mr. Chace was unable to hob worm-wheels that would be satisfactory. When tried in place in the machine and run with the worm, each one appeared to have five low spots, something as if the pitch line were a pentagon instead of a circle. The wheels were taken out and the thickness of the teeth in the center of the throat at the pitch line measured as accurately as possible. The results of one of these tests, made at the time of the writer's visit, is shown in Fig. 1, where it will be seen that there is a regular recurrence of thin teeth in each fifth of the circumference of the wheel with less marked series of fine intermediate thin teeth. The diagram in the center of the figure shows graphically (by the exaggerated radial distance from the center), the variation in the measurements obtained. The first thought would naturally be that the hob had warped out of true in hardening, in which case the ratio between the worm and the wheel of 5 to 1 would give the error indicated; but careful measurements failed to detect any error of this kind, either in the periphery of the hob or on the sides of the cutting edges.

The Imperfect Generating Action of the Hob.

To find what was really the trouble with the hob (or rather, with the work of the hob, for the hob was found to be all right), it will be necessary to study its action in cutting a worm-wheel. The diagram in Fig. 2 will serve to illustrate some of the important points connected with this action. In the upper part of the diagram at the right is shown an end view of a single threaded hob having six gashes. To the left of this is shown the pitch cylinder of the hob with a helix traced upon it, representing the center of the thread. Lines parallel with the axis of the work are drawn on this pitch cylinder, representing the intersection of the faces of the teeth with the cylinder. The intersections of the helix with these lines at *a*, *b*, *c*, *d*—*q*, represent the positions on the pitch cylinder of the center of each of the teeth of the hob. Below this representation of the pitch cylinder is shown a development of its circumference through an axial length equal to the linear pitch of the worm, represented in this case by the distance *c i*. On this development, the tooth helix between *c* and *i* becomes a straight line, as shown, and the center of the tooth faces *c*, *d*, *e*, *f*, *g*, *h* and *i* are developed, as before, by the intersection of this tooth line with equally spaced horizontal lines representing the six gashes in the circumference. Below this development of the circumference of the hob is shown a series of outlines of the cutting edges of the hob, each one of which has its center directly below the corresponding center c_1 d_1, etc., in the development. These outlines evidently represent the successive positions of the teeth of the hob as they pass the plane of the throat of the worm-wheel in hobbing its teeth. There are seven of these positions, but as one of them belongs to the next section of the hob, from *i* to *o*, the diagram shows six positions of the hob teeth in the linear pitch of the hob.

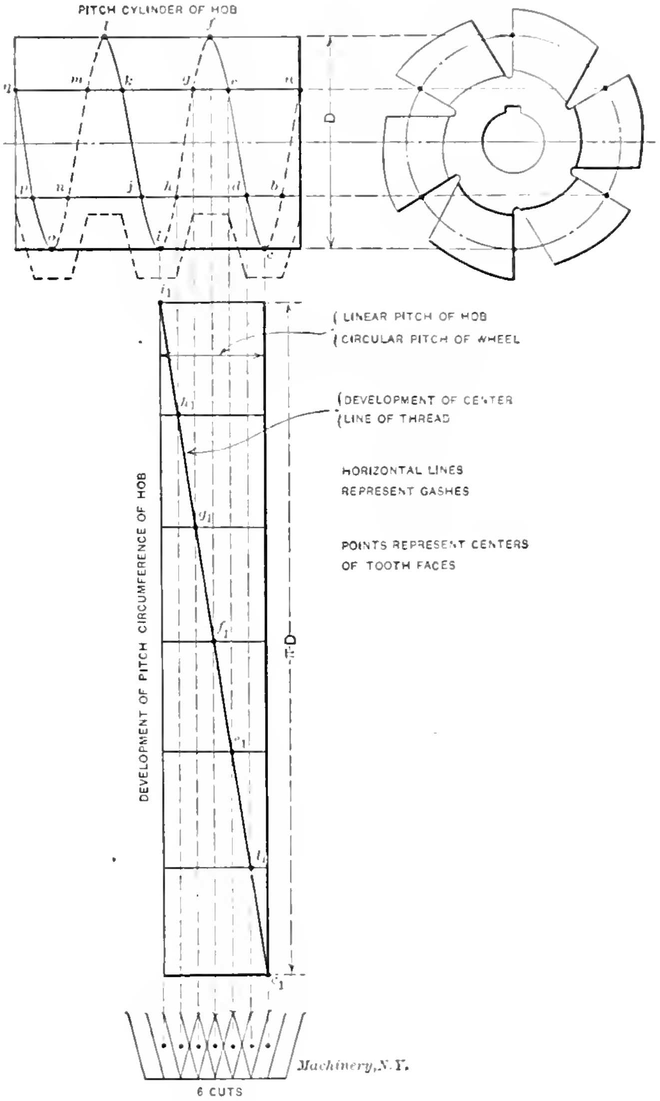

Fig. 2. Finding the Number of Cuts per Linear Pitch.

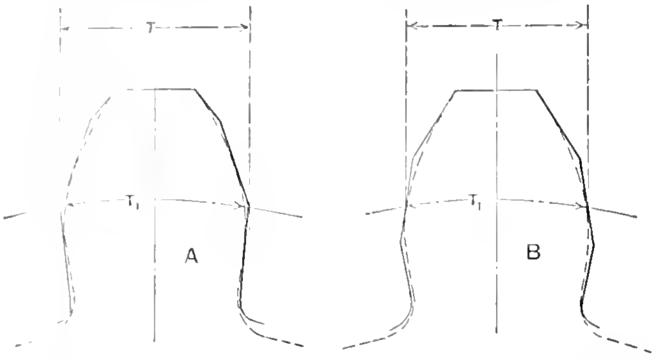
---

* Associate Editor of MACHINERY.

This means, of course that the hob does not accurately generate a tooth of the wheel, since it acts on it only in the six successive positions shown, instead of continuously throughout the whole distance of the circular pitch. In order to get smooth accurate teeth, the number of cuts in the linear pitch must be made as many as possible; the more there are, the more nearly perfect would the generating action be; the less there are, the rougher will be the tooth. Now, as will be shown later, there is but *one* cut per linear pitch in the example mentioned in the second paragraph of this article. Under these circumstances, the teeth of the worm, instead of being smoothly generated to a curve, are only slabbed out by a series of flat cuts, as indicated in Fig. 3. The reason for the five thin teeth in the circumference is now evident. At every fifth of a revolution those teeth of the hob which formed the outline near the pitch line of the gear gave it a shape similar to that shown at the right of the engraving. In the thick teeth, the conditions shown at the left are found, where the outline of the tooth at the pitch line is formed by cuts so placed as to make corners at this point instead of flats as at the right. This means that the teeth measured on the pitch line are thick at one point and thin at the other, giving high spots, as found by running the wheel with the worm, and as indicated also by the measurement shown in Fig. 1. The reason for the intermediate thin spots between the even fifths is not clear from the preceding explanation, but they are doubtless due to the particular arrangement of the flats on the tooth outline which happens in this particular wheel.



Machinery,N.Y.

Fig. 3. Example of Thick and Thin Teeth from Incomplete Generation.

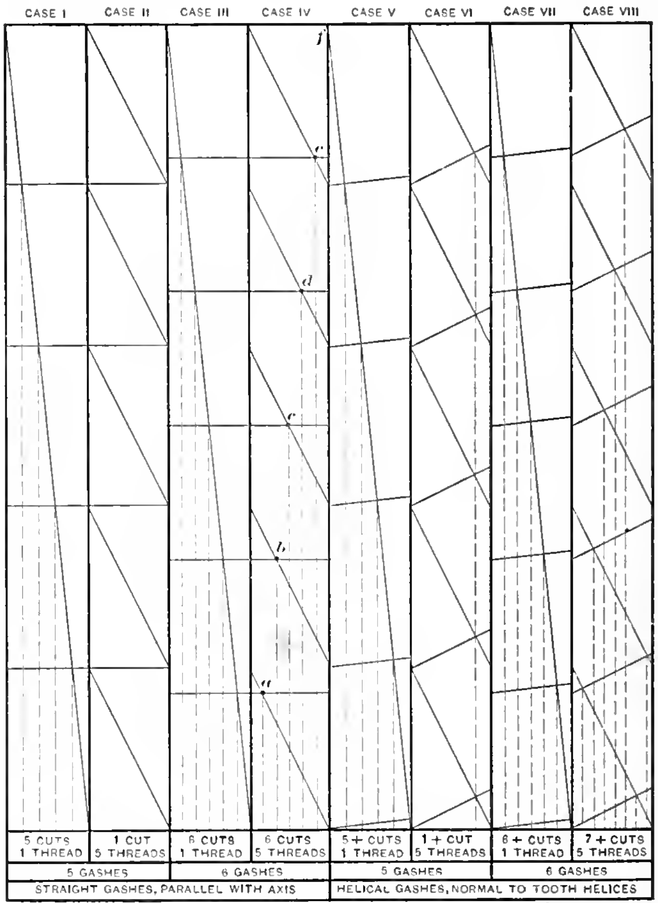
Diagrams for Finding the Number of Cuts per Linear Pitch.

It is evidently a simple matter to draw diagrams for any case showing the development of one linear pitch on the pitch surface of the hob, as in Fig. 2, and find out from that diagram how many cuts the hob gives in that distance. In Fig. 4 eight such diagrams are shown, for eight different cases. The first case is a single threaded hob, having five gashes. This diagram, which is similar to the one in Fig. 2, shows that there are five cuts to the linear pitch. In the second diagram a hob of the same diameter and the same linear pitch having also five gashes, but quintuple instead of single threaded, gives but one cut to the linear pitch. This is evidently a very bad condition and one to be avoided, if possible, and it is evidently brought about from the fact that the number of gashes is the same as the number of threads. In the third and fourth cases the number of gashes has been increased to six, with a single thread in one case and a quintuple thread in the other. In each case there are six cuts to the linear pitch. The fifth and sixth cases are the same as the first and second, except that the lines representing the gashes have been drawn at right angles to the lines representing the tooth helices as would be necessary for hobs which are gashed helically in a direction normal to the tooth helices. These cases will be seen to correspond to Nos. 1 and 2 except that the number of cuts has been increased in proportion to the cosine of the gashing angle, so that we have 5 + cuts for case five, and 1 + cuts for case six. In cases seven and eight are shown the same conditions as in cases three and four, except that the hob is gashed helically. In this case, also, the number of cuts is increased in inverse proportion to the cosine of the gashing angle, giving 6 + and 7 + cuts respectively for the two cases, the hobs having six gashes each.

In Fig. 5 are shown four more cases, considerably more complicated than those in Fig. 4. Here are four hobs, all of the same linear pitch and pitch diameter, and all octuple threaded, with threads of the same lead and helix angle, the only difference in the four being in the number of gashes and the method of cutting them. In Cases IX and XI there are eleven gashes, and in cases X and XII there are twelve. Cases IX and X are gashed parallel with the axis. This, of course, would be utterly impracticable in any hob having threading angles as great as those shown here, so the example is not a practical one, being used only for the sake of illustrating a principle. Cases XI and XII which are gashed helically and normally at right angles to the threads, represent what would be the practical construction of these hobs. Projecting the intersections of the thread lines with the gash lines, down to the bottom of each diagram, we get for Case IX, eleven cuts linear pitch; for Case X, three cuts to a linear pitch; for Case XI, 38 + cuts; and for Case XII 11 + cuts.

The Effect of the Number of Teeth in the Wheel.

But there is still another factor entering into this problem—the number of teeth in the wheel. This is the factor which gave so much trouble to the superintendent in the job mentioned at the beginning of the article. Take, for instance, Case IV in Fig. 4. Suppose that the quintuple threaded, six-gashed hob represented by that diagram, were cutting a 25-tooth wheel, it would not give the six cuts indicated by the diagram. The reason for this will appear by comparing Case IV with Case III. In Case III, where the hob is single threaded, all of the cuts represented by the points of the intersections of the thread and gash lines, are along the same thread. In Case IV, however, each of the five thread lines in the diagram has but one intersection. That means that if the number of teeth in the gear, as in the supposed example, is a multiple of the number of threads in the worm or hob, each of those threads will come back into the same tooth spaces in the wheel at each revolution of the latter, so that for each tooth space there is but one cutting



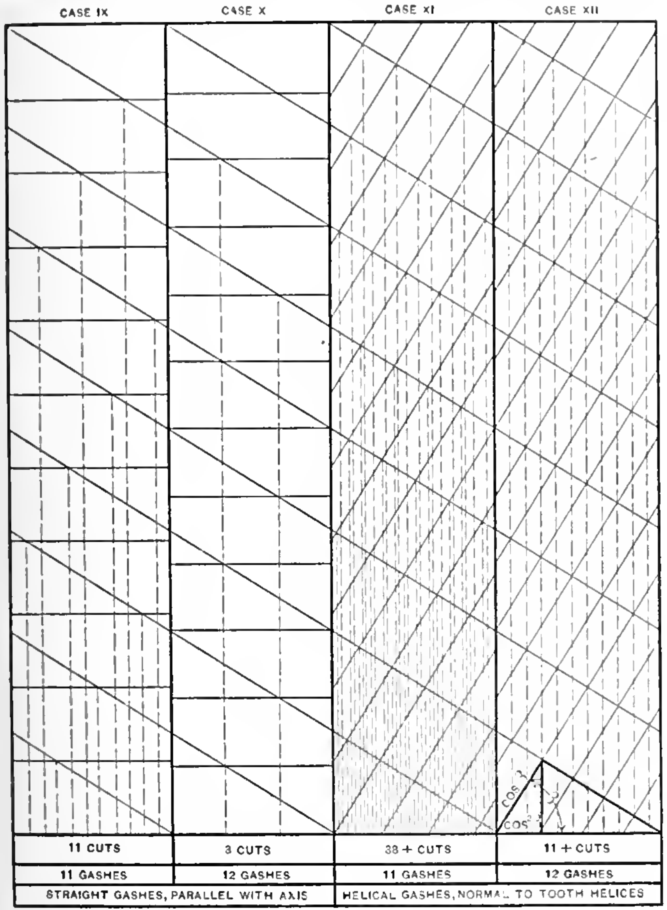
Machinery,N.Y.

Fig. 4. Diagram for Finding the Number of Cuts per Linear Pitch.

position of the hob tooth—that represented, for instance, by point *a* for one of the tooth spaces, point *b* for the next, *c* for the next, and so on. If, on the other hand, there were 26 teeth in the wheel, the first time it went around, point *a* would cut in a certain tooth space; the second time around point *b* would come in the same space, and the third time around point *c* would follow, so that each tooth space would get the benefit of each one of the six cuts, the same as in the single thread worm for case three. It is thus seen that, besides the other points mentioned, the number of teeth in the wheel has an effect on the number of cuts of the worm per linear pitch. In the practical case mentioned in the opening paragraph, there was a 35-tooth worm-wheel and a 7-threaded worm, giving the worst conditions possible.

A General Formula for Determining the Number of Cuts.

From the preceding description it will be seen that there are three points to be taken into consideration in determining the number of cuts per linear pitch (and the consequent generating efficiency of the worm) from the number of gashes in the hob. These factors are: First, the relation of the number of threads of the hob to the number of gashes. Second, the angle of the gashing. Third, the relation of the number of threads of the hob to the number of teeth in the wheel to be cut. [It might be considered that there is a fourth factor, that of the absolute number of teeth in the wheel, since the trouble that comes from a small number of cuts per linear pitch is exaggerated in the case of a wheel having very few teeth. This is not a matter of calculation, however, and would not enter into the calculations anyway, since for any given case for which a hob is being designed, the number of teeth in the wheel is determined approximately at least.]



Machinery,N.Y.

Fig. 5. Diagram for Finding the Number of Cuts per Linear Pitch.

Now, instead of drawing diagrams such as shown in Figs. 2, 4 and 5, it would be better if a simple mathematical expression could be obtained which would give the number of cuts per linear pitch directly. This can easily be done. The effect of the number of gashes with relation to the number of threads is as follows: *The number of cuts per inch varies inversely with the greatest common divisor of the number of threads and the number of gashes in the hob.* The influence of the number of teeth in the wheel is a similar one and may be expressed as follows: *The number of cuts per linear pitch varies inversely with the greatest common divisor of the number of threads in the worm and the number of teeth in the wheel.* The effect of the angle of the gashing may be expressed as follows: *The number of cuts per linear pitch varies inversely with the square of the cosine of the gashing angle, measured from a line parallel with the axis of the hob.* These statements are combined in the following formula:

$$X = \frac{G}{D \times D' \times \cos\beta}$$

in which

G = number of gashes,

β = angle of gashing with axis,

D = G. C. D. of number of threads and number of gashes in hob,

D' = G. C. D. of number of threads in hob and number of teeth in wheel,

X = number of cuts per linear pitch.

G. C. D., of course, stands for "greatest common divisor."

It is easier to see the relationships expressed above, from the foregoing diagrams and description, than it is to explain them. These relationships, though quite simple, are rather elusive. Perhaps, however, the effect of the angle will be understood from the figuring of the triangle at the base of the diagram for Case XII. Note that the formula is true only for the usual cases in which the gashing is either helical and normal to the threading, or straight and parallel to the axis. In the latter case, $\cos^2\beta = 1$, since $\beta = 0$ deg., and the effect of the angle disappears.

Applying the formula to the practical example given in the second paragraph, we have the following values:

$G = 9$,

$\beta = 20$ deg. (assumed, as the angle was not given),

$D = 1$ = G. C. D. of 9 (number of gashes) and 7 (number of threads),

$D' = 7$ = G. C. D. of 7 (number of threads) and 35 (number of teeth in wheel).

Solving for the number of cuts per inch we have:

$$X = \frac{9}{1 \times 7 \times 0.9397^2} = \frac{9}{6.181} = 1.45.$$

If the number of teeth in the wheel had been 36 instead of 35 the number of cuts would have been

$$X = \frac{9}{1 \times 1 \times 0.9397^2} = \frac{9}{0.883} = 10.19$$

which, it will be seen, would immeasurably improve conditions, giving a fine, smooth outline for this number of teeth in the wheel. In the actual wheel, as cut by the hob, the slab-sided effect shown in Fig. 3 was very noticeable, there being about three cuts to each face of the tooth.

Hobbing Methods which give a Complete Generating Action.

It should be noted that while this faulty generating is liable to occur with hobbing by the usual method of sinking the cutter in to depth in a blank, the same difficulty does not occur in the fly-tool process or in a machine using a taper hob fed axially past the work, as described for the Atlas, Eberhardt Bros., Wallwork and Reinecker machines referred to in the article on "Gear-Cutting Machinery" in the June, 1908, issue of MACHINERY. In the case of these machines, working with either taper hobs or fly-cutters, the number of cuts per pitch is, at the least calculation, the number of revolutions per linear pitch of advance of the cutter spindle; it thus runs up into the thousands, where the diagrams shown in Figs. 2, 4 and 5 give only from 1 to 38.

So far as the writer is able to see at present, this treatment of the hob question, suggested by the experiences of the superintendent of the western machine shop, takes care of all the factors which enter into a determination of the number of gashes to use in a hob, so far as this affects the accuracy of the generating action. Expressed briefly, the conclusions are:

Avoid having a common factor between the number of threads and the number of gashes in the hob.

* Avoid having a common factor between the number of threads in the hob, and the number of teeth in the wheel.

---

* Owing to special conditions, Mr. Chace was unable to meet this requirement.

HELICAL SPRINGS.

HENRY L. HANSON *

The four tables accompanying this article (see Data Sheet Supplement) give the greatest allowable pressure or load in pounds, and the corresponding compression or deflection in inches per coil of helical springs of various sizes. The same values for helical springs of square steel with like diameters, may be found by multiplying the greatest allowable loads for round stock by 1.2 and the deflections by 0.59.

It is proper to state in the beginning that helical springs are not spiral springs, as they are so often miscalled by the majority of machinists, and even by mechanical engineers. A spiral spring is one in which the coils lie in the same plane, being wound around a center and continually receding from it the same as a watch spring. A helical spring is one that is wound around an arbor, advancing like the thread of a screw. A volute spring, in a sense, might be said to be a combination of the two, being shaped like a cone.

As will be seen from the Tables, the values given therein are for springs made of a good quality spring steel, varying in fiber strength from 80,000 to 150,000 pounds per square inch of section. The maximum fiber strength of the larger sizes of common spring wire or rods has been shown by repeated tests to be somewhat less than the figures given in the tables, but for the smaller sizes of wire the fiber strength obtained by test compares very favorably with the figures given. The greater strength of the small size of spring wire, no doubt, is due to the fact that it is drawn down from large stock, each draft increasing its strength because of the refining effect of the dies on the surface of the metal. In the large sizes, the proportionate increase of strength due to the refined metal is not so much. In fact, large sizes of helical springs often are made from rods or bars taken directly from the rolling mill.

The tables are based on the J. W. Cloud adaptation of spring formulas given in "Kent's Mechanical Engineer's Pocketbook" on page 351 where $P = \frac{S \pi d^3}{16R}$; and $f = \frac{32 P R^2 l}{G \pi d^4}$ in which

$P =$ load of spring,
$S =$ maximum shearing fiber stresses in bar,
$d =$ diameter of wire or rod,
$R =$ radius of spring, measured to center of wire,
$l =$ length of rod before coiling,
$G =$ modulus of shearing elasticity,
$f =$ deflection of spring under load.

The second formula becomes on substituting for P its value in terms of S: $f = \frac{2 R S l}{d G}$; and neglecting the difference between the circumference of a circle and one coil of a helix, it can be written: $f = \frac{64 P R^3}{d^4 G}$. A large number of tests were recently made with springs of various sizes of wire and diameters of coil to determine the accuracy of these formulas and of these tables compiled. On the whole the formulas and tables derived were found to be very close to the average results, especially on springs made from small wire.

The load for a spring, as given in the tables, is the greatest allowable pressure; therefore, a factor of safety should be used for all spring installation, depending on the nature of the service. A spring being made of elastic material and of such shape as will permit of great relative deflection, will not be affected by sudden shocks or blows to the same extent as a rigid body. Consequently, a factor of safety very much less than for the rigid members of a machine body may be employed. The factor of safety varies, of course, according to the service, and the following are considered good practice. For no vibration, use a factor 1.5; for moderate vibration, 2; and for incessant vibration, 3. To illustrate the use of the tables, a few examples will be given.

Example 1: What is the greatest allowable load for a spring made of ¼ inch round wire, 1¾ inch outside diameter? The mean diameter of the spring, which corresponds to the pitch diameter of a gear, is the outside diameter minus the diameter of the wire, and in this case is 1¾ inch — ¼ inch = 1½ inch. From Table II. we find that the greatest allowable pressure or load is 513 pounds, and that the deflection is 0.338 inch per coil.

Example 2: Assuming that the foregoing spring has 15 coils, close wound, how much is the extension under a load of 513 pounds? In calculating the deflection, we consider the two end coils as inoperative; this then leaves 13 working coils, and the entire deflection of the spring would be 13 × 0.338 inch = 4.394 inch.

Example 3: A spring made of ½-inch round wire, close wound, and 4 inches mean diameter, is used in tension subject to moderate vibration where the load is not known. How can it be ascertained whether the spring is overloaded or not? Referring to Table III., we find that the maximum deflection per coil of a spring of a given diameter is 1.040 inch. If the opening between the coils is less than 1.040 inch ÷ 2 = 0.520 inch (2 being the factor of safety for moderate vibration), the spring is safe. The deflection always is directly proportionate to the load. For example, what will be the deflection of a spring 6 inches mean diameter, made of ¾ inch round wire, when carrying a load of 1,000 pounds? From Table III we find that with a load of 2,770 pounds, the deflection per coil is 1.440 inch; then for 1,000 pounds the deflection per coil would be $\frac{1.440 \times 1,000}{2,770} = 0.520$ inch.

The designing of springs, when using these tables, becomes simply a matter of multiplying the load the spring is to carry by a proper factor of safety and then selecting a resultant pressure in the tables; from this, the diameter of the wire and the deflection can be found readily. Dividing the deflection given in the table by the same factor of safety as was used for the load, will give the actual deflection per coil, and adding this value to the diameter of the wire will give the pitch for a compression spring. The number of coils will depend upon the amount of movement the spring requires, and knowing this, we divide the length of movement by the deflection per coil, which gives the number of effective coils, and then add 1½ coils for the ends. As a rule, the mean diameter of a helical spring should be from 8 to 10 times the diameter of the wire.

CORRESPONDENCE CARD FOR MFG. PLANTS.

In large manufacturing plants communications between the different departments are numerous, and any scheme that saves time and unnecessary writing in such correspondence is worthy of attention. The accompanying reproduction shows the head of the correspondence card used by the Ingersoll-Rand Co. Only a word of explanation is required to make its use clear. It will be noted that a list of departments is printed on the head, with numbers. If the foreman of the pattern shop, for example, wishes to communicate with the foundry, he simply draws a line through his own department and writes the number of the department to which the communication is to be sent. That constitutes all the direction necessary and identifies the source of the communication. If the note is to be sent on to another department with memorandum, the first number can be crossed off and a second number written in the places provided. Thus to forward the note from the foundry to the machine shop the number 15 is written in, the previous number 14 being crossed off.

THE MANUFACTURE OF TAPS—1.

While the methods involved in the making of a tap in the tool-room, when only one or a few tools are made at a time, are comparatively simple, and well-known to tool-makers and mechanics, the processes employed in the manufacture of taps in large quantities are entirely different from those which would be employed by the tool-maker. A great deal has been published in MACHINERY during the last few years regarding the design and construction of taps, but comparatively little has been published in the technical journals regarding the actual manufacturing processes employed by leading tap manufacturers. MACHINERY, therefore, obtained permission from the Wells Bros. Co. of Greenfield, Mass., to send an editorial representative to visit the works with the object of presenting to the readers of MACHINERY an illustrated description of the works and the methods employed.

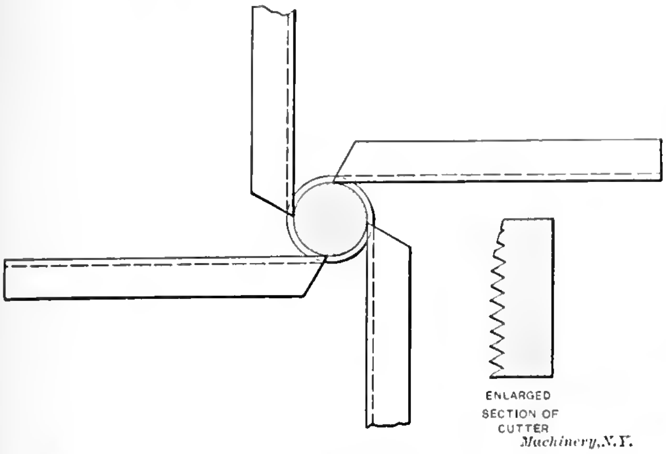

Fig. 1. Principle of Action of Dies with Inserted Chasers or Cutters, for Threading Taps.

It may well be said that Greenfield, Mass., although a small town of only ten or twelve thousand inhabitants, is actually the seat of the tap and die manufacture of the country. There are about half a dozen different firms in this town manufacturing taps and dies, and it is stated that 75 per cent of the total of these tools used in the United States is manufactured in Greenfield. The output of the Wells Bros. Co. constitutes a considerable proportion of this percentage.

History of the Wells Bros. Co.

The Wells Bros. Co. was started in 1876 by Messrs. F. E. Wells and F. O. Wells, who, together with their father, Mr. E. Wells, commenced the manufacture of taps and dies in a small factory. They began business with $1,100, and it is one of the remarkable features about the up-building of this concern that it has grown up entirely from this original investment, no money having ever been borrowed for the increase of the factory and equipment. At first the brothers employed no help. During the first year they met with some difficulties; the old factory which they occupied burned down six months after they had started business. Among the valuable things lost at that time was the tool chest of Mr. F. O. Wells, now president of the company, which contained a great many special tools employed in the making of taps, which he had been making for himself evenings, after having concluded the regular day's work. The brothers then hired a room in another factory for about a year, and, the business prospering, they concluded to erect a one-story brick building 25 x 50 feet, in 1877. From that time on there was an addition added every year, either on the top or on the sides of the original building, until the ground where this factory was erected was all covered, and further extension was impossible, or at least impracticable. In 1889, therefore, a new one-story factory 100 x 200 feet, with a power house 40 x 40 feet, was built on the present site of the works, and to this again an addition was added almost every year, except in 1893, until the present plant has reached the proportions of about 75,000 square feet of floor space. Although the factory has been added to in this manner from year to year, it presents at the present time a homogeneous appearance on account of being built in such a manner that units could be added without interfering with the general plans of the shop.

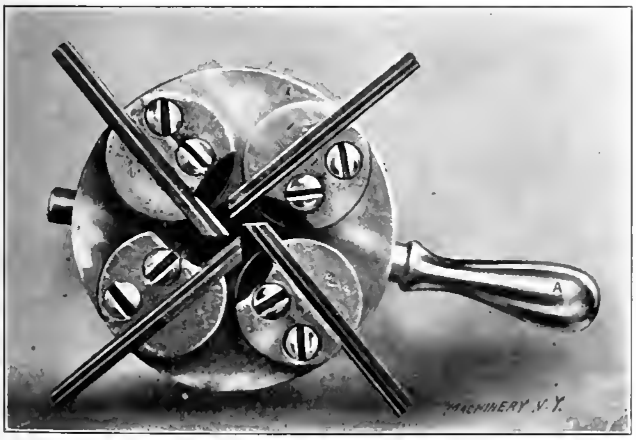

Fig. 2. Small Self-opening Die used for Threading Taps up to 3-8 inch Diameter, in Horizontal Machines.

Mr. E. Wells retired from business in 1880, at which time Mr. F. E. Snow, the present treasurer of the company, entered the firm. Mr. F. E. Wells left the business and sold out his interest about five years ago, leaving Messrs. F. O. Wells and F. E. Snow in control of the Wells Bros. Company. The growth of the company is well exhibited by mentioning the fact that while only seven or eight men were employed in 1880, about one hundred men were employed when the new factory was built in 1889, and at the present time, when running full force, the company employs about 300 men.

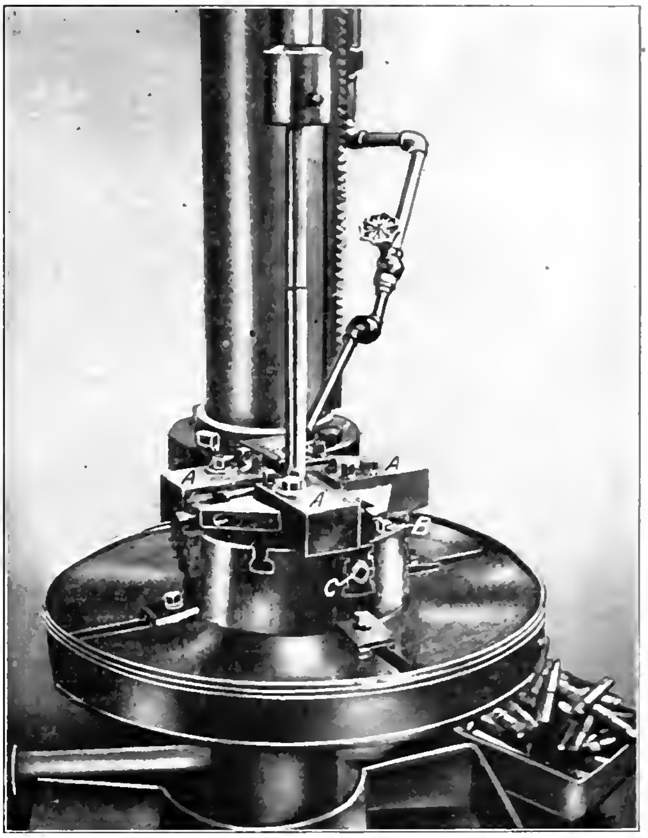

Fig. 3. Upright Tap-threading Machine used for Threading Stay-bolt Taps.

This short historical sketch of the shops will give an idea of the gradual growth of the business. It can easily be inferred that the methods employed in the manufacture of taps and dies are of the best, considering the length of time that has been allowed for the development of new ideas and special machinery. The various tools and methods described below are practically all due to the inventive ability of Mr. F. O. Wells, who has been, and who still remains, the active mechanical head of the works. After these introductory remarks we are now ready to enter upon a detailed description of the manufacturing methods employed in the making of taps.

Making the Tap Blank.

The ordinary method of turning up tap blanks in a lathe, from stock which is from 1/32 to 1/16 inch over the outside finished diameter of the thread, has been discarded except in the case of comparatively large taps, and simpler and more efficient methods adopted. Tap blanks up to 1¼ inch, or in extreme cases 1¾ inch, are turned and cut off from the bar in automatic screw machines. The bar is rolled to the finished size of the tap to be made plus 0.005 inch, the 0.005 inch being added to allow for unavoidable variations in the stock, and the over-size required in the finished tap; thus the bar for ¾ inch taps is rolled to a size of 0.755 inch. This obviates the necessity of turning the threaded portion of the tap, the only part required to be finished in the screw machine being the shank, which is turned down to the required size by hollow milling. During this operation, as well as during all subsequent cutting operations except the threading operation, soda solution is used for lubricant. When threading the taps, the cutting tools and the taps are flooded with oil. Taps larger than 1¾ inch are made from the rough bar, which in this case is 1/32 inch over the finished size of the tap. The blank, however, is hollow milled and turned in a screw machine the same as in the case of the smaller tap blanks. Very large taps, of course, are turned in lathes in the ordinary way. Most taper taps are turned in special turning lathes provided with forming attachments so that the tapered portion and the shank of the tap can be turned at one setting, the operator being able to run a number of machines. These turning lathes are of comparatively small size, a number of head-stocks and tail-stocks being placed on the same bed and run from the same shaft in the back of the machine, each machine having a clutch permitting its individual drive to be thrown in and out independently. It is interesting to note that while this system has only lately been introduced commercially for use in driving a number of small machines in factories working exclusively on small work, and in manual training schools, etc., it has been in use in these shops for over twenty years.

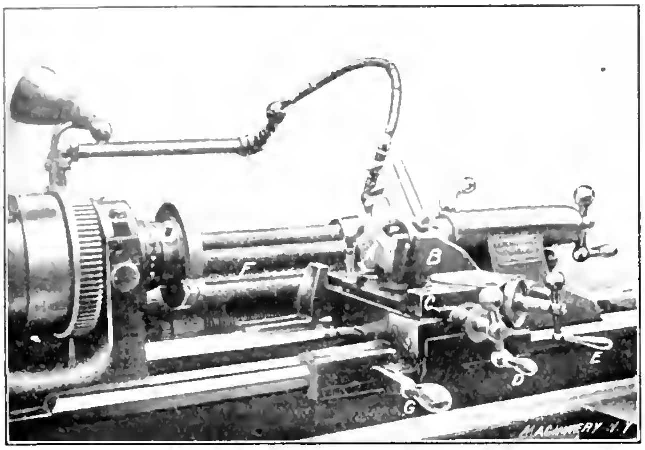

Fig. 4. Threading Lathe for Special Straight Taps.

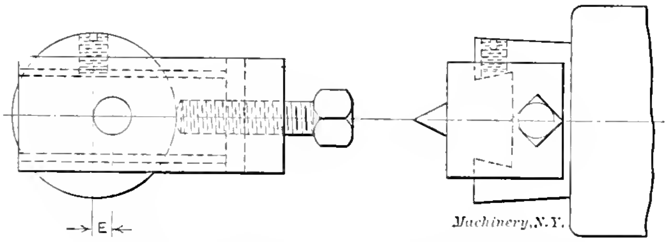

Fig. 5. Tail-center for Threading Lathes, permitting Slight Tapers to be obtained without Setting over Tail-stock proper.

Large tap blanks are cut off in cold-saw cutting-off machines. In order to save time in cutting off, and use the cold-saws to their highest capacity, holders have been devised permitting a number of bars to be securely clamped together and cut off simultaneously. A special carrier mounted on wheels and running on a track made from inverted angle irons, is provided behind the machine, and the bars rest on these carriers. This makes it easy to feed the bars along when one set of blanks has been cut off.

All diameters of the shanks and bodies of the tap blanks are measured by limit gages of the type manufactured by Wells Bros. Co. (shown in the September, 1907, issue of MACHINERY), of which a full set is illustrated in Fig. 19. These limit gages are, in fact, in use all over the shop. Referring to gages *A* and *B*, Fig. 19, it will be noted that there are two sets of adjustable gaging pins, one over the other, and when measuring the diameter of the shanks of the taps, for instance, it is only necessary to pass the gage directly over the shank which should slip easily in between the two upper gage points which determine the maximum dimensions, while the shank should not pass through the two lower gage points which define the minimum diameter permissible. It is easily seen that in this way but little dependence is placed on the operator's judgment as regards permissible limits, and the gaging is done instantly both for maximum and minimum sizes. It is far superior to the common method of using a gage with the maximum dimension at one end and the minimum at the other, because this requires that the gage be reversed, and more than double the time is required for gaging.

It is evident that when the tap blanks are cut off in screw machines in the manner described, they have no centers in the ends, and some method must be adopted for providing correctly located centers to be used in subsequent operations. In order to do this, the teat on the end of the tap blank, which is left from the cutting-off operation in the screw machine, is first ground off, and then the center is drilled in a special centering machine. Considering the fact that the finished stock used for the taps is only 0.005 inch over size, it is clear that the center must run perfectly true with the outside of the tap. An ordinary centering machine will hardly fill the requirements, but by the means adopted the object is easily accomplished. The tap blank is placed in a female center at one end which drives it, it being supported near the other end by an adjustable V-shaped rest. It is evident that when the tap blank revolves and the centering drill is brought up against it, the drill will either enter in the exact center of the blank or refuse to cut; if forced into the blank, although not being in the center, the drill, of course, would break. The adjustable V-rest is adjusted for the first blank in a set, until the operator sees that the blank is running true with the centering drill. He then drills the center of this blank, and can continue to put the centers in the remaining blanks of the same size with practically no attention other than putting shank end of the tap blank into the female center, placing the body of the blank in the V-rest, and feeding the centering drill into the other end. When a lot of taps has thus been centered at one end, the V-rest is adjusted so that the shanks run true in it, and the shank end of the taps is centered in the same manner.

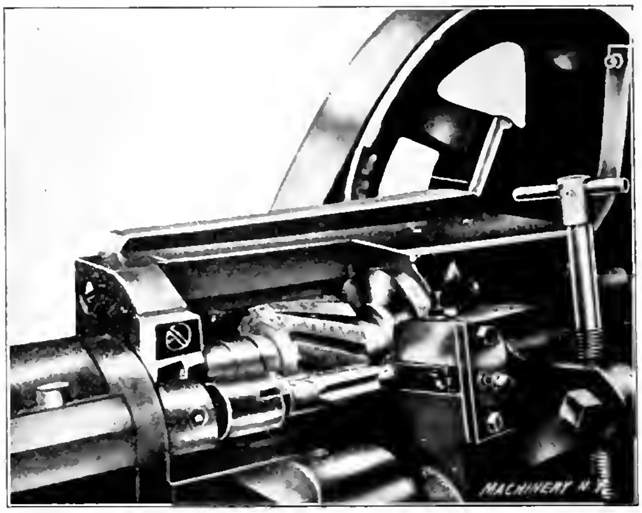

Fig. 6. Method of Threading and Relieving Ordinary Taper Taps, such as Pipe Taps, Boiler Taps, etc.

Threading.

The threading is one of the most important operations performed on a tap, and the methods employed in various tap manufacturing plants are of special interest for the rea-

son that a great many different processes are employed. The method employed by the Wells Bros. Co. consists in cutting the taps with dies, or rather with four threading tools placed in a die-holder. The principle of the action of the cutting tools and their relation to the tap being threaded is illustrated in Fig. 1. One of the die-heads, which also clearly illustrates the principle employed, is shown in the half-tone, Fig. 2. This die-head is used for small taps in a horizontal machine, and is provided with a self-opening device so as to permit the chasers or cutters to recede from the tap when this has been threaded, to permit it to be withdrawn from the die without reversal. The handle for the self-opening mechanism is shown at *A* in the illustration. Larger taps, say from ⅜ inch and up, are cut in machines with vertical spindles. In this case the tap passes clear through the die-head, and there is no self-opening adjustment for the dies; the chasers are inserted in holders which in turn are placed in a body, much in the same way as are the jaws of independent jaw chucks. There is an adjustment by means of a screw in the back of each chaser, and also an independent adjustment of each jaw in the chuck. One of these chaser-holding chucks or dies used in an upright machine and intended for threading stay-bolt taps, is shown in Fig. 3. The jaws holding the chasers are shown at *A*, the adjusting screws back of the chasers at *B*, and the provision for the adjustment of the jaws is shown at *C*.

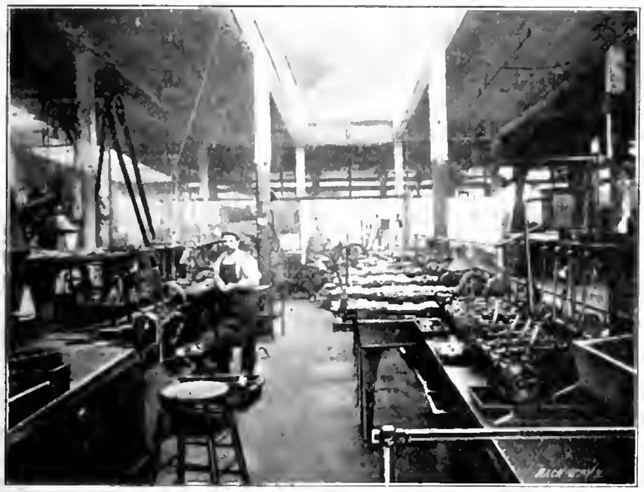

Fig. 7. View of the Special Threading and Relieving Department of the Wells Bros. Co.'s Shops.

The threading operation is performed on a special drill press having a spring balanced spindle, oil being provided from a central distributing tank by a pump driven by an independent motor. The cutting portion of the chasers is chamfered like dies, except that the chamfer is rather longer than that on ordinary die chasers. The angle of the chaser between the cutting face and the front of the tool is about 60 degrees, and the cutting point, when the chasers are adjusted, is a little back of the center of the tap. The chasers are from five to eight inches long, according to the size of die-head for which they are intended, and are provided with threads or grooves the full length, cut at an angle corresponding to the diameter and pitch of the tap to be threaded. They are hardened, by heating in lead, for a distance of about one to one and one-half inch at a time. If hardened for the full length at once, the distortion in hardening would make the chasers useless for accurate work.

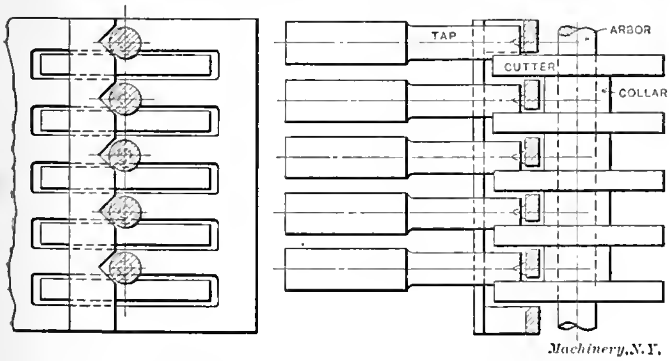

Fig. 8. Diagram showing Principle of Tap Squaring Fixtures.

With the exception of the machine shown in Fig. 3, for threading long taps, the other machines are multi-spindle tap threaders. They are all built by the company for its own use, and in general appearance they resemble ordinary drill presses. The small machines on which the threading is done horizontally, resemble horizontal tapping machines. On the vertical machines the taps drop right through the die when the thread is cut, and on the machine shown in Fig. 3, where the taps threaded are very long, there is a hole in the floor permitting any length of tap within reasonable limits to be threaded. Ordinarily the taps pass through the dies two or three times, the last time a very light finishing cut only, being taken. The stay-bolt taps pass through the die only once, at a somewhat slower speed than used when threading taps which pass through several times. The speed by which taps can be threaded when this method is employed, is rather remarkable. A ⅞-inch diameter tap having a length of thread of about 4½ inches can be finish threaded, passing through the dies three times, in about three minutes, while a stay-bolt tap having from 24 to 30 inches of thread is threaded in about five minutes.

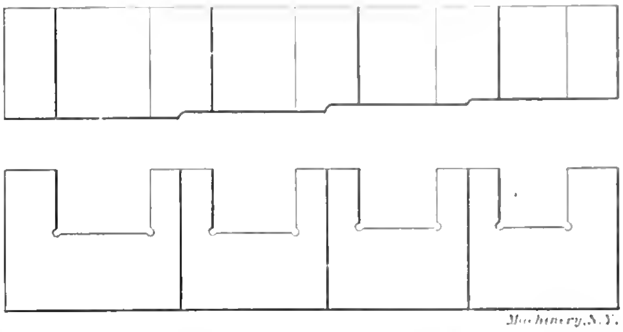

Fig. 9. Gages for the Squares of Taps.

Special Threading Lathes for Taps of Odd Size and Pitch.

When taps of odd size and pitch are to be made, it is not economical to rig up a machine with chasers held in holders of the type described, because the making of the chasers, as well as their adjustment, requires considerable skill and time; consequently these chasers are only made when a great number of taps of the same diameter and pitch are required. For odd cases, therefore, the threading of the taps is done in special threading lathes, one of which is shown in Fig. 4. The chasers for cutting the thread are somewhat similar in appearance to those used in the die-heads already described, and three of these are held in a special swiveling thread-tool holder shown at *A* in Fig. 4. Of course, when held in this manner these chasers are really nothing but ordinary thread-cutting chasers. Three of the chasers are used in one holder for the reason that the thread in the tap is produced by three cuts, one roughing, one semi-finishing, and one finishing. The swiveling tool-holder is provided with stops so that the operator can easily and quickly turn the tool from the position required for the roughing tool to the position

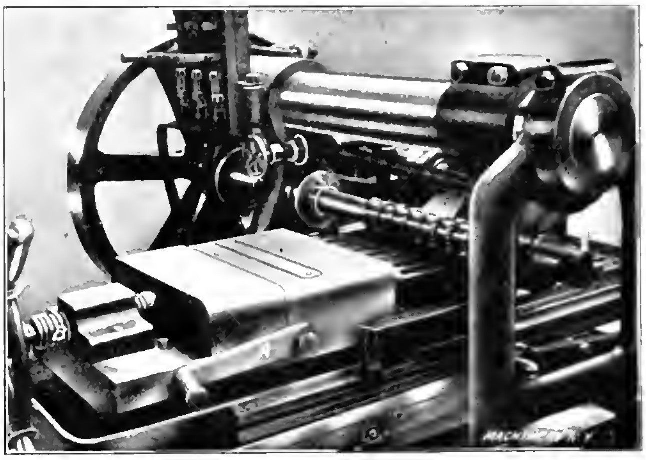

Fig. 10. Fluting Eight Taps at one Setting.

required when either of the other tools is in operation, and the holder is rapidly clamped in position after the adjustment. The holder is mounted in a special tool-carrying slide *B*, operated by handle *E*. This upper slide *B* is moved in an angle relative to the slide *C*, which latter is fed inward at right angles to the axis of the lathe spindle by the handle *D*. The handle *E* of the upper slide is operated when it is required to adjust the tool in a longitudinal direction so as to suit exactly the pitch of the thread being cut, while the handle *D* is operated when the slide is fed in and out for taking a heavier or less heavy cut.

One of the interesting details in the construction of this machine is the arrangement of lead-screws. It will be noted that in the back of the machine at *F* a number of lead-screws of different pitches are provided. These are placed in a turret-like horizontal holder, held by brackets placed in the back of the machine, and one lead-screw at a time engages with a half nut directly at the back of the carriage. Owing to the fact that the lead-screws are mounted in a turret, any one of these lead-screws, each having different pitch, can be placed in engagement with the half nut in the back of the carriage, this half nut, of course, being changed to suit the different screws. There are eight screws in the holder or turret containing them, and the pitch of each can be doubled by the use of a multiplying change gear at the head-stock.

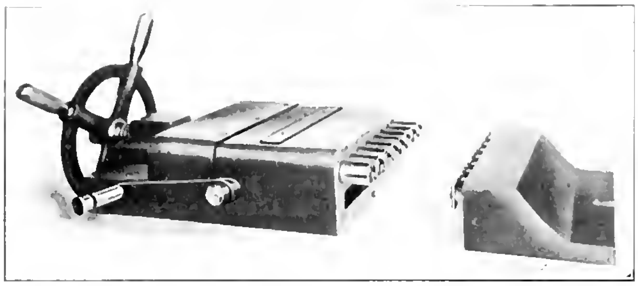

Fig. 11. Fluting Fixture shown in Place on Machine in Fig. 10.

The advantage of this arrangement is obvious, particularly with regard to the possibility of disengaging the lead-nut from the lead-screw and running the carriage back by hand, and still being sure to catch the thread in the tap being cut. The change for different pitches is also quicker than when change gears are used to effect the correct lead. The lead-screws are provided with special ratchet thread, perpendicular on one side and forming a 60-degree angle with the axis of the screw on the other. This form of thread largely obviates the difficulties due to too rapid wear of the threads in the lead-screw. In the front of the machine, at *G*, a handle is shown by means of which the tool slide can be moved back instantly so that the tool will be out of engagement with the thread cut, without interfering with the adjustment of the handle *D*. This improvement, which has lately been introduced in ordinary lathes of well-known manufacture, has been in use at the Wells Bros. Co.'s works for a great many years.

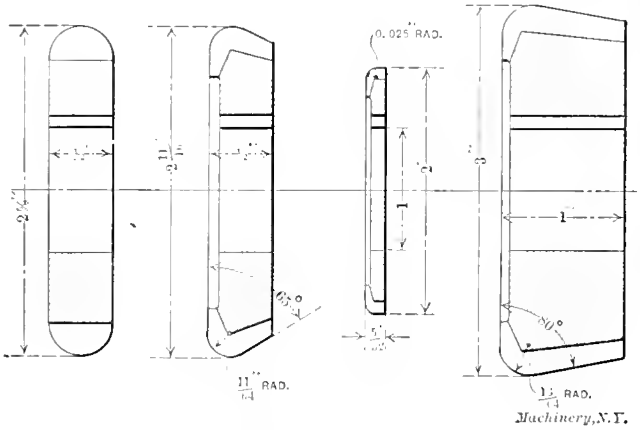

Fig. 12. Various Types of Fluting Cutters.

The taps threaded in these threading lathes are provided with a very slight back taper as commonly provided in taps of proper design. This taper is accomplished by moving the tail-stock over a very slight amount. In some cases an improvement has been introduced in the tail-center whereby the necessity of moving the whole tail-stock over is obviated, and simply the center itself is moved over towards the front. In this case the center is placed on a small adjustable slide which in turn is held in a holder which is placed in the tail-stock. The adjustment for taper turning is then done directly by adjusting this center back and forth without interfering with the tail-stock proper. The general principle of this tail-center is shown in Fig. 5, where *E* indicates the amount the tail-center is moved out of alignment with the spindle of the lathe.

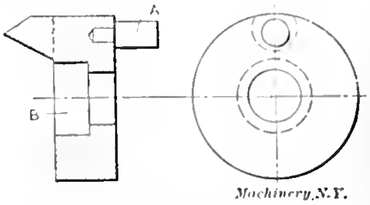

Fig 13. Special Center for Tap Fluting Fixturee.

A slight amount of back taper is also provided in the taps cut by dies in the horizontal and vertical tap threading machines. This is accomplished by having the axes of the spindle and of the dies a very small amount out of alignment. Then as the tap travels downward through the die, the angle of deviation of the tap from the absolute vertical line will increase slightly as the distance between the spindle and the die is diminished, and the dies will cut the thread slightly smaller in diameter at the upper end, due to a kind of a wabbling action of the tap in the die.

Threading Taper Taps.

Taps of comparatively steep taper, such as pipe taps, are threaded in special threading machines, the most important parts of one of which is shown in Fig. 6. These taps are threaded by a hob which mills the full length of the thread at once and relieves it simultaneously, the flutes in the taps in this case being cut before threading. The grooves or threads in the hob are not cut with a lead, but form circular grooves around the hob; the flutes are cut on a helix in this hob. The tap moves along the hob, while rotating, according to the pitch required in the tap, and it is only necessary to revolve the tap two or three times to cut a complete thread produced, in fact, by a roughing and a finishing cut, as each time the tap revolves, a complete cut of the thread all over the tap is taken. It will be noted that the tap is squared before threading, and is held by the square at one end and by the center at the other. The center is adjustable, as shown, so that the tap can be placed in proper position to give the correct taper, the hob being straight. The relieving is accomplished by giving the hob an oscillating motion while the cut is taken. Of course, it is clear that the hob, in reality, is nothing but a combination of individual thread milling cutters placed together, each cutting one thread, but made in this case in one solid piece. The relief can also be accomplished by rocking the end of the tap held in the adjustable center, back and forth by a cam placed on a cam-shaft and geared in the proper ratio to the driving spindle of the machine into which the tap square is set.

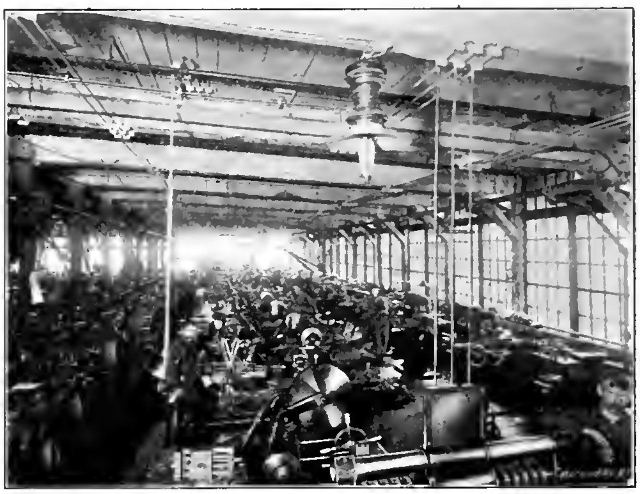

Fig. 14. Fluting, Squaring and General Milling Department.

Fig. 7 shows a general view of the department of the shop where the special threading and relieving machines are installed. This chamfering and relieving of straight taps, however, is, of course, not done before the taps are fluted, so that the taps leave this department after threading, to be squared and fluted, and are then returned to be chamfered and relieved on the chamfered portion.

Squaring the Taps.

The squaring of the taps is done in fixtures similar to those used for fluting, which are shown in Figs. 10 and 11, and cutters with inserted teeth are used for milling. The taps are squared only on one side at a time, as shown diagrammatically in Fig. 8, as many as eight taps, of some sizes, being squared at a time. The reason for squaring only one side at a time is that by so doing it is much easier to get the square exactly central with the axis of the tap, which is often not the case with taps which are squared with cutters which cut two sides of the square at once. The taps are fed longitudinally towards the cutters, so that while cutting the square, the center lines of the taps and the cutters form one continuous straight line. The size of the square is made exactly ¾ times the diameter of the tap which is the commonly employed size of square with all leading tap manufacturers. A gage used for measuring the sizes of the squares of different sizes of taps is shown in Fig. 9. It will be seen that both the length and the size of the square are gaged at one time.

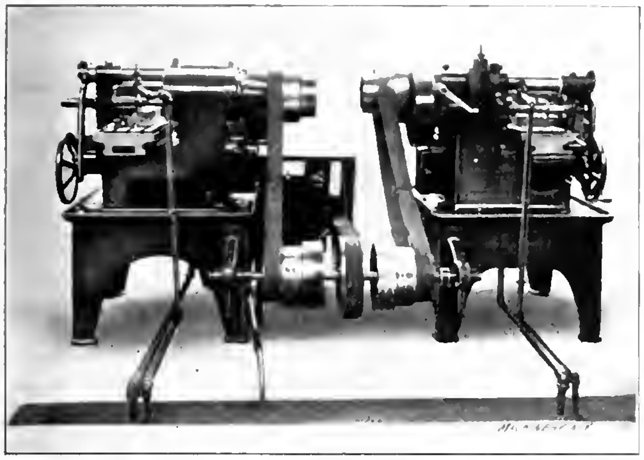

Fig. 15. Method employed for Driving Two Machines from One Motor—System of Piping for Oil and Electric Wires.

While squaring, the taps are held on male centers at the end being squared, and in female centers on the threaded end. The manner in which the centers are made in order to permit the milling cutters to pass closely by the center when squaring, is illustrated in Fig. 8. It will be seen that a small V-shaped groove is cut in a supporting plate below the tap shank. This is intended simply to support the tap when being put in place. When clamped between the centers, the tap, of course, does not rest in these V-supports.

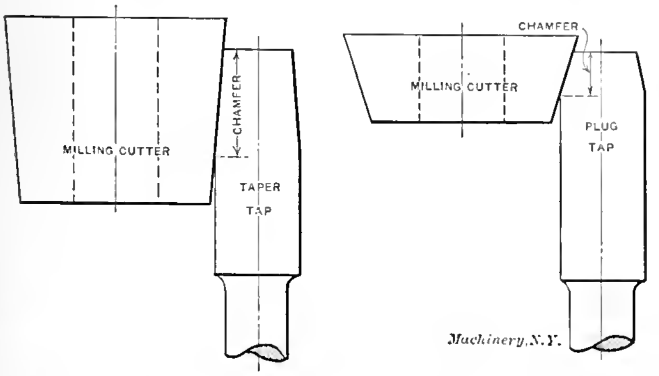

Fig. 16. Principle employed in Tap Chamfering and Relieving Machines.

Fluting the Taps.

When fluting, the taps are held in fixtures which take four, six, or eight taps at a time, according to the size of the taps. One of these fixtures, placed in the milling machine with eight taps being fluted, is shown in Fig. 10, the fixture by itself is shown in Fig. 11. It is evident that in order to permit the milling cutter to pass as close to the center of the tap as possible when cutting the flute, half centers must be employed. It has been found, however, that the ordinary half center has its disadvantages, it being required to mill off so much on the top of the holder for the half center that it gives the center a comparatively poor support. For this reason an interesting type of center, as shown in Fig. 13, is used. The pin *A* locates the center in the holder, and the counterbored hole *B* is intended for a binding screw which passes through the body of the center and binds it firmly to the body of the fixture. The simplicity of this center is plainly in evidence; it is held rigidly and is stronger than the ordinary half center.

When milling the flutes, the taps are held on these centers at the threaded end and in tapered square female centers at the squared end. The taps are all tightened in place at once by one binding screw *B*, Fig. 10, and an equalizing device is employed to make all the centers bind the taps to an equal degree. In front of the male centers a strap is placed similar to that employed in front of the male centers on which the taps are held when squared. This strap is provided with small V-grooves in which the taps rest until they are clamped against the male centers by means of the hand-wheel and binding screw. The indexing is accomplished simultaneously for all the taps by the lever *A*, Fig. 10, which is connected with the spindles for the different taps by spiral and spur gearing. Of course, bevel gears can also be used instead of spiral gears for the transmission of the motion from the transversal stud on which the index lever is placed, to the spindles which are set in a longitudinal direction. There is only one index hole on the side of the fixture, one complete turn of the index lever being required to index one-quarter turn of the tap holding spindles. As most taps have four flutes, this device, therefore, answers the purpose without any index plates, and without the use of a number of different index holes. Mistakes in indexing are thereby completely avoided. Several different types of cutters used for fluting taps are shown in Fig. 12. The first type, which is an ordinary convex cutter, is used for stay-bolt taps. The dimensions given are for a cutter used for a one-inch tap. The second cutter from the left is used for regular hand taps, the size shown being used for a ¾-inch tap. The third cutter is used for machine screw taps and small hand taps, ⅛ inch in diameter and less. Finally, the cutter to the extreme right is used for pipe taps, the size shown being for 1-, 1¼-, 1½-, and 2-inch taps.

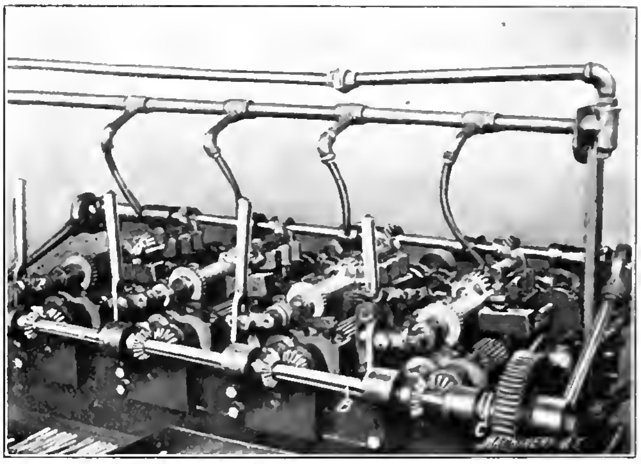

Fig. 17. Tap Chamfering and Relieving Machine with Eight Spindles, of which Four are shown in the Illustration.

A general view of the milling department is shown in Fig. 14. Directly in the foreground will be seen a machine for squaring ten taps at once, two fixtures being employed, each holding five taps, one on each side of the machine. It will be noticed that over-head counter-shafts are largely done away with in this department of the shop, and most machines are driven by individual motor drives. In some cases one motor is employed for driving two machines, and in other cases there are counter-shafts placed on the floor in the back

of the machines the object being to do away with over-head belting and line shafting.

Fig. 15 shows a simple and effective manner of coupling two machines to one motor, thus avoiding an excessive amount of counter-shafting and at the same time occupying no space that could be utilized for other purposes. It will be noted that the motor is placed in the background (which is really the front side of the machines) between the two machines which are turned end to end, having their fronts in opposite directions. Over the motor, as can be seen, is placed a bench on which work and cutters can be put. In this way the space occupied by the motor is utilized for a purpose for which space would be required in any event, and in a sense the motor does not occupy any space at all, inasmuch as the bench placed over it would be required whether the motor was under it or not. In the same illustration is also shown the manner in which the wires and oil are carried to and from the machines. The floor is made of concrete and provided with grooves or ducts covered by cast iron plates, as shown in the foreground of the illustration. The pipes supplying the lubricant to the cutting tool as well as the pipes carrying off the used lubricant, are seen emerging from the duct through the cast iron plates at both the right- and left-hand side, while the single pipe seen in the middle entering through the cast iron plate into the duct, contains the wires for the power.

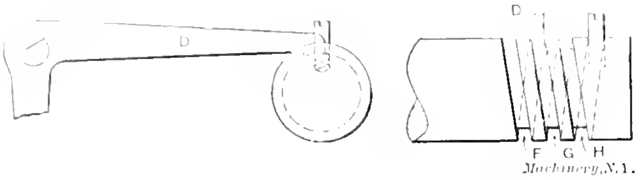

Fig. 18. Ingenious Automatic Trip for Drive of Chamfering Machines.

Chamfering and Relieving Taps.

The chamfering and relieving on the chamfered portion of ordinary straight taps is accomplished in special machines, and the principle involved in this operation is best illustrated by the line engraving Fig. 16 where two taps are shown, one taper and one plug tap being chamfered by milling cutters of different tapers. As will be seen, the whole length of the chamfer is cut at once by a milling cutter, and the tap is moved or rocked eccentrically while the cut is taken on each land so that the relief on the chamfered portion is produced simultaneously with the chamfer itself. The tap is held by the square in a chuck and on a center at the other end while this operation is performed and is mounted in a head which is journaled so that it can be swiveled or rocked by a cam. These chamfering machines, as shown in the right-hand foreground in Fig. 7, are built in units having eight spindles each; half of one of these machines is shown in enlarged scale in Fig. 17. Here the cutters which produce the chamfer are shown at *A* while the taps are practically hidden by the other parts of the machine. Oil or other cutting fluid is carried to the cutters by an oil pipe supplied from a central source.

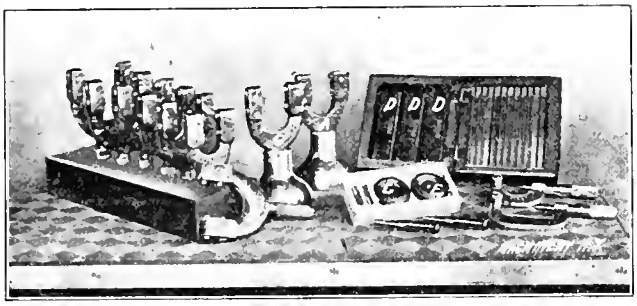

Fig. 19. Limit Gages and Gages for Testing Lead, used in the Shops for Working and Inspection Gages.

These machines are also provided with an interesting automatic stop which permits the operator to set the machine so that the cutters will go around the tap one, two, or three times, according to the requirements, before the drive is thrown out of engagement. The principle of this stop is shown in Fig. 18. It consists simply of a lever sliding in a helical groove on the driving shaft *B* in Fig. 17. The part with the helical grooves is shown in the same illustration at *C*. At one end of the helical groove the lever strikes against a screw and thereby trips another lever, by means of which the drive is thrown out of engagement. When the machine is started the operator can place the end of the lever *D*, Fig. 18, in either of the grooves *F*, *G*, or *H*, and it is evident that when placed in the groove *F*, the shaft must revolve three times before the machine will be tripped, whereas, if placed in groove *G*, it will revolve only twice, and when placed in groove *H* only once before tripping. This is a very simple and ingenious scheme for automatic and adjustable tripping of a machine of this description.

Marking the Taps.

For marking the taps, a number of devices working on the principle of an ordinary printing press are employed. The taps simply roll under the die containing the characters to be impressed in the tap shank, pressure being exerted on this die so as to give a clear and distinct marking on the shank.

The taps are now completed as far as the machining operations are concerned. They are inspected between each of the more important operations, particularly after the threading, the gages used for inspection being shown in Fig. 19. In this illustration the gages used for measuring plain cylindrical work, already referred to, are shown at *A* and *B*, and a gage of the type used for measuring the angle diameter of the thread is shown at *C*. Gages for measuring the correct lead are shown at *D* and micrometer gages used for sizes where no limit gages are available, at *F*. These limit gages are also supplied to each of the men performing the work on the taps, so that he can easily determine whether the work is done properly or not. In a coming issue of MACHINERY the hardening and final inspection of the taps will be treated, together with a description of other features of interest in the Wells Bros. Co.'s shops. E. O.

* * *

An interesting list of the largest steamships afloat is given in *International Marine Engineering*. The growth of steamships is also referred to. It is interesting to note that the average length of the twenty largest steamships in the world in 1848 was 230 feet; and in 1873, twenty-five years later, the average was 390 feet. After another quarter century, the average of the twenty largest liners was 541 feet, whereas now the average length is 700 feet. If we include the two new White Star liners, the building of which has just been begun, the list of the thirty largest steamships is as follows:

	SHIP.	Launched.	Line.	Length, Feet.	Gross Tonnage.
1	*Olympic**	1910	White Star	860	42,000
2	*Titanic**	1910	White Star	860	42,000

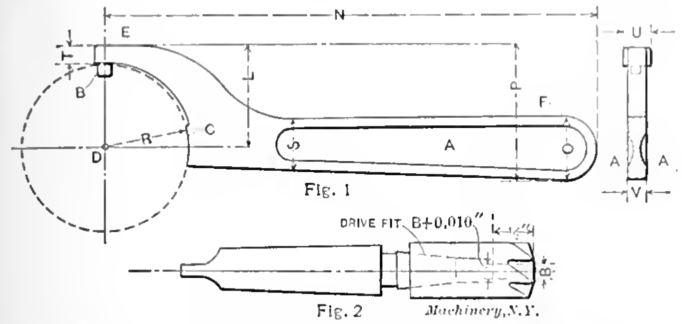
Ships not yet afloat are marked (*); those afloat but not yet in service (†).

In this connection it may be remarked that the gross tonnage of a ship is the cubic contents of the vessel below the deck, one ton being considered as equal to 100 cubic feet. The net tonnage is the cubic contents of the vessel when the space occupied by the machinery, quarters for the crew, etc., has been deducted. The displacement is the actual weight in long tons of the vessel.

THE MAKING OF SPANNER WRENCHES.

The qualities required in a spanner wrench are, in the first place, that it should correctly fit the working parts for which it is intended, and secondly, that it should be strong, light in weight, and neat in appearance. The appearance of the spanner wrenches, the making of which is described in the following, is shown in Fig. 1, where the outline of the nut for which the wrench is used is shown in dotted lines. The wrench blank should be drop forged, so that it is practically finished, except for the dimension of the pin *B* and the surface *C*. The pin is then subsequently finished by milling, as will be referred to later, so that it may fit snugly in the required size hole in the nut for which it is intended, and the surface *C* is milled off to give the correct diameter from the center *D*, which, of course, is also the center of the nut, for which the wrench is used. It is evident that by drop forging the lug *C* so that it extends far enough out from the body of the wrench, the same drop forging can be made to suit a number of different sizes of nuts, within a certain range, depending upon how much of this lug is milled off in finishing surface *C*. In the drop forging, raised letters can also be provided in the hollow portion *A* of the handle, these letters giving the name of the maker, the size of the wrench, etc. This not only adds to the neat and finished appearance of the wrench, but, at the same time, produces a cheap means of marking the maker's name on every wrench, and of recording the size for which it is intended. The pin *B* should always be made solid with the wrench. Inserting a loose pin, as is the custom of some makers, usually causes trouble, as the pin is liable to work loose or break.



Figs 1 and 2. Spanner Wrench and Hollow Mill for Finishing Spanner Pin.

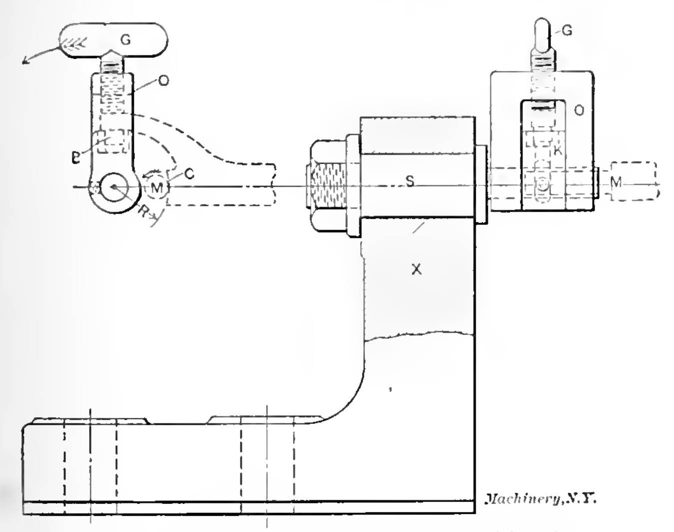


Fig. 3. Fixture for Milling Seat for Nut on Wrench.

The drop forged blank, when delivered from the forge shop to the machine department, is taken first to the drill press. The first operation is to finish the pin *B* to proper diameter, which is done with a solid hollow mill, it not being possible to use an adjustable hollow mill, because there would be no room in milling for the adjusting collar. The mill, as shown in Fig. 2, is rounded or relieved on the end to conform to the radius *R* of the wrench, so as to clear the body of the wrench when milling. The hollow milling operation is performed in a drill press, the wrench being held in a vise, resting on the surfaces *E* and *F*, while the as yet unfinished surface *C* acts as a stop against a pin driven into one of the vise jaws. Allowance must, of course, be made in locating this stop pin for the difference in radius in the rough forging and the finished radius *R* of the surface of *C*.

When the vise has been correctly set on the drill press table, it is clamped in position, and the drill press table itself is clamped in place. If the setting is not disturbed, all the wrenches of the same size will then have the pin *B* hollow milled in proper relation to the surface *C*.

The next operation is to finish the surface *C* to the correct radius *R*. The manner of performing this operation is shown in Fig. 3. The surface *C* is finished by milling with an end mill *M*, using the fixture shown for obtaining the proper radius. The fixture is mounted on the milling machine table, but can be used by fastening it to the cross-slide of a lathe, and the end mill *M* mounted in the spindle. When the fixture has once been set in proper relation to the spindle of the machine, whether it be on a milling machine or a lathe, all slides are secured, so that no accidental motion of the slides will take place, in order to insure all the wrenches being milled alike. It is very essential that the circular surface of *C* be correct in relation to the pin *B*, as these are the elements of the wrench which fit the nut. If the end mill is sharpened, and its diameter thus reduced, it will be necessary to reset the table in relation to the spindle of the machine, in order to retain the radius *R* on the wrench.

GENERAL DIMENSIONS OF SPANNER WRENCHES.

See Fig. 1 for notation used in Table.

Dimensions of Nut for which Wrench is used.		R	Maximum Diameter of Pin *B*.	N	L	P	O	S	T	U	V
Diam.	Min. Width.										
1 1/8	1/2	9/16	7/32	5	7/8	1 1/8	5/8	7/16	3/16	9/32	3/16
1 1/4	1/2	5/8	7/32	5	7/8	1 1/8	5/8	7/16	3/16	9/32	3/16
1 1/2	9/16	3/4	15/64	5	7/8	1 1/8	5/8	7/16	3/16	9/32	3/16
1 3/4	9/16	7/8	15/64	6	1 1/4	1 3/8	3/4	9/16	7/32	5/16	7/32
2	5/8	1	1/4	6	1 1/4	1 3/8	3/4	9/16	7/32	5/16	7/32
2 1/4	5/8	1 1/8	1/4	6	1 1/4	1 3/8	3/4	9/16	7/32	5/16	7/32
2 1/2	5/8	1 1/4	1/4	6 3/4	1 1/2	2 1/8	7/8	5/8	1/4	11/32	1/4
2 3/4	11/16	1 3/8	17/64	6 3/4	1 1/2	2 1/8	7/8	5/8	1/4	11/32	1/4
3	11/16	1 1/2	17/64	6 3/4	1 1/2	2 1/8	7/8	5/8	1/4	11/32	1/4
3 1/4	3/4	1 5/8	9/32	7 1/4	1 3/4	2 1/4	1	3/4	9/32	3/8	9/32
3 1/2	3/4	1 3/4	9/32	7 1/4	1 3/4	2 1/4	1	3/4	9/32	3/8	9/32
3 3/4	3/4	1 7/8	9/32	7 1/4	1 3/4	2 1/4	1	3/4	9/32	3/8	9/32

The principle of the device will easily be seen from the illustrations. The wrench is placed in the fixture and held by screw *G* bearing on the top of the wrench directly over the pin *B*, which, in turn, fits in a hole in a block *K*, so that the wrench is thereby held securely in position. The block *K*, in turn, is placed between the ends of a fork *O* in which the screw *G* is inserted. Bushings provided with different sized holes to take different sizes of pins *B* are inserted in the block *K*, these bushings, of course, all having the same outside diameter. The yoke *O* and the block *K* are both mounted on an extension of the stud *S*, which is fastened to the bracket *X* clamped to the milling machine table.

It will be seen that the handle of the wrench itself is used as a lever for the hand feed when the surface *C* is milled. The operator holds the wrench so that the mill, which should run in the direction indicated in Fig. 3, starts in cutting at the lower edge of *C*; the wrench is then fed slowly until the surface *C* is machined. As yoke *O* and block *K* are pivoted at what would be the center of the nut, for which the wrench is intended, it is evident that the mill *M* will cut a surface that will fit this nut accurately. When the surface *C* is finished, the thumb-screw *G* is loosened, the yoke *O* is swivelled towards one side, as indicated by the arrow, and the wrench is simply lifted out. The pieces *O* and *K* could, of course, be made solid with one another, but this would necessitate unscrewing the thumb-screw *G* for the whole length of the pin *B*, so as to permit the lifting out of the pin from its seat in *K*. This would consume an unnecessary amount of time. This method for finishing the surface *C* of a spanner wrench is, without question, the simplest that the writer has seen used anywhere. The most commonly used method employed in

finishing surface *C* even in so-called up-to-date shops, is by means of holding the wrench on a lathe face-plate and jacking off the surface by means of a turning tool.

The next operation to which the wrench is subjected is the filing off of the burrs left by the milling operations, and the polishing of all surfaces except the hollow surface *A*, Fig. 1. The polishing is generally done by means of a belt charged with emery, in a regular belt polishing frame, the belt permitting the polishing of all curves, nicely. This is very important, as nearly all parts of the wrench are curved one way or another. Hardly any other means of polishing would be permissible on account of the time required. The polishing, however, is hardly necessary when considering the nice surface left by the drop forging operation, but most firms turning out high grade work, polish spanner wrenches in order to add to the neatness of the appearance of the tool and to permit that nice finish on the polished surfaces, which a "case-hardening for colors" produces, to show properly.

The wrench should be case-hardened in a mixture of 10 parts of charred bone, 4 parts of charred leather, 6 parts of charcoal, and one part of powdered cyanide potash. These ingredients should be thoroughly mixed together and the wrenches laid separately in a box, so that they are not in contact with each other at any point. A cover is put on the box to keep out the air. The box is then heated until the wrenches reach a good cherry red color, the length of time, of course, depending upon the size of the wrenches and the box. Then the whole contents of the box, both mixture and wrenches, are dumped in clear water, care being taken that the wrenches pass through the air for a short distance before striking the water.

The accompanying table will give a general idea of good proportions of these wrenches. The dimensions, of course, are given merely for guidance, as wrenches of this type must be made in many cases to suit special requirements. The total length, however, and the general appearance and proportions, will probably prove valuable to those having to determine upon the design of spanner wrenches. A.

ARTISTIC BLACKSMITHING.

Longfellow's beautiful poem, "The Village Blacksmith," strikes a responsive chord in most human hearts familiar with the sights and sounds of the rural smithy. It is a paean to labor, exulting in honest toil and the sense of independence of a master workman:

Fig. 1. Wonderful Example of Skill in Forging.

> "His brow is wet with honest sweat,
> He earns whate'er he can,
> And looks the whole world in the face,
> For he owes not any man."

The sentiment of the verse is honesty, strength, industry; and it admirably expresses the common regard in which the blacksmith is held. There is in it no hint that the blacksmith's art can be the means of artistic expression; the smith is not there pictured as one on the plane with the sculptor. His work is too ordinary and too useful to be classed with the creations in clay, marble and bronze symbolizing lofty sentiments and deeds of valor. The blacksmith has always been a doer and provider; he is the oldest of craftsmen and enjoys the distinction of being the only one who *can* make all his own tools, as well as the tools for others. His may appear rude and clumsy, but they suffice unto his needs, and that is enough. But that these rude tools in the hands of a master may become the means of finer expression, calling into being creations in iron that almost rival nature's own handiwork in delicacy of tracery and beauty of outline, is the object of this tribute to the skill of one who daily earns his living at the forge.

The pieces here illustrated are beautiful examples of "sculpture in iron," requiring skill and technique that put the carver of mere marble to shame when one considers the practical difficulty of the work. One illustration shows a rose branch sixteen inches long and nine inches wide on which there are two buds and two blooming roses. An idea of the delicacy of the work is gained from the weight, it being only thirty-three and one-half ounces. The illustration brings out the delicacy of detail and fidelity to form in the original, and speaks for itself. It should be known, too, that this is no creation on which weeks or months of painstaking labor were spent; fourteen hours is the shop time required.

Fig. 2. Rose Branch with Roses, hammered out in Fourteen Hours.

The first piece shown is even more artistic, and it has the added merit of being useful. It is a card tray or an ash receiver, the tips of the leaves and the stem acting as the supports. It represents a large leaf with a rose spray twined along the edge, there being one bud and a full blooming rose exquisitely formed. These pieces were forged, fashioned and welded in Swedish iron by our contributor, Mr. James Cran, foreman blacksmith of the Pond Machine Tool Works, Plainfield, N. J., and are samples of the work he does occasionally to delight his friends and to fill in the odd moments of a busy life.

* * *

Following the establishment of two-cent first-class postage between the United States and Great Britain, comes the agreement between the United States and German postal authorities for a two-cent per ounce rate on first-class postal matter routed direct. The new agreement provides that after January 1, 1909, letters for Germany paid at the reduced rate of two cents will be dispatched only on steamers sailing from New York to German ports and *vice versa*. Letters from Germany by way of Great Britain or France must pay the five cent rate for the first ounce and three cents for each additional ounce.

JIGS AND FIXTURES—10.

EINAR MORIN.*

PRINCIPLES OF BORING JIGS.

Boring jigs are, at the present time, as commonly used as drill jigs, in interchangeable manufacture, and the requirements placed on drill jigs apply in nearly all respects to boring jigs. Boring jigs are generally used for machining holes where accuracy of alignment and size are particularly essential, and also for holes of large sizes where drilling would be out of the question. Two or more holes in the same line are also, as a rule, finished with the aid of boring jigs.

The boring operation is performed by boring bars having inserted cutters of various kinds, and boring jigs are almost always used in connection with this kind of boring tool, although boring operations may be satisfactorily accomplished with three or four lipped drills and reamers. The reamers may be made solid, although most frequently shell reamers mounted on a bar and guided by bushings are used. The majority of holes produced in boring jigs, whether drilled or bored out, are required to be of such accuracy that they are reamed out in the last operation.

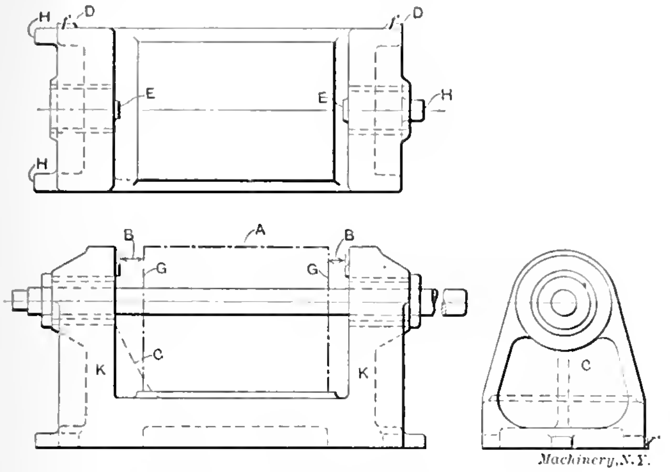

Fig. 109. General Outline of Simple Boring Jig.

The boring-bars are usually guided by two bushings, one on each side of the bored hole, and located as close as possible to each end of the hole being bored. The bar is rotated and simultaneously fed through the work, or the work with its jig is fed over the rotating bar. Boring jigs may be used either in regular boring lathes, in horizontal boring and drilling machines, or in radial drills.

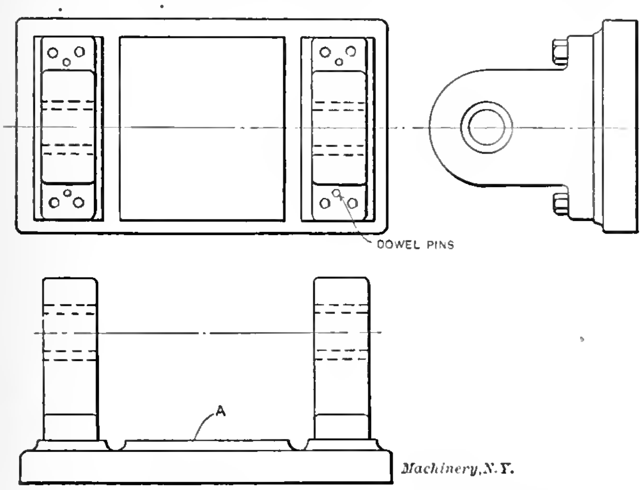

Fig. 110. Boring Jig with Base separate from Side Standards.

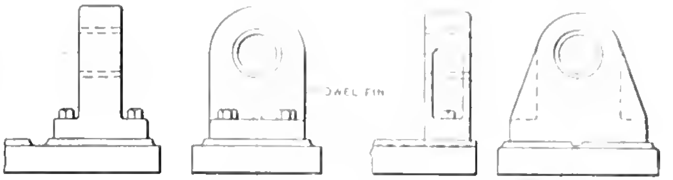
The jig body is made either in one solid piece or composed of several members the same as in the case of drill jigs. The strain on boring jigs is usually heavy, which necessitates a very rigidly designed body with ribbed and braced walls and members, so as to allow of the least possible spring. As boring jigs when in operation must be securely fastened to the machine table, means must also be provided in convenient and accessible places for clamping the jig without appreciably springing it.

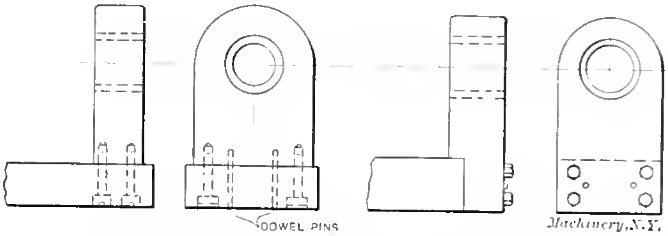
The places in the jig where the bushings are located should be provided with plenty of metal so as to give the bushings a substantial bearing in the jig body. Smaller jigs should be provided with a tongue or lip on the surface which is clamped to the machine table; this permits the operator to quickly locate the jig in the right position. As an alternative, finished lugs locating against a parallel or square may be provided. It is frequently advantageous to have small sized boring jigs provided with feet so that they can be used on a regular drill press table in cases where holes to be bored out are to be opened up with a drill piercing the solid metal. It is both easier and cheaper to do this rough drilling in a drill press.



Figs. 111 and 112. Different Methods for Securing and Locating the Uprights on Base Plate of Boring Jigs.

The guide bushings, of the same type as the bushings for drill jigs, are made either of cast iron or steel and ground to fit the boring-bar which is also ground. The bars are made of machine steel and should be made as heavy as possible, in order to prevent them from bending or springing too much should there be a heavier cut on one side than on the other. The bushings should be made rather long to insure good bearing.

The most common type of boring jig for small and medium size work is shown in Fig. 109. In this engraving, *A* represents the work which is held down by straps or clamps. In many instances when the work is provided with bolt and screw holes before being bored, these holes are used for clamping the work to the jig. In some cases it is important that the work be attached to the jig in the same way as it is fastened to its component part in the machine for which it is made, and also that it be located in a similar way. If the work is located by V-slides when in use on the machine, it is preferable to locate it by V's in the jig. In other cases the locating arrangement for the work in the machine where it is to be used may be a tongue, a key, a dowel pin, a finished pad, etc. The same arrangement would then be used for locating it in the jig. In Fig. 109 enough clearance is left at *B*, at both ends, to allow for variations in the casting and to provide space for the chips; also, if the hole is to be reamed out, and the reamer be too large to go through the lining bushing, then the space left provides room for inserting the reamer and mounting it on the bar. In nearly all cases of boring, a facing operation of the bosses in the work has also to be carried out and provisions must be made in the jig to permit the insertion of facing tools.



Figs. 113 and 114. Alternative Methods for Fastening Uprights to Jig Base.

A great deal of metal may be saved in designing heavy jigs by removing superfluous metal from those parts where it does not materially add to the strength of the jig. In Fig. 109, for instance, the jig can be cored out in the bottom and in the side standards as indicated, without weakening the jig to any appreciable extent. The rib *C* may be added when necessary, and when it does not interfere with the work to be finished in the jig. It will be seen that extended bosses are carried out to provide long bearings for the bushings. The bosses may be made tapering, as shown, providing practically the same

---

* Address: Borlänge, Sweden.

stiffness as a cylindrical boss containing considerable more metal. They must be given a rather liberal diameter, as they may not always be placed exactly correct on the pattern, and consequently be a little out of center in the casting. Finished bosses should be located at suitable places to facilitate the laying out and the making of the jig, as shown at *D* in Fig. 109. The finished faces of these bosses are also of advantage when locating the jig against a parallel, when it is not provided with a tongue for locating purposes.

In some cases bosses are placed where measurements may be taken from the finished face to certain faces of the work,

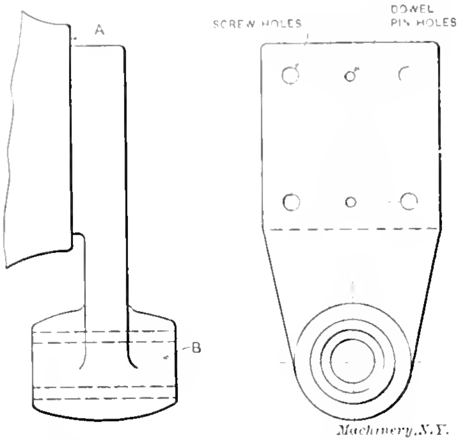


Fig. 115. A Case where the Bushing Hole is Bored Previous to locating and fastening Bracket on Jig Body.

in which case the finished bosses, of course, must stand in a certain relation to the locating point; such bosses are indicated at *E*, from which measurements *B* can be taken to surfaces *G* on the work. The three lugs *H* are provided for clamping purposes, the jig being clamped in three places only to avoid unnecessary springing action. If the jig is in constant use, it would be advisable to have special clamping arrangements as component parts of the jig for clamping it to the table, thereby avoiding loss of time in finding suitable clamps.

The walls or standards *K* of large jigs of this type are frequently made in loose pieces and secured and dowelled in place as shown in Fig. 110 to 114. In such a case the most important thing is to fasten these members firmly to the base, preventing shifting by tongues, keys, or dowels. It is evident that when the standards are made loose as in Fig. 110. it is easier to finish the pad *A* of the face, and this is of importance, particularly when difficult locating arrangements are planed or milled in the face; the pattern-maker's and the molder's work is also simplified. As a rule the standards are screwed to the face permanently and then the bushing holes are bored. In some cases, however, it may be easier to first bore the hole in a loose part, and then attach it to the main body. Such an instance is shown in Fig. 115. It is easier to locate the bracket with the bushing *B* by working from the finished hole in connection with other important holes or locating means, than it would be to first screw the bracket in place and then expect to be able to get the hole to be bored, located exactly in the center of the hub of the bracket.

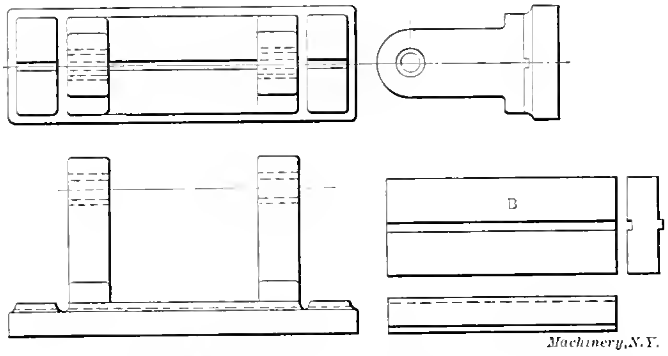

Fig. 116. Jig adjustable for Different Sizes of the Same Class of Work.

When boring jigs are designed for machine parts of a similar design but of different dimensions, arrangements are often made to make one jig take various sizes. In such a case one or both standards may have to be moved, and extra pads are provided on the face as illustrated in Fig. 116. This shifting of the standards will take care of different lengths of work. Should the work differ in height, a blocking piece *B* may be made as indicated in the same illustration. Sometimes special loose brackets may be more suitable for replacing the regular standards for shorter work. If there is a long distance between two bearings of the work, a third standard may be placed in between the two outside ones, if the design of the bored work permits, as shown in Fig. 117; this may then be used for shorter work together with one of the end standards. In Fig. 118 is shown another adjustable boring jig. Here the jig consists of two parts *A* mounted on a common base plate or large table provided with T-slots. The work *B* is located between the standards. A number of different standards suitable for different pieces of work may be used on the same base plate. The jigs or standards are held down on the base plate by screws or dowels, and generally located by a tongue entering the upper part of the T-slots.

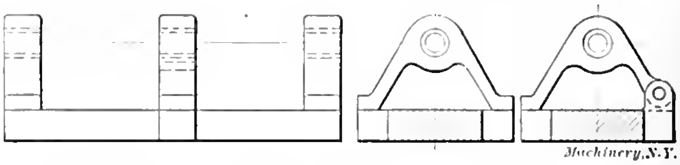

Fig. 117. Boring Jig with Removable Bearing in the Center, adapting it to Different Sizes of Work of Similar Character.

In the examples thus far given the work has been located on the jig, but it is apparent that boring jigs are frequently made which are located and supported on the work. Fig. 119 shows such a jig. The work *A*, which in this case represents some kind of a machine bed, has two holes bored through the walls *B* and *C*. This jig may guide the bar properly if there be but one guide bushing at *E*, but it is better if it can be arranged to carry down the jig member *D* as indicated to give support for the bar near the wall *B*. It may sometimes be more convenient to have two separate jigs located from the same surfaces on the top or sides. In other cases it may be better to have the members *D* and *E* screwed in place instead of being solid with *E*, and in some cases adjustable. Of course, these variations in design depend on the conditions involved, but the principles remain the same. The jig or jigs are held to the machine on which they are used by clamping arrangements of suitable type.

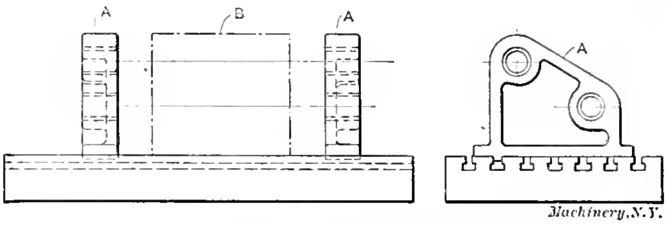

Fig. 118. Universal Base Plate for Standards of Various Descriptions for Different Classes of Work.

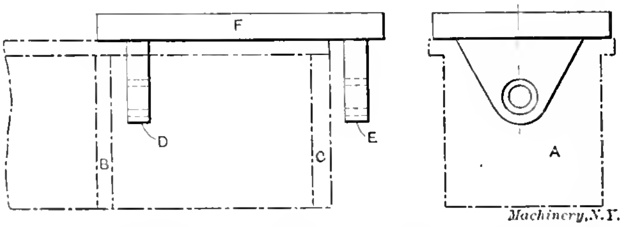

Fig. 119. A Case where the Jig is located on and supported by the Work.

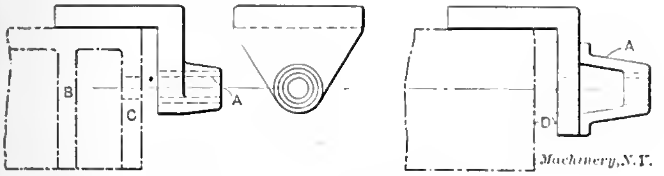
The type of boring jigs described above supports the bar in two or more places, and the cutting tools are placed at certain predetermined distances from the ends of the bars, depending on the shape and size of the work. Sometimes it may prove necessary, however, to have a cutting tool inserted just at the end of the bar. Sometimes a boring jig may consist of simply one bracket as shown in Fig. 120. A very long bearing *A* is then provided so as to guide the bar true. The arrangement shown in Fig. 121 is sometimes used to insure

a long bearing for the bar. A special bracket *A* is mounted on the jig and bored out at the same time as the jig proper is machined. This provides, in effect, two bearings. In these cases bars with a cutting tool at the end are used. The reasons for using the kind of boring jig illustrated in Figs. 120 and 121 are several; in Fig. 120, for instance, there is a wall *B* immediately back of the wall *C* in which the hole is to be bored. Other obstacles may be in the way to prevent placing a bearing on each side of the hole to be finished. Instead of having a space *D* between the jig and the work as shown in Fig. 121, the jig can many times be brought up close to the work and clamped to it from the bushing side. A combination between this latter type of jig with but one bearing for the bar, and the type previously described with two bearings, is shown in Fig. 122.

Each of the different holes in boring jigs has, of course, its own outfit of boring-bars, reamers, and facing tools. In making the jig it must be considered whether it will be used continuously and what degree of accuracy will be required. When extreme accuracy is required there should be a bar provided with cutting tools for each operation to be performed. It is cheaper, of course, to use the same bar as far as possible for different operations and, ordinarily, satisfactory results are obtained in this way. It is desirable to have bushings fitting each bar, but often this expense can be reduced by using the same bushing for bars having the same diameter.



Figs. 120 and 121. Examples of Guiding Arrangements where no Support is obtainable on One Side of Hole to be bored.

It sometimes happens that one or more holes form an angle with the axis of other holes in the work to be bored. In the jig shown in Fig. 123 the bushings *A* guide one bar for boring one hole and the bushings *B* the bar for boring another hole, the axis of which is at an angle with the axis of the first hole in the horizontal plane. Then an angle plate *C* can be made in such a manner that if the jig is placed with the tapered side of plate *C* against a parallel, the hole *B* will be parallel with the spindle. This arrangement may not be necessary when universal joints are used between the spindle and the bar. If a hole is out of line in the vertical plane, a similar arrangement as that used for drill jigs, and previously described in this series, can be used.

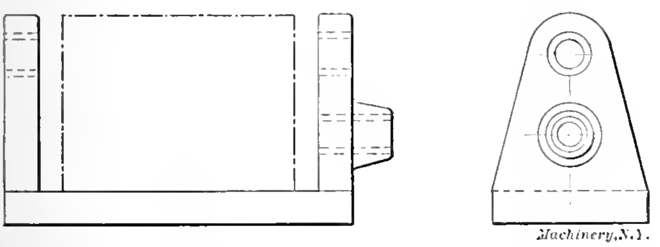


Fig. 122. Boring Jig in which One Bar has Single and One Double Bearing.

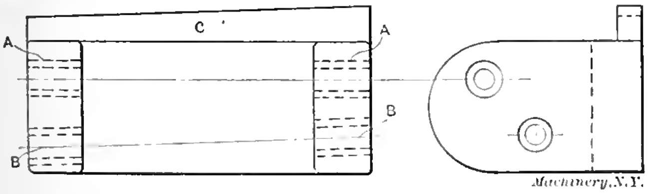

Fig. 123. Boring Jig for Boring Holes placed at an Angle to each other.

As a rule but one hole is bored out at a time owing to the fact that machines for boring generally have but one spindle. Several holes, however, could be bored out in a large size multiple spindle drill, in which case the jigs naturally ought to be designed somewhat stronger. Another method of designing jigs for boring two or more holes at the same time is illustrated in Fig. 124, the outlines only being shown in this illustration. *A* is the gear box containing the main driving gear which is mounted on a shaft *B* which in turn is driven by the spindle of the machine. The gear on shaft *B* drives the gears and shafts connected with the boring-bars passing through the bushings *C*, *D*, *E*, *F*, *G*, and *H*. The gears are proportioned according to the speed required for each bar, which in turn is determined by sizes of the holes. The housing or gear box *A* slides on a dove-tail slide *K*. A particularly good fit is provided, and the gear box can be fed along in relation to the work either by table or spindle feed. If boring operations are to be performed in two directions, a jig on the lines indicated in Fig. 125 is designed. This jig may be mounted on a special revolving table permitting the work and the jig to be turned and indexed so as to save resetting and readjusting the work and jig when once placed in position on the machine.

Fig. 124. Principle of Multiple Bar Boring Jig

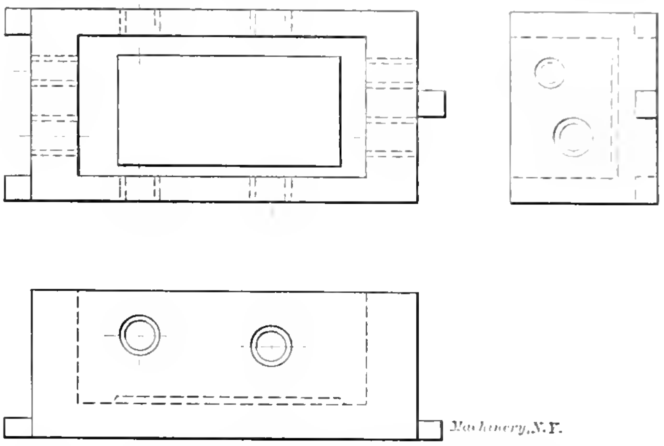

Fig. 125. Jig for Boring Holes through Work both from Sides and Ends.

The outline given above of boring jigs illustrates only the fundamental principles involved, it being considered more important to state the fundamental principles in this connection than to describe complicated designs of tools in which the application of such principles may be more or less obscure or hidden.

* * *

Messrs. Alfred Herbert, Ltd., of Coventry, England, give the following figures for general cutting speeds, to be used on milling machines: for taking roughing cuts on cast iron with ordinary carbon steel cutters, 40 feet per minute; for machine steel, 60 feet per minute; for tool steel, 24 feet per minute; and for brass, 75 feet per minute. Finishing cuts may be taken at speeds of from 50 to 55 feet for cast iron, 75 to 80 feet for machine steel, 30 to 35 feet for tool steel, and 95 to 100 feet for brass. These figures, however, should not be taken as representing the maximum rates of cutting speed which can be successfully used even with ordinary cutters, and with high-speed steel cutters it is possible to increase the cutting speed in some cases three times that used when working with carbon steel cutters.

* * *

A mix-up appeared in the note in the November issue on the use of gas engine exhaust for heating. The values should have been 11 to 15 pounds of steam evaporated per horsepower hour, from and at 212 degrees F., and 60 to 82 pounds of water raised from 32 degrees F. to the boiling point, instead of the figures given. They are approximately ten times too small in one case and ten times too great in the other. Obviously the thermal efficiency of the gas engine is figured low in order to obtain the evaporative and heating results indicated above.

GERMAN DESIGNS OF INTERNAL GRINDING MACHINES.*

OSKAR KYLIN †

The possibility of obtaining accuracy and high finish on machine parts by means of grinding has been the fundamental cause of the rapid development of grinding machines in recent years. Of late, grinding machines have also been designed which have been intended particularly for removing the greatest quantity of metal in the shortest time, the question of accuracy here being secondary. These latter designs, however, are exceptions. The many special operations to which grinding adapts itself has also caused the design of a great number of grinding machines intended for special purposes. A number of these latter machines have been brought out by the firm of Mayer & Schmidt, Offenbach, a.M., Germany, and a few of these are illustrated below. This firm is specializing along the lines of grinding machines, and besides the building of these, there is a large department devoted to the making of emery and carborundum wheels, emery cloth, and kindred products.

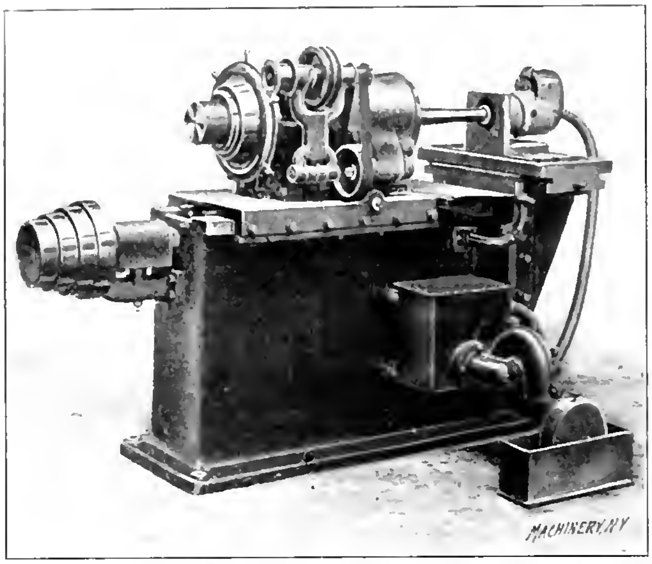

Fig. 1. Rear View of Small Size Internal Grinding Machine, showing Dust Exhausting Arrangement.

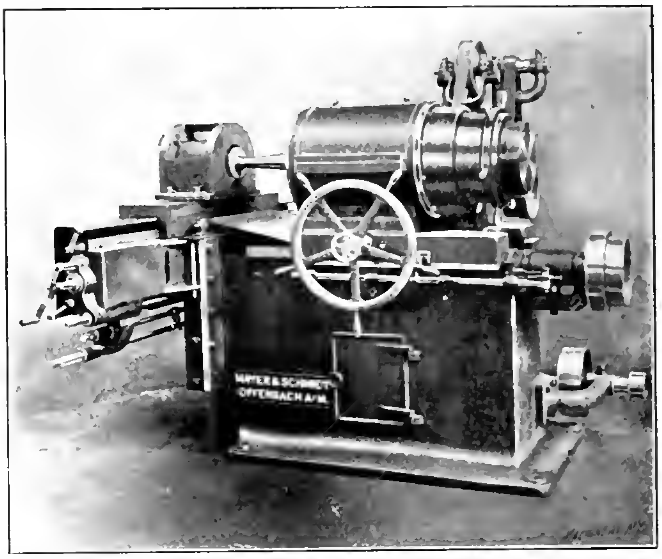

Fig. 2. Front View of another Type of Internal Grinding Machine.

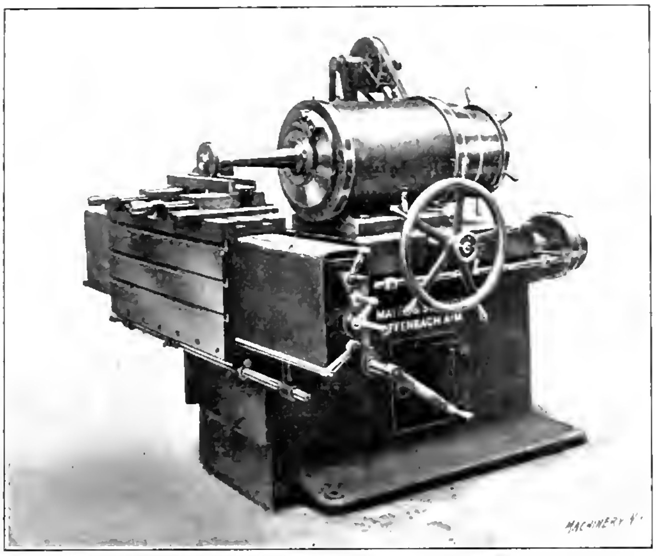

Fig. 3. Internal Grinding Machine with Planetary Motion Locked, used for Surface Grinding.

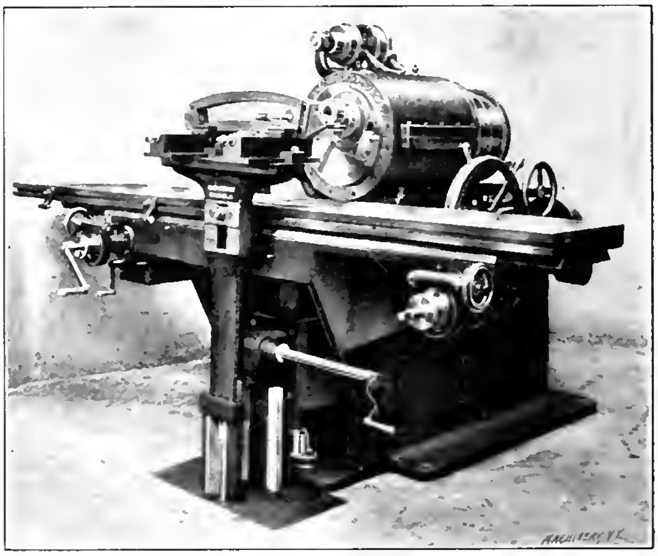

Fig. 4. Grinding Links for the Reversing Mechanism of Locomotives.

The firm's machine shop is divided up into two separate departments, one of which is exclusively working on special grinding machines, while in the other only universal grinders are made. The middle bay of the latter department, showing the space devoted to the assembling, is shown in Fig. 5. The side bays in this building are occupied by machine tools and all machining is done there. The shop is lighted in an excellent manner, due in a large measure to the saw-tooth roof construction, and in general is typical of a modern German machine shop.

One of the most interesting of the products of the firm is the type of internal grinding machine, of which various sizes are shown in Figs. 1, 2, and 3. It is more than likely that the automobile industry is largely responsible for the development of this machine, as in this industry the demand for a simple and accurate means of finishing the cylinders is imperative. The writer has seen this machine employed in most of the leading Italian automobile factories. Larger sizes of this type of machine are also built for finishing the cylinders for steam and gas engines. The first impression on examining the illustrations of this machine, is that of great rigidity throughout the design. The grinding head is mounted on a slide provided with longitudinal feed motion. The slide on which it is mounted rests directly on the bed, the sliding surfaces being, according to the common German practice, made flat instead of V-shaped, as is more common in America. The grinding head is fed forth and back automatically by means of a pulley which, in turn, drives a screw in the center between the two sliding surfaces or ways. An automatic reversing mechanism is provided, as shown in Fig. 2, where the reversing rod is plainly indicated on the side of the machine; faster or slower feeds are provided for by the cone pulley.

The most interesting feature of the machine is the eccentric or planetary motion of the grinding spindle and wheel. The spindle, in addition to its rotary motion, has also a motion around the axis of the grinding head, the grinding

---

* See also the following articles on internal cylinder grinders, previously published in MACHINERY: Internal Grinding Machines, February, 1908, engineering edition; Automatic Cylinder Grinder, January, 1908.

† Address: Asklanda, Sweden.

spindle being eccentric in relation to this axis. In other words, the center line of the wheel spindle moves in a circle about the center of the head itself, at the same time as the spindle rotates about its own axis. This motion around the axis of the head is, of course, very much slower and entirely independent of the rotation of the spindle around its own center. The radius of the eccentric motion can be adjusted by hand or automatically, as required. In connection with the mechanism for adjusting the eccentricity of the spindle, a device is provided having a scale by means of which the machine can be set to grind a certain predetermined diameter of cylinder. When the diameter of the cylinder, according to this setting, is reached, the feed will stop automatically, the grinding spindle will recede from the work, and a bell will ring in order to attract the attention of the operator.

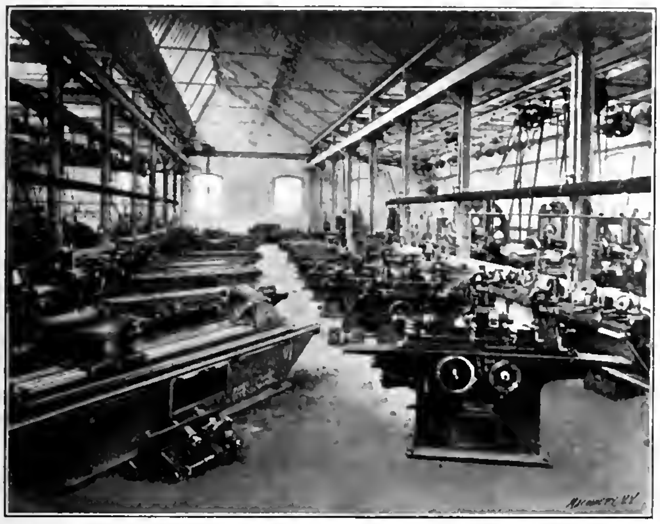

Fig. 5. Interior of One of the Shops of Mayer & Schmidt, Offenbach, a.M., Germany.

As is shown in Fig. 1, the grinding spindle is driven through a movable counter-shaft, which follows the eccentric motion of the spindle. The cylinder or work to be ground internally remains stationary during the grinding operation. As plainly indicated in the illustrations, the work is mounted on a slide having a transverse as well as a longitudinal adjustment, this being provided in order to facilitate the exact setting of the work. In Fig. 3 this type of machine is shown arranged for surface grinding of small pieces, the planetary action of the wheel spindle then being locked and out of operation.

A well devised arrangement for removing the dust and grindings, from the cylinder is shown in Fig. 1. The apparatus consists of a rotary fan which exhausts the dust through a flexible pipe from the cylinder, and delivers it into a box where the dust is collected. This feature is of great importance, on account of the means it affords for preserving the general purity of the atmosphere throughout the shop, and, as a consequence, the health of the operators.

A machine designed for the grinding of the links for the reversing gear of locomotives, is illustrated in Fig. 4. Of course, it can also be employed on a great variety of work of similar character. The general design of the machine is somewhat similar to the type of internal grinding machine already described. The work holder is adjustable transversely and horizontally, the same as in the internal grinding machine, and the work is clamped by means of two vises with parallel jaws. A swinging motion is imparted to the work holder, the radius to which the link is ground being adjustable at will.

The centrifugal pumps installed in the 39th Street pumping station, Chicago, have handled a volume of water in one day that a few years ago would have seemed quite impossible for any practical outfit of pumping machinery to cope with. This station pumped 2,000,000,000 gallons of water and sewage in twenty-four hours, a quantity sufficient to flood a square mile to a depth of nine feet! The total capacity of the pumping stations in Chicago handling sewage and sewage water is about 3,000,000,000 gallons daily.

THE ADVENTURES OF A WATER-COOLED BORING MILL.

"Say Mr. Brown," said Foreman Higginbotham to the superintendent, "wouldn't it be a good idea to put a reservoir, pump and some piping onto that boring mill over there that we keep busy on cast steel gear blanks? Water cooling works well in cutting steel in the lathe, and it seems as though it ought to help us to get more work out of the boring mill."

"Good idea!" said the superintendent. "Funny we never thought of it before. Don't know as I ever saw a boring mill rigged up for water cooling. Go ahead and try it."

So Foreman Higginbotham cut out a strip of sheet iron of the proper length, which he screwed into place around the table with a packing strip under it to keep it from leaking; then he brazed the ends together to make a tight joint. He thus had a rim on the table that would keep the water from running off the edge instead of down through the hole in the center. The next thing he did was to make a pan, which he placed in the base of the machine under the spindle, where it would catch the chips and water as they ran down through the central hole. Then he attached a B. & S. pump to the side of the frame, and connected up the proper piping and valves, and a flexible tubing connection leading to the point of the tool. After belting the pump to the counter-shaft, everything was ready for a trial trip.

Brown and Higginbotham were both present at the opening ceremonies. The operator was told to use the regular feed, but to speed the table up a couple of notches higher. The machine was started, the stream turned onto the point of the tool, and the feed thrown in. Brown, Higginbotham and the operator leaned over the table to watch results. The results came. The table was revolving rapidly, and as soon as the water struck it, it hurried for the outside diameter at top speed, where it banked up against the retaining rim. As it accumulated there, standing at an angle of 45 degrees or so, in less than no time it had reached the upper edge of the rim and was running over in a wet, swirling sheet which struck the three spectators amidships, marking a distinct water line on their outer garments. Of course! What else could be expected? They compromised on letting the water drizzle onto the tool at such a rate that it would bank up almost to the top of the rim at the completion of each operation, when the stopping of the table let it run back through the center hole into the pan prepared to receive it.

Fig. 1. The Boring Mill plays a Practical Joke.

Shortly after this compromise, an editor (who, unlike friends Brown and Higginbotham, shall be nameless) appeared on the scene. The editor was a man of ideas. He had just stepped off a train on a trunk line railroad, where the stops were too far apart and the schedule too fast to permit the locomotive to line up opposite the water tank for a drink every time it needed one. Instead, the fireman dropped his scoop into a

trough between the tracks and filled the tender on the run. With this idea in his mind, the brilliant editor suggested the plan of making a scoop for the boring mill, dipping it into the banked up water inside the table rim, then draining it, through a rubber tube, into the reservoir. No sooner said than done. The scoop was made and at the proper angle set. The editor, Higginbotham, Brown, and the operator gathered around the machine for a second trial. The water accumulated as before, but the scoop picked it up and delivered it to the reservoir in a very satisfactory and fascinating way. As the operation proceeded, however, the chips also began to accumulate close to the rim, and before long these had banked high enough to strike the scoop. Zip! Its front lip was bent backwards. Zip! It struck the chuck jaw and was sent out through the window, and the fountain display which had been a feature of the first performance, was again repeated. Having important business on hand, the editor was forced at this stage of the proceedings to catch a train for a distant city, so his clients were deprived of his valuable advice at this juncture.

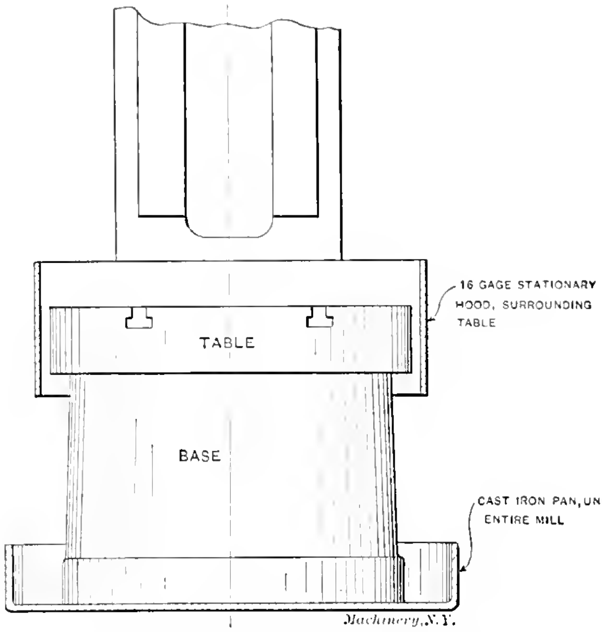

Fig. 2. The Guard which did the Work.

A few days ago the editor got a letter relating to the doings of the only man concerned who had as yet offered no suggestions. It was now the operator's turn. This gentleman, after profound thought, had removed the rim from the table and replaced it with a stationary guard (as shown in Fig. 2), which entirely surrounded the table, and served simply as a splasher to stop the course of the water, as it was thrown off by the revolving table. After striking this guard, the water dropped down into the pan in which the boring mill was set; from here it was drawn by the pump and forced back onto the tool again, none of it flying beyond the confines of the machine, even when the tool was flooded.

By the way, why should not the tool be flooded when cutting steel in the boring mill as well as in the lathe, and is there any simpler or more effective way of controlling the water than the scheme last described?

* * *

The German government is employing very commendable methods for increasing its foreign trade and for gaining knowledge of foreign trade conditions. Instead of making its consular service largely a department through which payment is made for loyal service during political campaigns, the German government endeavors to place only men known as commercial and technical experts at important German consular posts. The work of these officials has been of great benefit to German industries. The important work done by special agents sent out by our government could in a large measure be done by the consuls if men of commercial and technical ability and insight were appointed to these offices. In this respect it would be beneficial to our industries if our administration followed the example of Germany.

DON'TS FOR INVENTORS.

H. S. BUSEY.

Don't wait for inspirations. The faculties for inventing must be trained by careful study and diligent research.

Don't allow difficulties to discourage you. Persistent effort seldom fails to overcome them.

Don't overlook the little things, but practice the "art of taking pains."

Don't be satisfied with your invention until you have learned every thing possible relating to previous efforts and achievements in that particular line.

Don't submit your invention for a patent until you have made all possible improvements. If this requires much time get a caveat.

Don't send sketches or drawings to the patent attorneys without your signature and date on every sheet. Have a witness to sign them also. The attorneys file these sketches, which can be used to advantage in proving priority of invention.

Don't talk about your invention to every one you meet, but without going into details, get the opinion of one or more trusted friends.

Don't demonstrate your invention in public until you have applied for a patent, or better, have been granted one.

Don't exhibit any but a neat working model of your invention in public, and make sure it will work perfectly.

Don't exaggerate the advantages of your invention; hold your enthusiasm in check, while explaining its merits to anyone.

Don't show disappointment if your invention is not immediately appreciated; persistent and untiring effort on your part will bring reward if the invention has real merit.

Don't make any agreement or assignment without consulting a reliable lawyer. It pays to have them written in a legal manner.

Don't employ any but the best patent attorney to write up the specifications and claims of your patent, otherwise it may prove to be worthless.

Don't employ any patent attorney not registered by the Patent Office.

Don't fail to get a Canadian patent if your invention is patented in the United States.

Don't wait too long before applying for foreign patents. Get as many as can be profitably worked with your particular invention. Patents in Great Britain, Germany, and France are specially desirable.

Don't assign even a small part interest in your invention; if necessary, assign a certain portion of the net profits derived therefrom. The holder of an undivided interest in your patent can, if he choose, use the same to your disadvantage.

Don't forget that many inventors have practically lost their patents by assigning undivided part interests, or by signing agreements that they did not fully comprehend. Don't be hasty in such matters, but go over every point carefully, and consult a trusted lawyer before signing or taking any action whatever.

Don't overestimate the value of your patent or invention. Remember that the value of an invention cannot be foretold and that much depends on the way it is managed in placing it upon the market.

Don't, when offered a cash price, refuse to take it, if the sum be sufficient to cover your expenses and leave a reasonable reward for your efforts. The purchaser relieves you of all further responsibility and is taking chances on making it a commercial success.

Don't overlook the fact that shop-rights and territorial rights are sometimes more profitable than selling the patent outright.

Don't try to promote a company of your own to market your invention unless you are experienced in such proceedings, and have assurance and plenty of capital to carry on the business.

Don't assign your patent rights to an incorporated company without having positive knowledge of its financial standing, and the ability of its management. Otherwise, should the company fail, or go into the hands of receivers, the patent rights will be sold to the highest bidder.

ITEMS OF MECHANICAL INTEREST.

ICE TUMBLERS.

Drinking tumblers made entirely of ice are a novelty which has recently been introduced in Europe by the Nederlandsche Ysbeker Maatschappy (Procédé Huizer), Hague, Netherlands. One of these tumblers inserted in a paper shell for convenience in handling, is shown in Fig. 1, while Figs. 2 and 3 illustrate the mold in which it is formed and frozen. If desired, the tumbler can be made with varying degrees of transparency, or even colored by the addition of some harmless coloring matter, and, as it is only used once, it is ideal from the hygienic point of view.

Fig. 1. Ice Tumbler.

Fig. 3 shows a sectional view of the mold in which the tumbler is frozen. A measured quantity of water is first poured in the mold *a*, and then the core *c* is inserted, which forces the water upwards in the space between the two. The mold is then placed in the brine *m* through an aperture in cover plate *l*. The freezing soon begins, because of the thin layer of water exposed, and the tumbler is ready for use in from 6 to 15 minutes, with brine temperatures of 14 and —4 degrees F., respectively. In order to facilitate the removal of the frozen tumbler, the mold is made of a material expanding more rapidly than ice, and the core of a material expanding slower than ice. By sinking the apparatus into a special heater giving off just enough heat to expand the mold without injuring the tumbler, the latter is withdrawn from the mold, but still clings to the porcelain core, principally by the raised ring of ice bearing against it at the bottom; this pressure is due to the different coefficients of expansion of the ice and the porcelain, the latter being smaller. By pushing the piston *d*, which is connected with the handle *g* by the rod *f*, downward, the tumbler is removed from the core and caught in the paper shell which prevents it from coming into direct contact with the hand. The tumbler is then ready for use.

Fig 2. Mold in which the Tumbler is Frozen.

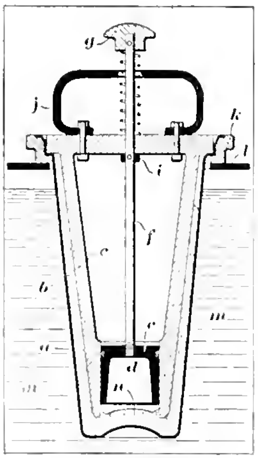

Fig. 3. Sectional View of the Mold.

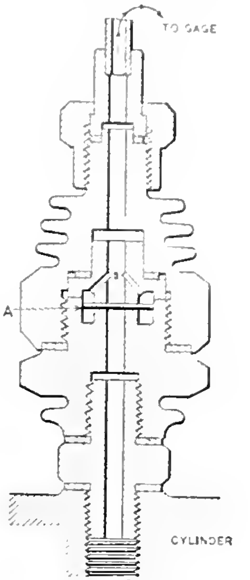
It is estimated that about one hundred of these ice tumblers can be made in one hour, with the expenditure in energy of one horse-power, and at a cost per tumbler, encased in a paper shell, of one-half a cent each. A small refrigerating machine will produce these tumblers in considerable quantities, and after being made they can be stored, until ready for use, in refrigerators.

PRESSURE INDICATOR FOR INTERNAL COMBUSTION ENGINES.

It is a rather difficult matter to take satisfactory indicator diagrams for high speed internal combustion engines, and it is particularly difficult to determine from the diagrams exactly the amount of compression and the maximum pressure developed, as well as the degree of vacuum during the suction stroke. These quantities, however, can be ascertained by a simple pressure indicator, which has been introduced by Messrs. Negretti & Zambra, 28 Holborn Viaduct, E. C., London, and described in the October 30, 1908, issue of *Engineering*. This instrument is of French origin, and has been named the "acrometer." It consists essentially of a light non-return valve, interpolated in a pipe connecting the cylinder with an ordinary pressure gage, this valve with its connections being shown in the accompanying line engraving. Gases from the cylinder can flow through this valve into the gage, but cannot return, so that when the gage is put into communication with the engine cylinder the pointer of the gage will almost instantly indicate the maximum pressure in the cylinder and continue to do so even if the latter be followed by more or less throttling of the gas supply. If more gas is admitted, a higher maximum pressure will be recorded. If, on the other hand, the gas supply is throttled, thus reducing the maximum pressure, the continual loss of heat through radiation from the gage and connecting pipe, soon causes the pressure indicated by the gage to fall to that developed in the cylinder. This fall of pressure in the gage to correspond to the pressure in the cylinder is hastened by the fact that the joints above the non-return valve are not made absolutely gas-tight. To obtain the compression pressure, a few successively missed ignitions are arranged for. The pressure already indicated in the gage is then released by a valve, and when it is again closed the gage will indicate the degree of compression. In the accompanying engraving the non-return valve itself is shown at *A*, and consists simply of a disk of a platinum alloy, access to which can be gained by unscrewing the cap above it. The lower part of the instrument which screws into the cylinder is made from chrome steel, so as to better resist the action of the hot gases from the cylinder. It is stated that the device in question is used considerably in France.



Section of Valve used in Conjunction with Gage for Recording Gas Engine Pressures.

* * *

A few years ago (November, 1905) a note appeared in these columns relative to the limitation of the speed of the sewing machine because of the heating of the needle due to friction in the cloth. With ordinary thin fabrics the limit is about 3,000 to 3,500 stitches per minute, but if two or three double folds of the same material are sewed, the working speed must be reduced to say 2,500 stitches per minute, as otherwise an ordinary sewing machine needle will become so hot that it will turn blue and lose its temper. Curiously, it has been found that nickel plating sewing machine needles materially increases their working speed. The latest improvement is a peculiar alloy substantially the same as high-speed steel. The fact that the limitation of sewing speed is the endurance of the needle, makes the improvement of direct bearing upon the cost of clothing, and it is an excellent illustration of the far-reaching effects of the discovery of high-speed steel. On lock-stitch machines the limit of speed now is the ability of the mechanism to stand the tremendous strain on its reciprocating parts; no matter if the needle does become blue with heat, its temper is not affected, but on the contrary, it is even harder when hot than cold. In this case the line of future improvement is in the direction of improving the machine rather than the tool or needle.

DESIGN CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1909.

PAID CIRCULATION FOR DECEMBER, 1908, 21,943 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

AN INDUSTRIAL DEMOCRACY.

The opinion that Germany will be America's chief competitor in the manufacture of machine tools in the future has been voiced by every one who, of late, has studied industrial conditions in Germany; and the subject was brought prominently before American machine tool builders at their recent convention by Captain G. L. Carden.

Without question, Germany has recently developed an extraordinary industrial efficiency; and it is interesting to examine the different causes which have placed that country and America in leading positions in the industrial field. In America, one of the fundamental causes of development in the machinery industry has been the free scope given to individual initiative, and the possibility thereby afforded for utilizing the intelligence of the workman on the problems connected with his work. In Germany, encouragement for the individual, so common with the rank and file in America, has been generally lacking; but this lack has been made up, to some extent, by the more thorough training of the few who occupy supervisory positions. In a sense, the Germans have built up an industrial aristocracy, while in America the development has been along the lines of an industrial democracy.

Captain Carden, in his address, called attention to the beneficial effect, industrially, of the military training imparted in the German army service; and this is true in so far as it is desirable to build up an industrial community which follows, more or less blindly, a few appointed leaders, but in which the individual initiative, so important a factor in the development of American industries, is almost entirely lacking. Military training, as practiced in Europe, is the most effective means of suppressing individuality, its first principle being to teach the masses to obey. In most European countries the ambition of the worker is dulled by the knowledge that he is expected to fill his place as a mere machine; and while he may attain high efficiency in his work, he is not encouraged to independent activity.

The German system represents thorough technical training, experiments intelligently planned and carefully carried out, and scientific principles applied to machine design. These have been the most important factors in the recent development of the German machine tool industry. The American system, as previously stated, is exemplified by the possibilities for individual initiative, the incentives to ambition, and the prizes for originality and development offered the masses. A combination of American and German methods and forces, working harmoniously together, should therefore produce the ideal industrial democracy.

MOVING PICTURES AN AID TO TEACHING TRADES.

The present day conditions in manufacturing, which so seriously affect the education of young men in useful trades, are attracting wide-spread interest among educators, manufacturers, workmen, capitalists, and practically all who realize the difficulty of acquiring the skill and knowledge essential to any workman who aspires to be a master of his trade. The principle of manufacturing, as now conducted, is essentially antagonistic to the education of skilled workmen, except as specialists; but a condition which results in too many specialists, and too few master workmen is detrimental to the trade.

There are many plans for the education of industrial workers, but none complete or entirely satisfactory, although all may have some very good features. The chief fault of most plans of industrial training is that the learner is removed from the commercial shop atmosphere if he receives the individual instruction desirable. If trained in the shop, he receives little individual instruction, the learner's interests being sacrificed because of the commercial necessity of promoting production.

The moving picture machine offers a partial solution of the problem of imparting individual instruction in the trades. Next to actually doing the thing or seeing a skilled workman do it, is the seeing of it done in a series of moving pictures. For example, take the operation of accurately filing a flat surface on a piece of cast iron held in a vise: A series of pictures showing the correct position and manner of handling the file, could not help making a strong impression on earnest learners of the machinist's trade. The same method would apply to the operation of chipping with the hammer and chisel, scraping, lapping, laying out, and many other hand operations almost impossible of complete description without working examples.

In machine work, the moving picture scheme could be employed with even greater success. The operation of chucking a casting on the face-plate of a lathe and boring and facing, could be shown vividly. Dozens of other operations shown in this way could be repeated indefinitely for the instruction of countless numbers of young men. They would be impressed by the methods illustrated and the spirit in which a skilled workman proceeds in doing the things portrayed. The first investment for films illustrating shop operations would be very heavy, and the plan must be worked out cooperatively in order that manufacturers may avail themselves of this system of imparting apprenticeship instruction cheaply. In our opinion there is merit in this idea as one feature of a general scheme of industrial education.

* * *

Automobile racing is of doubtful value as regards the proper development of the automobile. Under conditions governing past events, the manufacturer was free to build the automobile of practically unlimited power, consequently the speed of an automobile, that could be obtained in racing, was limited only by the purse of the manufacturer and the physical limitations that must be met in the designing of a road machine. Hereafter, however, entries for the Vanderbilt cup races must conform in cylinder diameter to the following maximum dimensions: The bore of cylinder will in future be restricted to 130 millimeters and the stroke to 130 millimeters. With this limitation of cylinder diameter and stroke, the manufacturer who hopes to succeed in future racing contests must design his engine and transmission for the highest possible efficiency, and thus some good may result because of the enforced superior mechanical design.

MANUFACTURERS VS. MONOPOLISTS.

FRED J. MILLER.[*]

What appears to us to be one of the most unpleasant incidents of the political campaign, happily now ended, is the revelation of the fact that the *Manufacturers' Record*, of Baltimore, has received at least one of the now famous "certificates of deposit" from John D. Archbold of the Standard Oil Company. Though we have endeavored to do so, we have found in the columns of our contemporary nothing like an adequate or satisfactory explanation. It publishes a letter received from John Skelton Williams in which Mr. Willilams says "They (the Standard Oil Company) had a legitimate motive for wanting to promulgate sound views regarding the products and advantages of this (the South) section." Mr. Williams tries to make it appear that the certificate of deposit was a payment made for extra copies of the paper, or for other documents issued from the publishers' office and in which the "sound views" referred to are "promulgated." The fact that this payment of $3,000, like those made to certain prominent and hitherto more or less influential public men, by Archbold, was in the form of a certificate of deposit instead of a check, indicates clearly enough that the payer, or the recipient, or both, had reasons for not wishing it to be known to others that the $3,000 had been paid. What may we fairly suppose these reasons to be? In view of the record of the Standard Oil Company, can we suppose them to be legitimate business reasons?

The *Manufacturers' Record* vigorously defends child labor as practiced in the Southern cotton mills. Is this because it has received a certificate of deposit from some one whose interests lie in that direction, or does it really and sincerely believe that this abomination, condemned by practically all disinterested sociologists, is actually a good thing for the South?

The ultimate best interests of manufacturers, North or South, can be served by no paper which is not free to express its honest convictions, or whose circulation is not based upon entirely legitimate subscriptions received from those who buy the paper because they want to read it.

A manufacturer is one thing; a monopolist is another. Sometimes the two are combined in one individual or organization; but the Standard Oil Company, though it is a manufacturer, is preeminent as a monopolist. Manufacturers, as such, do not scatter certificates of deposit among members of Congress or in newspaper offices, and those who receive such certificates from representatives of monopolies do not in return for them, give much consideration to the interests or rights of manufacturers.

The interests of manufacturers and of monopolists are usually directly opposed, and one of the most serious mistakes being made at the present time is in the failure to more generally recognize that fact. No writing upon any wall was ever more plain than is now the fact that monopolies of all kinds are to be much abated or abolished. The faces of the people in practically every country are set in that direction. It cannot be too much insisted upon that a manufacturing enterprise, though it may be large and prosperous and even incorporated, is not necessarily a monopoly; it may on the contrary be honest and beneficent, and usually is so when conducted in the face of actual or potential competition.

There is too much of confusing manufacturers with monopolists, and perhaps the most discouraging feature of the situation is that this confusion exists in the minds of many manufacturers who are by no means monopolists and whose interests are opposed to monopoly.

Such misapprehension and confusion will, we fear, be somewhat increased by the wide publication of the fact that a Standard Oil "certificate of deposit" for $3,000 has been received by a journal which by its title and for other superficial reasons, may be supposed to especially represent manufacturers and to stand for their interests.

[The above editorial, written by Mr. Fred J. Miller, fits in with an idea we have had in mind for some time, to invite short editorials from practical men, published over their own signature, on subjects of current interest. In publishing them MACHINERY assumes no responsibility for the opinions expressed. The editors reserve the right to reject articles which may not reflect ideas of sufficient importance to warrant publication.—EDITOR.]

WHY IS THE BLACKSMITH SHOP NEGLECTED?

In any thorough comparison made between the conditions under which the average machinist and blacksmith work in most of our industrial plants, the blacksmith shop usually suffers. This department is commonly housed in one of the darkest and most dismal of the shop buildings, provided with no other heat than the radiation from the forges, with no ventilation, sanitary appliances or wash rooms, and with an equipment which compares very poorly with that used in the machine shop. It is difficult to account for this difference in surroundings and conditions, because there is no valid reason why the blacksmith should not have as good light or as much comfort as the machinist. The existence of these conditions, however, indicates that the blacksmith and his work are not considered as important an adjunct to the machinery industry as the machinist and his work, and therefore may be treated with less consideration. This view, if it is held by those in responsible positions, is unsound, and shows that most men in authority over such enterprises have received no early training in the blacksmith shop, and have therefore been brought up to consider it as an adjunct of small importance to the department in which they were trained. These men are naturally slow to change their ideas in later years, and consequently the belief that "any old thing" is good enough for the blacksmith shop, has in many cases become the prevailing one. Such a condition is deplorable, because the blacksmith and his work are important enough to deserve the same consideration as the men and the work in other departments. The possibilities of blacksmithing are far greater than most mechanics appreciate; and if the blacksmith be given proper tools and equipment, and the blacksmith shop itself proper attention, a large amount of machining and expensive work done in the machine shop could be largely eliminated by forging to shape; but if the blacksmith shop is neglected, it is not likely that men who can originate new ideas will be attracted to the trade, and this will undoubtedly result in a loss to the machinery industry as a whole. Efficient men are needed in all departments—in the blacksmith shop fully as much as in other departments, in order to develop it properly and in harmony with the rest of the business.

There is no reason why the blacksmith should be subjected to more physical discomfort than other workers in the shop, and it has been demonstrated in many cases that the outlay to provide comfortable surroundings for industrial workers yields ample returns in increased efficiency. Physical discomfort and mental capacity are seldom found together; and the development of the blacksmith shop has not kept pace with the remainder of the establishment simply because mere physical strength has been considered the chief requisite in a blacksmith, and mental ability of less importance. This conclusion needs modification if the full possibilities of the blacksmith shop are to be realized.

* * *

As every technical graduate has discovered, there are many factors entering into the design of machinery which cannot be calculated by mathematical processes or determined from standard tables. One of the commonest and most important of these factors is the commercial one, which deals with the tastes and prejudices of the purchaser, and the possibility of persuading him to exchange good money for a good machine. The instinct for commercially correct design is one of the most difficult, and at the same time one of the most valuable qualifications that an engineer can acquire.

A very striking example of one of these incalculable commercial factors came to our notice the other day in connection with a certain special machine tool, which was being built for a customer located in a region where the trade unions are particularly active. One of the rules of the union to which the prospective operators of this machine belong, is that no member shall operate two machines. As a consequence of this rule, and of the desire of the manufacturer to increase his output and his profits, the simple expedient was evolved of building two machines on one base. The design was preposterous from any imaginable mechanical view-point, but from the purchaser's position the logic of the construction was very clear. The machine has been in use some time, and appears to satisfy both the workmen and the employer.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

One of the French railroads has ordered special railway cars for transportation of automobiles. These cars are provided with stalls and appliances for securing the automobiles in the cars so as to safeguard against injuries to the automobile while in transportation.

Count Zeppelin's new airship, the fifth one of his construction, has been completed, and at the initial flight carried ten passengers and maneuvered for three and one-half hours in the air, rising to a height of 600 feet and attaining a speed of about 30 miles.

It has often been pointed out that the limiting factor of large ocean vessels is the harbor facilities of the various ports of call. In order to accommodate the new White Star Liners, *Olympic* and *Titanic*, of which mention was made in a previous issue, negotiations have been completed for the construction at Southampton of a large dock to have a depth of 40 feet of water at low tide, so that it can accommodate these vessels at any hour of arrival.

Experiments have been undertaken by the British Admiralty at Portsmouth, England, for testing the De Forest system of wireless telephony. Communications were kept up between vessels out of the barbor, and vessels lying in the harbor, and messages were distinctly heard over a distance of more than fifty miles. Some interruptions occurred, however, owing to the use of wireless telegraphy by the ships in the neighborhood.

The first mono-rail passenger line to be installed in the United States is likely to be built within the limits of New York City on the route of the old horse-car line from the New Haven Railroad tracks to City Island. The cars will be carried on two 2-wheel trucks, the wheels running tandem on a single rail. Stability is obtained by two overhead trucks carried on arms, each truck running on L-shaped overhead rails, carried on standards. These guide rails also act as conductors for the current. It is not conclusively proved, however, that any real advantage, either as regards cheapness of construction or operation, is to be gained by this construction over the ordinary two-rail track.

The hour-glass is commonly regarded as an ancient timepiece of no practical importance to-day, and more of a historical curiosity than anything else, but the hour-glass and modifications of it still have important uses. For timing hardening and tempering heats in twist drill manufacture and for similar purposes, where the operator requires to have an accurate gage of the time elapsed in seconds or minutes, there is nothing so simple and so reliable as a sand glass, of such proportion that the sand will run out in a specified number of seconds or minutes. No calculation is required of the operator; he has no timepiece to watch but simply the running stream of sand. It has a valuable characteristic in that it enables the user to anticipate the exact moment at which the sand will run out and thus gage the time to a fraction of a second. This is very difficult to do with a watch.

The National Conservation Commission intends to take a comprehensive census of the standing timber in the United States. Several estimates have been made in the past, but, of course, the figures given are more or less unreliable. It has been assumed that there is an available stumpage of 1,400 billion feet, and that the annual use is about 100 billion feet. Assuming these figures to be correct, and neglecting growth in the calculation, it will be seen that our timber supply will be exhausted in 14 years. Assuming the same figures to be true, and also an annual growth of 40 billion feet, we would have a supply for 23 years. Some estimates of our stumpage give as high as 2,000 billion feet, which would give us a supply for 20 years, neglecting growth, and a supply for 33 years assuming an annual growth of 40 billion feet. It is apparent from these figures that we are much nearer the exhaustion of our timber supply than most people have ever imagined.

The Westinghouse Electric & Manufacturing Company has been awarded the contract to electrify the Manhattan and Queens terminals of the Pennsylvania Railroad, the initial amount of the apparatus required under the contract amounting to $5,000,000. The electrification of the terminals will include the long stretch of track between Newark, in New Jersey, and Jamaica, L. I. The Westinghouse Co. has already built a huge electric locomotive and this engine, operated over a special track on Long Island, has met the requirements for speed and power. A speed of 120 miles an hour has been reached in tests and the engine will develop 4,000 horse-power. A hundred of these engines, bigger and more powerful than any electric engines ever built, will be built for the Pennsylvania. The model engine has been put to severe tests for elasticity of construction, for power, speed, and action on rails and curves. A rough estimate of the amount of horse-power to be used in the electric zone, under river and land, is about 250,000 horse-power.

In a note in *Engineering*, issue of October 30, 1908, a comparative table compiled by the Swedish Patent and Registration Office is given, showing the percentage of patents in force in various European countries after a certain number of years from the issue of the patent. The patents, it appears, lapse on account of non-working, which, of course, indicates that the patent has proved to be of small or no value. The term of patents in most European countries is fifteen years, and the table shows that during the fifteenth year only six per cent of the total number of patents issued are still in force in Sweden, while in Germany and Great Britain this figure is 3.5 and 3 per cent, respectively. Italy shows the smallest percentage of patents alive for a period of fifteen years, there being only two out of every 100 patents in force for that number of years. This indicates how few inventions are really of practical value. Of the patents, those for inventions in the chemical field proved to have the greatest longevity. Next come the electrical patents, and the patents that appear to be of the smallest value in proportion to the number issued are those relating to ordinary mechanical appliances.

An interesting example of the increase in land values following an important engineering undertaking is given by *Mercator*. Referring to the Assuan Dam in Egypt, this publication states that the total cost of the dam will be $12,000,000, but this expenditure has so far made possible the irrigation of an area of about 175,000 acres, and the increase in the land value has amounted to about $25,000,000. During the next three years about 275,000 acres additional land will be irrigated, and the increase in the value of this will be about $40,000,000. It is the intention later to increase the height of the dam about 25 feet, which would enable the irrigation of an additional 500,000 acres. The expense for this work would be about $2,400,000 and the increased value of the irrigated land $75,000,000. Something like a total expenditure of $14,400,000 will thus be followed by a corresponding increase in land value of $140,000,000. This is simply a single example of how all improvements of a public character tend to increase the value of land. If this increase in value were turned into the public treasury, it could be made to pay easily for all public improvements required. A similar example may be had in New York City, where the building of the subway produced an increase in the value of the land in the upper part of Manhattan Island and the Bronx largely exceeding the cost of the subway itself. If this increased value, due to public improvements, reverted into the public treasury, there would always be ample means for extending public works.

INTERCHANGEABLE INVOLUTE GEAR TOOTH SYSTEMS.

Abstract of Paper by Mr. Ralph E. Flanders, read before the American Society of Mechanical Engineers, December, 1908 Meeting.

The purpose of this paper is to investigate and compare various interchangeable involute gear tooth systems, including the standard form. This investigation was suggested by the many departures from the standard form which have been made in recent years. These departures are becoming more and more numerous, and their increasing use on certain classes of work suggests that the standard form may be unfitted for a considerable part of the field it was intended to cover.

Briefly, the results of this investigation may be summarized as follows: First, the present standard system is involute for but a comparatively short portion of its outline—in fact, for not over 35 per cent of its total height; the shape of the remaining portion of the tooth is known only to the makers of the cutters, so that the system is a private commercial standard instead of an open public engineering standard. Second, marked improvements can be effected by adopting a new standard, in the direction of avoiding interference, giving greater length of involute contact, increasing durability, and, especially, in the matter of increasing the strength; it seems to be clearly shown that a new standard should be adopted, at least for heavy gearing.

Scope of the Investigation.

The standard form of gear tooth for cut gearing has a pressure angle of 14½ degrees and an addendum (in a one diametral pitch gear) of one inch or $1 \div P$. The pressure angle of an involute gear is the angle that the line of action makes with the common tangent to the pitch circles of two gears in mesh; or it may be stated as the angle made by the side of a rack tooth of a given system, with the perpendicular to the pitch line (see a in Fig. 4). In any system of involute gearing the pressure angle remains the same for all gears in the series. The addendum is the height of the tooth above the pitch line. As this also remains the same for all the gears in a series, a system of interchangeable involute gearing may be defined by giving the pressure angle and addendum.

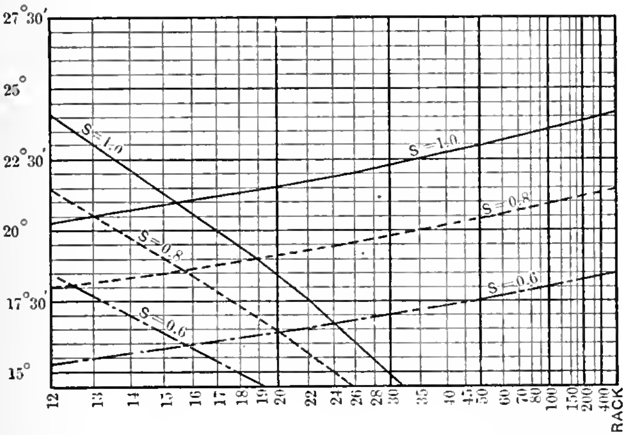

Fig. 1. Effect on Interference of Changes in Addendum and Preseure Angle.

For the sake of simplicity, in all the calculations herein recorded, the teeth are supposed to be of one diametral pitch. The pressure angles investigated range from 14½ to 27½ degrees. Three heights of addendum are considered: 1.0, 0.8 and 0.6 inch respectively, for one diametral pitch. These limits are thought sufficient for the purposes of this paper. It should further be stated that in all calculations where it is necessary to assume the number of teeth in the smallest gear of a series, that number is taken to be 12, the same as in the standard system. The following reference letters are used:

S = height of addendum,
a = pressure angle,
N = number of teeth,
n = number of teeth in continuous action.

Effect of Varying the Pressure Angle and Addendum.

The effect of varying the addendum and pressure angle is investigated with reference to the following practical considerations: Interference; number of teeth in continuous action; side pressure on journals; strength; efficiency; durability; permanence of form; quietness and smoothness of action; suitability for practical cutting processes; and miscellaneous practical considerations.

Fig. 1 illustrates the effect of changing the addendum and the pressure angle on the question of interference. The lines rising toward the right in the diagram indicate the largest number of teeth in the gear in any given system of interchangeable gearing, which will mesh with a 12-tooth pinion without correction for interference with the flanks of the teeth of the latter. Thus, in a system of interchangeable gears in which $a = 17\frac{1}{2}$ degrees and $S = 0.6$, the diagram shows that all gears having more than 50 teeth must be corrected to avoid this interference with the 12-tooth pinion. The lines rising toward the left indicate the minimum number of teeth possible in the smallest pinion in an interchangeable series, to avoid entirely the phenomenon of interference. Thus with the standard form in which $a = 14\frac{1}{2}$ degrees and $S = 1.0$, if 32 be taken as the number of teeth in the smallest gear of the series, instead of 12, it will not be necessary to correct the rack of any other member of the system for interference.

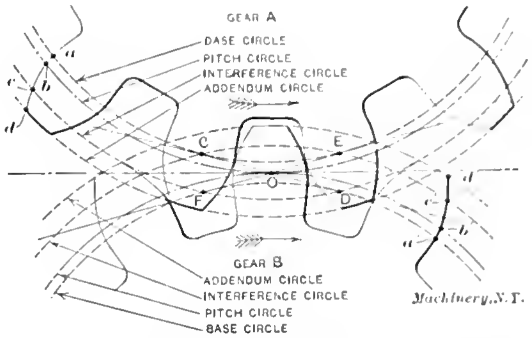

Fig. 2. Extent of Interference between Two 12-tooth Standard Pinions.

The following formulas were used in calculating this diagram. For the maximum number of teeth possible without interference with the 12-tooth pinion,

$$N = \frac{36 \sin^2 a - S^2}{S - 6 \sin^2 a}$$

For the minimum number of teeth possible without interference with an uncorrected rack,

$$N = \frac{2S}{\sin^2 a}$$

It will be seen from the diagram that with the standard form of gearing, in which $a = 14\frac{1}{2}$ degrees and $S = 1.0$, interference occurs to such an extent that the correction of the face of the tooth has to be carried clear down to the smallest gear in the series, it being impossible for two uncorrected 12-tooth pinions to mesh without interference. This condition is shown in Fig. 2. The contact between the two gears, running in the direction indicated and with gear A as driver, takes place along the line CD, being determined by the points of tangency of this "line of action," as it is called, to the "base circles" of the two pinions. That part of the face of the teeth of gear A (see shaded portion at the right) which lies outside of the interference circle passing through point F, extends beyond any possible contact with the mating

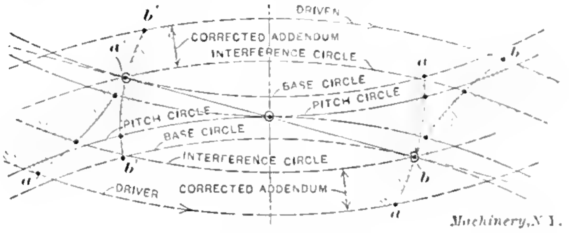

Fig. 3. Limits of True, Involute Action with Two 12-tooth Standard Pinions in Mesh.

pinion, and so is useless for conjugate action in its uncorrected form. Not only is it useless but it is positively harmful as well.

Fig. 3 shows, in diagrammatic form, the positions of the teeth of the two gears in Fig. 2 at the beginning and end of their action; contact begins at *C* and ends at *D*. As the gears continue to revolve, tooth face *aa* of gear *A* will interfere with tooth flank *bb* near the base circle, making proper meshing of the teeth impossible, no matter what the form given to the flanks of the teeth below the base circle. This phenomenon of interference is discussed in all treatises on gearing.

Everything outside the interference line then, in Fig. 2, must be corrected for interference. The amount of this correction increases with the number of teeth in the gear, reaching its maximum in the rack as shown in Fig. 4. As will be explained later, the nature of the correction depends on the form arbitrarily given to the flanks of the teeth of the smallest pinion, below the base circle.

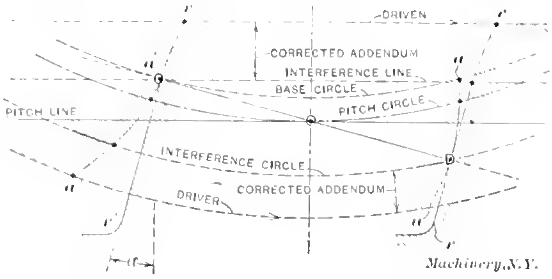

Fig. 4. Limits of True Involute Action with a 12-tooth Pinion and Rack (Standard) in Mesh.

The next thing to consider is the number of teeth in continuous action. Fig. 5 shows the maximum and minimum number of teeth in contact, for any system of interchangeable involute gearing in which the 12-tooth pinion is the smallest. The minimum contact occurs in the case of two 12-tooth pinions in mesh, and the maximum in the impractical case of two racks in mesh. As will be seen, the 14½-degree series of whatever height of addendum, gives less than continuous action, being about 0.987. It will also be noticed that below the points of interference for the 12-tooth pinion (represented by the junction points of the maximum and minimum lines with the interference line) the contact is constant. Thus, for a system in which $\alpha = 20$ degrees and $S = 1.0$, the amount of contact between any two gears of the series from 12 teeth to a rack, is constant at about 1.40, while for a system in which $\alpha = 22$ degrees 30 minutes, and $S = 1.0$, the amount of contact varies between 1.36 for a minimum and 1.58 for a maximum. Figs. 3 and 4 show this condition, which indicates that if in any series there is interference in the case of the two pinions having the smallest number of teeth allowed by the series, the amount of action obtained in that case is constant for any other case throughout the whole series, up to that of two racks meshing with each other. As far as the author knows, this condition has never before been noticed.

In Fig. 3, which shows two minimum pinions of a series meshing with each other, the action is limited to the line *CD*. In Fig. 4, which shows the minimum pinion meshing with a rack, the action is still limited to the same line *CD*. It cannot extend beyond *C* in one direction, because it cannot pass the point of tangency in the base circle of the pinion. It cannot pass beyond *D* in the other direction, because the points of the pinion teeth are corrected beyond the interference circle, losing their true involute form. In the case of any other gear meshing with a rack, the action is limited to *C* on one end owing to the correction for interference of the points of the rack teeth, and at *D* on the other end owing to the correction for interference of the points of the gear teeth. And in the case of any two gears, the action is similarly limited to the line *CD* by the corrections for interference at the points of the teeth. As may be seen, then, a pure involute system in which $\alpha = 14\frac{1}{2}$ degrees and $S = 1.0$, just fails of continuous conjugate action in the case of any two gears of the series.

The formula used for calculating the maximum curves of Fig. 5, above the interference points, is as follows:

$$n = \frac{2\,S}{\sin\alpha \times \cos\alpha \times \pi}$$

The formula used for calculating the minimum curves is as follows:

$$n = \frac{2}{\pi\cos\alpha}\left[\sqrt{(6 + S)^2 - (6\cos\alpha)^2} - 6\sin\alpha\right]$$

The formula for calcuating the interference line, which gives the contact below the interference points, is as follows:

$$n = \frac{12\tan\alpha}{\pi}$$

One of the great practical advantages of the involute gear is the possibility of varying the center distance without interfering with true conjugate action. The comparative amount of separation possible for any two proposed systems, without losing continuous action, may be estimated from Fig. 5 by comparing the amounts of continuous action for the two cases. Naturally the one having the greater number of teeth in continuous action will stand more separation than one which has less. This point could be calculated, but by processes so devious that it did not seem worth while to spend the time for it.

With increase of the pressure angle there is an increase in the side pressure on the journals. Since the side pressure on the journals is the resultant of the tangential pressure between the mating teeth at the pitch line, and the radial outward thrust due to the angularity of the meshing surfaces at the pitch line, it varies directly with the secant of the angle. The curve shown in Fig. 6 is therefore a secant curve.

The rational formula for the strength of gearing is the well known one developed by Mr. Lewis.*

As the strength varies directly with his factor *y*, this factor forms the basis of comparison for different forms of teeth.

Fig. 7 shows the maximum and minimum values of *y* for certain selected forms of gear teeth. It will be seen that the values of *y* rise rapidly with the decrease of the addendum, and more slowly with an increase of the pressure angle, which does not affect it so much.

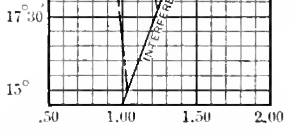

Fig. 5. Maximum and Minimum Number of Teeth in Continuous Action.

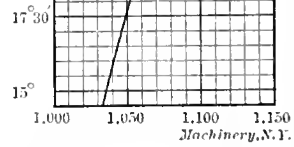

Fig. 6 Side Pressure on Bearings.

Fig. 8 shows that the values obtained for *y* vary somewhat from those obtained by Mr. Lewis (it will be noted that his values have been multiplied by π to make the formula read for diametral pitch). This variation is probably due to the fact that in this investigation the outlines from which the factors are calculated have their teeth corrected for interference, thus bringing the normal pressure at a greater angle at the points of the teeth; and to differences in the method of laying out the fillets.

The work lost in friction in the case of two gears meshing with each other is proportionate to the product of the rate of sliding and the normal pressure on the surfaces in contact. This rate of sliding varies directly with the distance of the point of contact from the pitch point *O* (Figs. 3 and 4, etc.) of the gears. The pressure is constant throughout

---

* Kent's Pocketbook, page 901.

the action, except that when two teeth are in contact it may be considered that the pressure is evenly divided between them. The diagram in Fig. 9 was calculated by a modification of the method devised by an English engineer, Mr. Bruce.* The calculations are made for a single case of gearing, an 18-tooth pinion driving a 60-tooth gear. This case was selected as typical.

The diagram for durability is shown in Fig. 10. The wear between the teeth of two gears is proportionate to the continued product of the pressure, the rate of sliding, and a third factor which depends on the shape of the surfaces in contact. This factor is greater for sharply curved convex surfaces and less for a large radius curve rubbing on a flat surface, for instance. This being the case, it seemed to the author that a reasonable basis of comparison for different systems of gearing could be made by multiplying the values given in the diagram of Fig. 9 by a factor determined from the shapes of the surfaces in contact, and plotting the reciprocal. In determining this factor, the author has followed Mr. C. H. Logue,† who obtains it by adding together the sums of the curvatures (that is, the sums of the reciprocals of the instantaneous radii) of the gear teeth at the pitch line. This should give a value which is approximately an average of the conditions existing throughout the entire action. (It should be understood that Figs. 9 and 10 indicate comparative values only. Positive calculations of efficiency or durability are not here contemplated.)

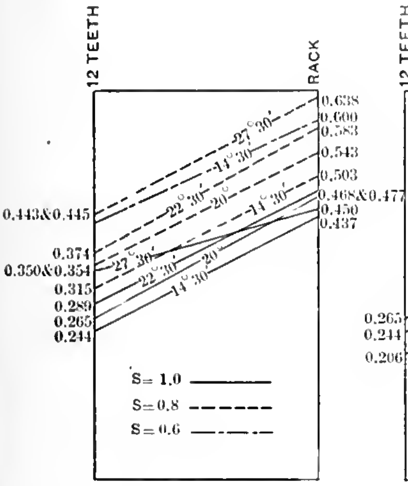

Fig. 7. Maximum and Minimum Values of Strength Factor for Typical Cases.

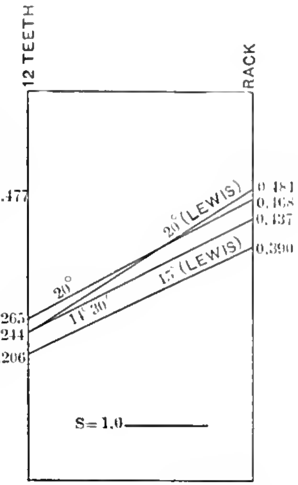

Fig. 8. Comparison of Values for y Here Obtained with those Calculated by Mr. Lewis.

The question of permanency of form may be considered aside from that of durability. By durability we mean the lasting quality of the gear, without reference to whether or not it keeps its shape in the wearing process. A gear which has permanency to a high degree might wear out very rapidly, but it would retain nearly its true form throughout the whole of its short life. In Fig. 11 is given a series of diagrams showing the tendency of a correctly formed tooth to wear at different points of the tooth outlines, in the case of a 12-tooth pinion and the rack, and for the same pressure angles and addendums that were selected for the strength diagram of Fig. 7.

Besides the various factors for which diagrams are given, there are a number of important ones of such a nature as to be incalculable. One of these factors is the suitability of a system for use in different methods of tooth cutting. Any form of tooth which involves interference is very unsatisfactory for use in any generating process, for instance. The formed cutter process works with equal facility on any form of tooth, except that the increase in the pressure angle gives somewhat more side clearance, leading to a freer cutting action.

The vital incalculable factor is smoothness of running. Smoothness of action depends theoretically on perfect conjugate action between the mating teeth. In practice it depends as well on accuracy of cutting tools and accuracy of machine setting. The cutter may be set out of center, or set deeper than required, or have its face ground at an angle considerably away from the radial plane required to give the true cutting shape. The standard form of gear tooth, developed by the Brown & Sharpe Manufacturing Company, has been improved by long practical experience, to a point where it takes care of these practical inaccuracies in a very satisfactory way.

Relative Importance of the Various Considerations.

As to the importance of the various considerations mentioned above being affected by changes of the pressure angle and addendum, it may be said that the difficulty due to interference (apart from its effect on strength, efficiency, etc., which is considered under those heads) is that of making the shape of the gear indeterminate. The design of the standard gear is empirical. While the writer has followed the plan of making the flanks of the 12-tooth pinion radial, and generating the fillet by means of an extended and rounded rack tooth, produced by such a radial flank, he does not know that this is the form of the standard tooth. The exact form is known only to the makers of standard cutters and is not public knowledge. It will be seen that this matter of interference makes of the standard system practically a short tooth system so far as the theoretical bearing is concerned. This is plainly shown in Fig. 11, for Case 1, which is the standard involute gear tooth. The bearing extends over but a very small part of the tooth faces and flanks. The bearing can, of course, be carried clear to the points of the teeth by making the non-involute parts of the teeth on some other conjugate system. This would give more action than Fig. 5, but since only a part of it is involute, the excess of action would be lost as soon as the center distance is changed. A conjugate correction of this kind is made by the manufacturers of standard cutters.

The number of teeth in continuous action, shown in the diagram of Fig. 5, is of importance principally in relation to smoothness of action. It is not generally considered possible to count on distributing the load evenly between two teeth in calculating the strength of gearing, though it will be noted that where n is slightly more than unity, two teeth are in bearing at the beginning and end of the action, when the fiber stress in the teeth is at the greatest. In the matter of smoothness of action, it is necessary to have one pair of teeth take up the load before the previous pair drop it. Increased smoothness of action, due to smoothing out irregularities in cutting, could be effected by having two, three or more sets of teeth in action at one time, but this is impracticable with interchangeable involute gearing. A considerable length of contact is also of advantage in permitting a considerable variation in the center distance, without loss of continuity of action, as previously explained. In this respect the increased pressure angles will be seen to have considerable advantage over the standard form.

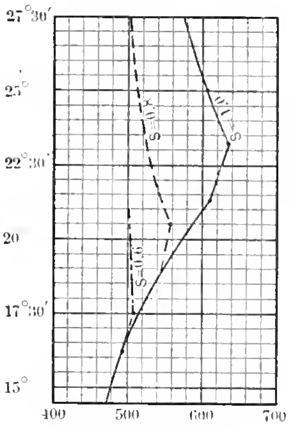

Fig. 9. Comparative Amount of Lost Work.

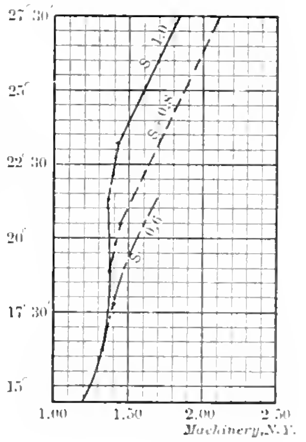

Fig. 10. Comparative Durability.

The side pressure, shown in Fig. 6, is an almost negligible factor. As may be seen, the increase for even so great an angle as 27½ degrees is only 9 per cent above that given by the standard form. At 22½ degrees it is 3 1/3 per cent

---

* *American Machinist*, October 10, 1901.
† *American Machinist*, February, 1908.

above. As the shaft bearings can take care of this slight increase of side pressure in a perfectly normal and satisfactory way, the question scarcely enters into consideration.

The matter of strength is an important one. If a stronger form of tooth can be used, many mechanisms can be gotten into a much smaller space than is otherwise possible. A case in point is the design of geared speed and feed mechanism for machine tools, in which the space problem is usually serious. By decreasing the face of the gear to correspond with an increase in the strength factor *y*, the problem of the designer would be greatly simplified. Instead of reducing the width of the gear by using a stronger form of tooth, advantage can be taken of the stronger form to increase the number of teeth and make them of finer pitch. This gives smoother action, owing to the small inaccuracies in the fine teeth. Smoother action at high speed also means increased strength, owing to the lessening of stresses due to impact.

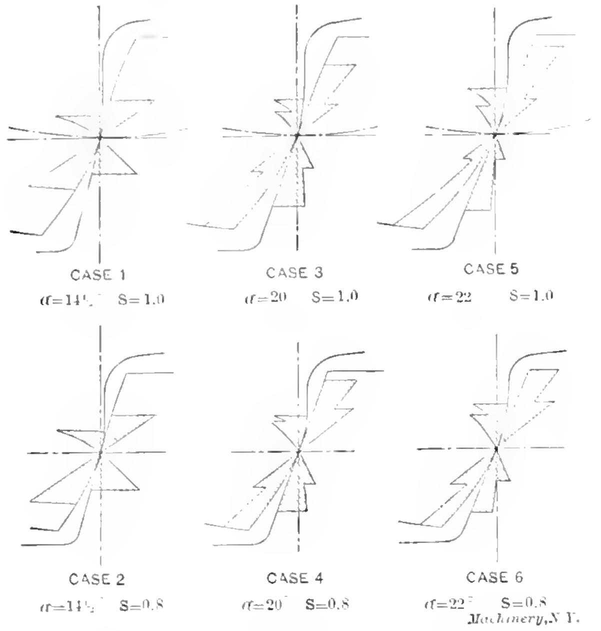

Fig. 11. Permanence of Form.

It is becoming recognized that impact at high speeds is greatly affected by the accuracy of the surfaces in contact; and even where the strength is sufficient, the matter of noise in high speed gearing is of great commercial importance. People would not buy noisy gearing if they could help it, even if it fulfilled their requirements in every other particular.

The question of lost work (plotted in the diagram of Fig. 9) is not a matter of serious moment. The efficiency of well-made spur gearing is so high[*] that the slight variations indicated by the diagram are of small practical importance. This diagram, of course, takes no account of the increase in lost work due to increase in journal pressure, which is an inconsiderable factor with well made bearings.

Durability is of much more importance. Gears have been almost invariably designed hitherto for strength rather than durability, but it is becoming recognized that in many cases the principal factor in gear design is the wear of the teeth. If then the methods by which the diagram of Fig. 10 is calculated are rational, the results there shown are of considerable importance.

Permanency of form is another important factor. Gears which the writer has seen worn out in hard service, show very plainly the severe concentrated wear inside the pitch line indicated in Case 1 of Fig. 11. The advantageous effect of an increased pressure angle on permanency is worthy of consideration.

The fitness of a tooth form for various cutting processes is of importance in determining the future of the apparently attractive generating method of cutting gear teeth. One form of generating process has come into extensive use in spite of the handicap of the 14½-degrees angle, with the various corrections for interference required. There is reason to believe, however, that this process works better with forms of teeth in which the angle is increased or the addendum decreased. Were the change advisable for other reasons, this fitness for generation would be an added advantage, though it would scarcely be worth changing on this score alone. So far as cutting teeth by the formed cutter process is concerned, an increase in the pressure angle is favorable, as more side clearance is obtained for the cutter; while decreasing the addendum gives less volume to cut out, and a consequent cheaper production of gears. It might also be mentioned in this connection that the decrease in face or pitch that could be obtained by the use of stronger forms of teeth, would also result in cheapening the gear, owing to the fact that less metal would have to be removed.

Comparison of Typical Involute Tooth Systems.

It is proposed to give, in connection with this discussion of the effect of the variation of pressure angle and addendum, a comparison, by the diagrams herewith presented, of varous typical forms of gearing in relation to the practical points just discussed. For the purposes of this discussion the following forms are considered:

Case 1: $\alpha = 14\frac{1}{2}$ degrees, $S = 1.0$.
Case 2: $\alpha = 14\frac{1}{2}$ degrees, $S = 0.8$.
Case 3: $\alpha = 20$ degrees, $S = 1.0$.
Case 4: $\alpha = 20$ degrees, $S = 0.8$.
Case 5: $\alpha = 22\frac{1}{2}$ degrees, $S = 1.0$.
Case 6: $\alpha = 22\frac{1}{2}$ degrees, $S = 0.8$.

Case 1 has the standard pressure angle and addendum. Case 2 is practically the system employed by the C. W. Hunt Co.; 3 is the system used by William Sellers & Co.; and 4 is practically the "stub tooth" system. The last two will show the effect on the Sellers and "stub tooth" systems respectively, of increasing the pressure angle from 20 to 22½ degrees. The table, in which these various forms with their corresponding advantages and defects are tabulated, suggests that by a change in the present standard of gearing, marked advantages could be obtained on the following scores: avoidance of interference, giving a greater number of teeth in true involute action, and permitting more separation with continuous contact; increase of strength; increase of durability; increase in permanency of shape; and increase in fitness for generation and cutting by formed cutters. On the other hand, such changes mean an increase in side pressure, comparatively little change in efficiency, and an incalculable

[*] Mr. Lewis' Experiments, Kent's Pocketbook, page 899.

and unknown change in smoothness of action. Side pressure and efficiency (as has been shown) are of comparatively minor importance. Smoothness of action is of prime importance. The results of a change in this respect can only be arrived at by learning the experience of the users of the various forms of gearing.

It should be noted that the above comparison relates to pure involute action only. As the shape of the non-involute portion of the standard tooth is not public knowledge, it was impossible for the author to analyze its action. Could it have been analyzed, it would doubtless have shown better results for the standard form in Figs. 5 and 11, and not quite such good results in Figs. 9 and 10.

Whatever the condition relative to high speed work, however, it seems to the author that the preceding discussion points clearly to the wisdom of an alternative gear tooth standard of shorter addendum and increased pressure angle for such work as heavy mill gearing and slow speed gearing in general, in which smoothness of action is not a prime requirement. Increased strength and permanence of form would appeal particularly to engineers whose work permits them to design machinery by rational rather than by empirical methods.

Aside from the specific cases mentioned, correspondence and conversation with makers of cut gearing bears testimony to a growing demand for, and use of, a stronger form of tooth. The adoption of a standard for this work would give all the advantages which come from standardizing; the preparation of tables of dimensions and of strength; the devising of odontographic tables for the fillet at the root of the tooth, and for the correction—if any is needed; and the reduction in the stock of form tools necessary for doing a general line of gear cutting work.

In any event, a standard of gearing of known form, which can be laid out by any engineer who desires to employ it, would be an advantage, if such a consummation is possible without sacrificing any of the good qualities which we are accustomed to expect from the present standard.

ALCOHOL AS A FUEL FOR INTERNAL-COMBUSTION ENGINES.

Abstract of article by Thos. L. White in the *Engineering Magazine*, September, 1908.

It is the purpose of this article to consider the suitability of alcohol as a gasoline substitute, and as there are many types of engines, designed to fill widely varying needs, the subject is one which has many sides and may easily be made confusing or misleading unless the issue under discussion is very clearly defined. In considering the difficult matter of changing over from gasoline to alcohol, it is important to remember that the two fuels differ in a dozen essential particulars; that the current type of motor is a gasoline instrument evolved under gasoline conditions; and that the greatest variety of opinion exists as to how far the accepted rules of construction will have to be modified to suit the change. Moreover, there is the important economic fact to be considered that some millions of gasoline motors are at present in use, and that it is not only a sound but a necessary policy to try to maintain their constructional features as far as possible, changing nothing unless there is a distinct necessity for each change, or a distinct advantage resulting from it. That there are to be had special alcohol machines, which are excellent for certain purposes, is beside the real issue which is concerned with using alcohol in the high-speed, low-compression engine.

The evolution of engine types in the past has not been so much along the lines indicated by considerations of fuel economy as along the lines indicated by considerations of handiness, reliability, and flexibility. If alcohol possesses advantages of this character, when burned in the present type of gasoline motor, and if any operative disadvantages incidental to its use (such as difficulties of starting up) can be eliminated, and some increase of efficiency attained by recourse to less radical means than high compressions, then there will be no need to consign the present engine to the scrap-heap in order to be able to burn alcohol. It is the opinion held in this article that alcohol has several such advantages, and that its efficiency in the gasoline motor can be increased without virtual reconstruction. Incidentally, it is well to remember that in the matter of compression there is no golden mean. The gasoline engine compresses to 80 pounds at most, and till this is increased to over 130 pounds, the gain in thermal efficiency resulting is not worth the trouble of the alteration.

While it has always been the aim of designers to make the gasoline motor as flexible as the steam engine, the narrow range within which a charge of gasoline and air can vary in composition and yet remain explosive has always prevented any regulation of the power by the manipulation of the mixture. In the case of alcohol and air, however, the variation of the proportions compatible with perfect combustion is four times as great, and it has been determined by experiment that the specific power of the working stroke of an alcohol engine can be reduced to 25 per cent of maximum, by the operation of an auxiliary air throttle. In automobile practice this means that the adoption of alcohol would tend toward fewer cylinders and simpler gears. The actual limits within which alcohol and gasoline mixtures are respectively explosives are 4 per cent to 14 per cent, and 2 per cent to 5 per cent, tested at atmospheric temperatures and pressures.

The alcohol motor has been severely criticised because of the alleged difficulty in the matter of carburation, which is occasioned by the high latent heat in alcohol. It is difficult to see wherein the drawback from this cause exactly lies, and as far as one can tell the criticism seems to arise from the widespread notion that all preheating of the in-going charge is prejudicial to the efficiency of the motor. The fact is that preheating the mixture *after* the fuel is in a state of vapor is harmful in two ways: First, the whole body of the ingoing mixture being thereby expanded, the actual weight of mixture that enters the cylinder during the suction stroke is decreased, so that the specific power of the motor is lessened; second, the efficiency of the motor is reduced, for while there is no lessening of the negative work done during the compression stroke, the energy of the succeeding expansion stroke on which it is a *pro rata* tax is less, there being less fuel present. Preheating the mixture, however, or its constituents separately, within limits and before the fuel (in this case alcohol) has become converted into vapor, has no tendency whatever to rarefy the charge, and is consequently without effect, at any rate on that score, on either the specific power or the efficiency of the motor.

To the question of carburation is closely related the question of starting up from cold. The alcohol motor has been widely attacked in this connection and as widely defended, and the only satisfactory course seems to be to disregard all evidence of a merely general character. Even specific cases cannot be regarded as having much weight, unless the accompanying conditions were normal, for the pertinent issue is not whether a start can be made from cold under the most favorable conditions, but whether a start can be made under any conditions that are likely to occur in practice. The question also seems to be a separate one for each type of motor, technically because the character of the difficulty to be overcome varies with different constructions, practically because the matter is of more importance in the case of the automobile engine than in the case of the stationary engine. The high pressure German motors may be considered separately, as they constitute a class in themselves, being unsuited to burn gasoline. According to the principle adopted for vaporizing the fuel, they fall naturally, for the present purpose, into two divisions respectively, typified by the Durr motor, in which pre-heat is relied on, and the Deutz motor, in which the alcohol is sprayed into the ingoing air, vaporization being effected by the aid of the heat generated during the compression stroke. In neither case can a start be made from cold, for in the one the necessary pre-heat is wanting while in the other the compression by hand is too slow to volatilize the alcohol in the mixture.

In the case of the low-pressure or gasoline motor, it is impossible to make any accurate subdivision, the type varying all the way from the farm motor, with a rate of 100

R. P. M and a ratio of stroke to bore of 2 to 1, to the fastest automobile motor with a rate of 2,000 R. P. M. and a ratio of stroke to bore of 1 to 1. Carefully conducted experiments go to show that when the speed is moderate and a good expansion is provided for, the gasoline motor will start up from cold on alcohol under laboratory conditions, but there is little evidence to prove that any gasoline motor can be set in operation when the circumstances are unfavorable, as, for instance, in moderately cold weather. So far as the fast running type is particularly concerned, the problem is not so much to be able to start up at all times and under all conditions on alcohol, as to be able to run at all on this fuel with any show of efficiency; and there are many reasons for agreeing with the statement of the Fuels Committee of the Motor Union, that the solution lies in combining the alcohol with benzol or acetylene, not merely to facilitate starting up, which is regarded as an incidental gain, but to bring the alcohol nearer in character to gasoline, so that it can be used under the gasoline conditions by which the limitations of the ordinary motor are determined.

The principal difficulties experienced when alcohol is used in the high speed motor, arise from the fact that this fuel ignites slowly, compared with gasoline, and that when ignited the propagation of the flame throughout the mixture is not sufficiently rapid to suit a piston velocity of over 12 feet per second, and a piston travel which, at any rate in the case of the automobile motor, is strictly limited in range. The disadvantages, direct and indirect, which result from this sluggish ignition and tardy inflammation are several, and all important. Combustion, instead of being completed when the compression and temperature are greatest, is continuous during the entire expansion. From a thermodynamical standpoint this means that a portion of the heat units contained in the alcohol are not being liberated to the best advantage. It has been claimed for the alcohol motor that this phenomenon of delayed combustion is a positive advantage, giving a smooth, even thrust on the piston and a high mean pressure. That such an effect has been observed in alcohol motors is beyond doubt, but it must be attributed, not to the sustained inflammation, since it is most noticeable in very slow-running motors in which combustion is completed during the early portion of the expansion stroke, but to the presence of steam produced from the burning of the alcohol and from the water with which this fuel is always diluted. Provided that this steam (which is of course superheated almost up to the dissociation point) receives its heat content at the maximum temperature of the expansion, its presence and action is in every way an advantage, for it represents internal as against external cooling of the cylinder walls, and the retention of heat units in the working fluid, which would otherwise pass into the water jacket.

If, however, the superheat of the steam is regenerated as the expansion proceeds by the continued burning of the fuel, this regeneration is effected at the cost of the thermodynamic loss stated above, a loss which is avoided if the steam receives its whole energy at the beginning of the expansion. To the credit of delayed combustion must be laid not only the work losses due to a portion of the fuel being burned at a disadvantage, but also losses due to a portion of the fuel being only partially burned or not burned at all. The exhaust is found to be contaminated with products of combustion other than water and carbon dioxide, and ceases to be odorless and unobjectionable.

Once it is clear that the problem of substituting alcohol for gasoline as a fuel in the high speed motor, reduces itself to seeking a more vigorous ignition and a more speedy inflammation, and conceded that these desirable ends can be obtained by the addition to the alcohol of some compound which will generally accelerate its action in the motor, the natural suitability of acetylene as a corrective can hardly be overlooked. This gas, which has the same formula of composition as tar benzol, has the further property, which is shared by no other fuel, that it is an endothermic compound. In its formation heat is absorbed, and there resides in the acetylene molecule the power of spontaneously decomposing and liberating this heat, if it is subjected to a temperature or pressure beyond the capacity of its unstable nature to withstand.

If the liberation as heat of the reserve energy of acetylene (which, it should be noted, is an operation quite distinct from combustion, in that it can take place in the absence of oxygen) is effected when the acetylene is diffused through the body of an inflammable mixture, it is found that each detonating molecule of acetylene becomes a center of inflammation and the whole mass is burned with a speed and vigor that is only limited by the proportion of acetylene present. In the case of alcohol, the practical question is whether the conditions favorable to the spontaneous decomposition of acetylene are induced, when air carburated with alcohol and acetylene is compressed and ignited in the motor in the usual way; and the experimental answer is that they do. The rise of pressure set up in the mixture when the ignition takes place is accelerated by the detonation of the successive portions of acetylene as they are involved in the advancing pressure wave, and it is found that the ignition line in a pressure-volume diagram taken on a motor burning a mixture of alcohol and acetylene is even at 2,000 revolutions, as vertical as the corresponding line in a pressure-volume diagram taken on the same motor when it is burning gasoline.

All denatured alcohol contains a percentage of water, and it is a fact that alcohol containing from 10 to 15 per cent of water is in every respect a better fuel than pure alcohol. The action of the water is very obscure, and it has not been satisfactorily determined how far the percentage can be increased without the consequent lowering of the calorific value of the mixture more than offsetting the benefit in the motor. What is relevant here is that the advantages derived from the presence of comparatively large percentages have been principally experienced in connection with high compressions, and to get similar results in the low-compression high-speed motor, the damping effect of a large admixture of water calls especially for the accelerative action of acetylene on the inflammation and ignition.

In conclusion, if we consider that the automobile motor is an instrument in which power must be sought by high piston velocities, and that starting with Daimler's motor this condition has been accepted without question as the basic canon of construction of this class of engine, it seems almost inevitable that the use of alcohol, in the automobile field at any rate, will continue along the lines of carburating the alcohol.

* * *

It is not improbable that the United States government will soon authorize plans for the construction of a gas-engine battleship. The gas engine and gas producer plant has peculiar advantages for battleships. In the first place, there is the saving of fuel and space—in themselves very important. The chief features of the gas-engine battleship that command the attention of naval experts, however, are the absence of smoke and funnels. The funnels are a great source of danger in time of attack as it is impossible to armor them so as to insure non-penetration, and the smoke betrays the coming of a fleet long before the vessels themselves can be discerned. The strategic importance of avoiding funnels and smoke, therefore, can scarcely be overrated. It is probable that future battleship design will center around the use of gas engines and gas producers as the motive power.

* * *

A great deal of time is spent in the average machine and metal working shop in clearing away the chips which accumulate on drilling and other machines while at work. The application of the rotary pressure blower for blowing these chips away and keeping the work clear, is a recent innovation. By directing a jet of air from the blower directly onto the work a close observation may be kept by the workmen without the necessity of constantly wiping away the chips by hand or with a brush. Perhaps 10 per cent of the total working time on each job would be a low estimate for the operation of simply clearing the work of these chips. This being true, the small cost of a pressure blower pays for itself many times over in doing the work. Besides this, a certain amount of the air may be diverted to other uses at the same time.

NOVEL PUMP CONSTRUCTION FOR PRESSES.

W. M. FLEMING *

Many interesting problems are presented to manufacturers of power pumping machinery, in the adaptation of power pumps to replace the less economical but somewhat more flexible direct-acting steam pump. The Deane Steam Pump Co., Holyoke, Mass., recently supplied a special small triplex power pump equipment for use in connection with a hydraulic press system, which is a case in point. The triplex power pump installation replaces a direct-acting steam pump and materially reduces the cost of operation.

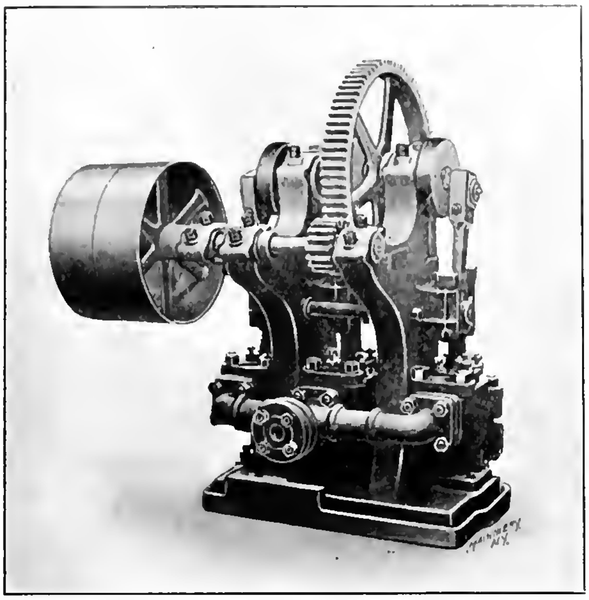

Fig. 1. Low-pressure Deane Single-acting Geared Pump.

The problem presented to the manufacturer in this case was to provide, for any one of three presses operating successively: first, a comparatively large quantity of water at low pressure for advancing the press ram until it met with considerable resistance, due to the load, and second, to supply a gradually diminishing supply of fluid at gradually increasing pressure, until the maximum desired load on the press platen has been obtained, at which point the discharge from the pump must cease automatically, but the pressure must be maintained on the press for a period of several hours.

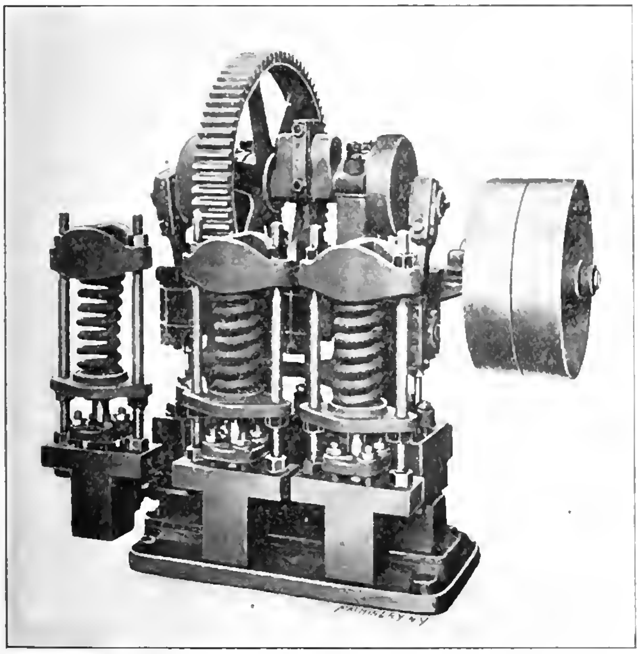

Fig. 2. High-pressure Deane Triplex Geared Pump with Spring Alleviators.

These peculiar conditions of service were taken care of by the installation of two pumps: a low-pressure and a high-pressure machine. The low-pressure pump is shown in Fig. 1, and as can be seen, is simply a power pump of the vertical triplex outside packed single-acting pattern, designed for a working pressure of 1,000 pounds. This machine is connected with a header from which water may be drawn through a check valve into any one of the three presses supplied. It is started manually and stopped by means of an automatic hydraulic belt shifter, when the pressure in the header or discharge from the pump rises to 1,000 pounds.

The special high-pressure pump shown in Fig. 2, and in section in Fig. 3, has the discharge from each individual cylinder piped to a press through a proper three-way operating valve, and operate continuously, discharging back to the suction when not to the press. This pump is novel in that it has a separate spring-controlled alleviator directly connected to the pulsation chamber of each cylinder. The alleviators are designed with a capacity equal to the capacity of the pump plunger and the springs of the alleviators are of such size that, when the pressure in the pump cylinder exceeds 1,000 pounds per square inch, the springs just begin to compress. When the pressure rises to 6,000 pounds per square inch, the springs compress to such an extent as to permit the alleviator cylinder to take the entire amount of water displaced by the pump plunger, and under these conditions no discharge from the pump occurs.

As previously stated, there are three presses supplied by the two pumps, the presses being worked consecutively. When the first press is made ready for operation both pumps are started manually. The low pressure operating valve is opened, advancing the press ram until the ram strikes the load, and the resistance increases so as to raise the pressure in the discharge line from the low pressure pump to 1,000 pounds per square inch. At this point this pump is automatically thrown out of action. A check valve in the line between the discharge header from the low pressure pump and press No. 1 closes, and the high-pressure pump, Fig. 2, continues to advance the plunger of the press until the maximum required pressure of 6,000 pounds per square inch is reached. As this pressure is approached, the alleviator goes into action and ultimately receives all of the fluid displaced by the pump plunger, returning the fluid to the pump cylinder on the suction stroke of the plunger, thus reducing the load on the pump to practically friction load. The second press is made ready meanwhile, and the low-pressure pump again started manually and the operation repeated on the second press.

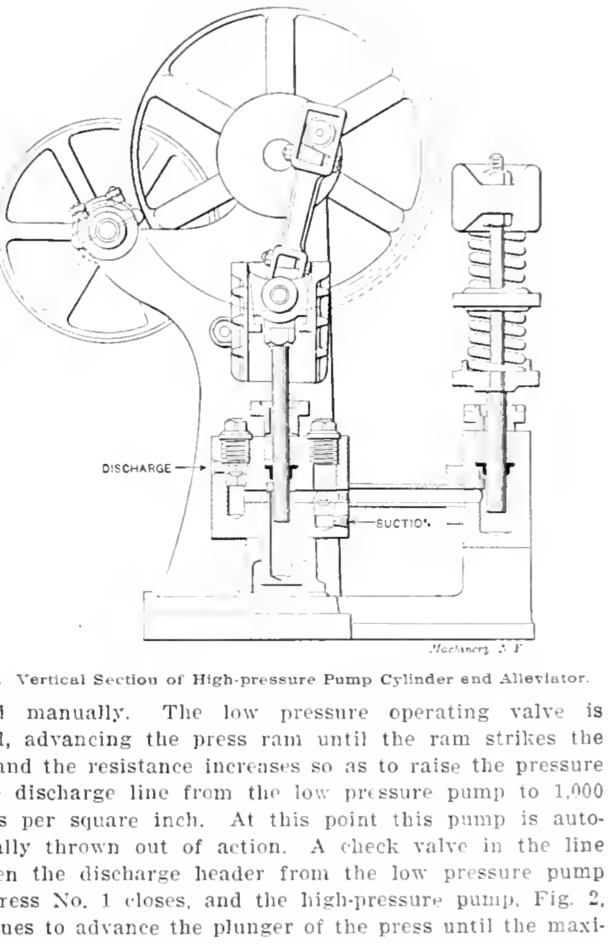

Fig. 3. Vertical Section of High-pressure Pump Cylinder and Alleviator.

From this description and from the drawing, it will appear that this outfit constitutes a very compact and mechanically efficient pumping plant for the service described. The saving of power by its use over the use of the direct-acting steam pump is appreciable, and the use of the low-pressure pump materially reduces the time of what may be termed, inactivity of the presses.

MACHINE FOR CUTTING OUT METAL SHEETS.

The machines illustrated in Figs. 1 and 2 are specially constructed for the purpose of cutting out metal sheets into any desired shape. With them, templets of all sorts, sweeping boards for foundries, and similar pieces can be blanked out with great rapidity. This type of machine is not intended for repetition work, as such work is done more suitably by means of special dies and punches; but it is essentially a machine to replace the hammer and chisel work which is often necessary when only one or two pieces of a similar shape are required.

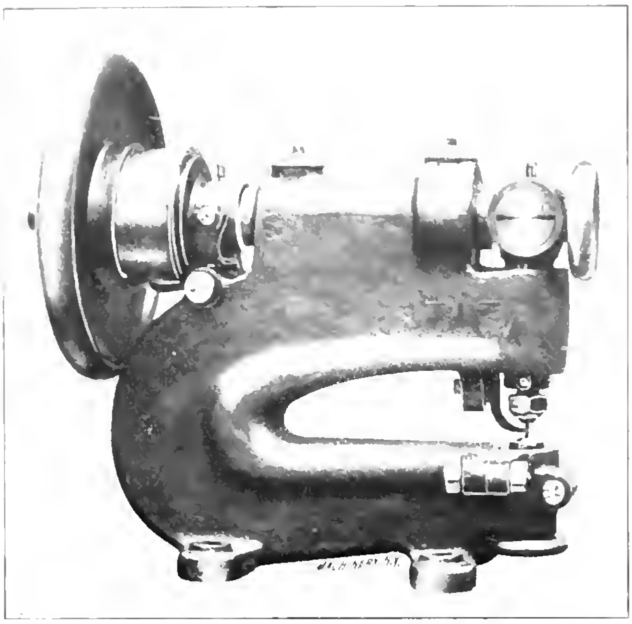

Fig. 1. Machine for Rapidly Blanking out Special Irregular Shapes in Sheet Metal. Size from Punch to Throat, 12 Inches.

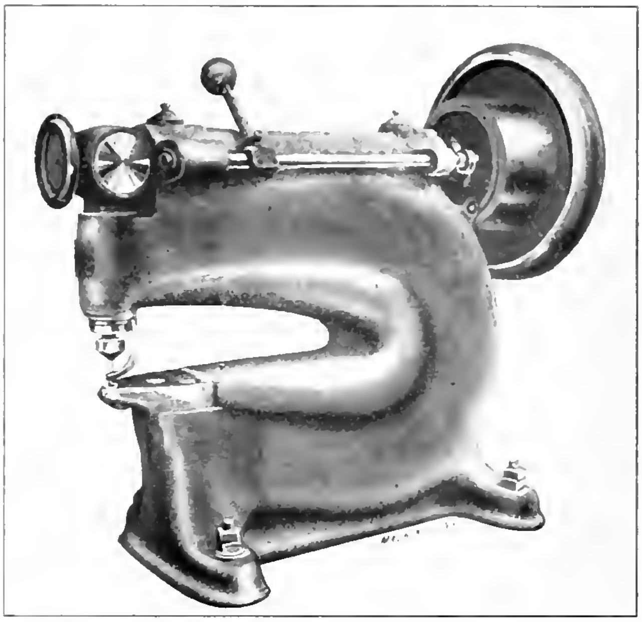

Fig. 2. View, from the Opposite Side, of a Larger Type of the Machine shown in Fig. 1. Size from Punch to Throat, 24 Inches.

Two sizes of these machines are illustrated. The one shown in Fig. 1 has a 12-inch gap, is suitable for plates up to 1/8 inch in thickness, and runs at comparatively high speed, making 300 revolutions per minnte. Fig. 2 illustrates a larger machine, having a gap of 24 inches, but it is also limited to plates having a thickness of 1/8 inch or less. The speed of the larger type is 250 revolutions per minute. These machines are provided with a round punch of a special shape, such as shown in the enlarged view at *A*, Fig. 3. The cutting edge of the tool is in front, and can be set in any direction to suit the work. The back of the punch is prolonged to act not only as a stay for the punch, but also as a guide for the sheet being cut. This extension, which works in the die held in the anvil just below the punch, is long enough to work up and down in this die throughout the stroke. The die can be raised or lowered by means of a screw, to enable the operator to pass a sheet of metal under the punch, so that he may begin to cut at some point in the middle of the plate.

When the machine is in operation, the sheet being cut is guided by the operator so that the punch removes the metal as close as possible to the desired outline previously scribed. The sheet is fed by being pressed lightly against the punch, which causes it to feed inward against the punch extension with each upward stroke. As the end of the punch extension is never above the die, it acts as a guide and greatly facilitates in feeding the work which moves in quite rapidly, owing to the high speed of the machine.

The stroke of the machine is slightly greater than the thickness of the piece to be cut, and the movement is obtained by a special eccentric motion which is illustrated in the sectional view, Fig. 3. As will be seen, an eccentric or off-set pin is journaled in a cylindrical piece which reciprocates horizontally as the ram moves vertically. This method of transmitting the motion from the shaft to the ram greatly simplifies the construction. In the engraving, Fig. 4, the shape of the chip taken at each stroke is illustrated by the dotted lines. In Fig. 5 some of the examples of the work done on this machine are shown. The locomotive connecting-rod templet seen in the upper part of the engraving, is approximately 0.118 inch thick, and was blanked cut in 12 minutes, while the moulder's strickle shown just below it, which is 0.078 inch thick, required but a single minute. Work of this kind can be done so easily that very little practice enables the operator to cut out forms so closely to the previously scribed lines, that a little filing will finish the work.

THE DIPLOMATIC DRAFTSMAN.

TIBBAB.

In the drafting-room of a certain shop manufacturing a number of articles requiring special automatic machines, I once witnessed a deception practiced by one of the draftsmen, that always ended in saving money for the shop, time in getting out the machine, repeated changes in design, and annoyance for the draftsman. This latter result may have been the ruling passion, yet the other things accomplished must not be forgotten. I have somewhere seen diplomacy defined as the art of getting something from the other fellow and at the same time making him believe that he has gotten something from you. If this is true, then the draftsman in question was a past-master as a diplomat. This game of diplomacy was played with the shop superintendent.

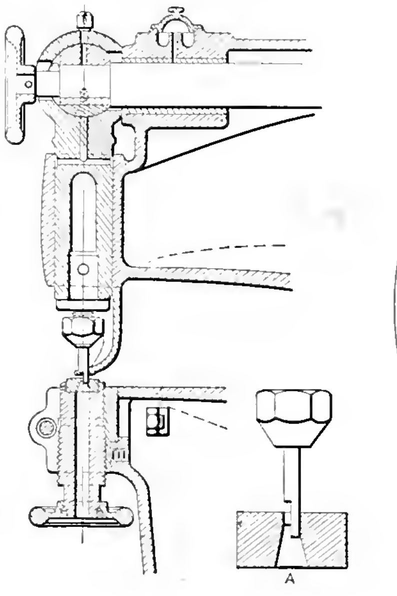

Fig. 3. Sectional View of Reciprocating Parts and Die-holder.

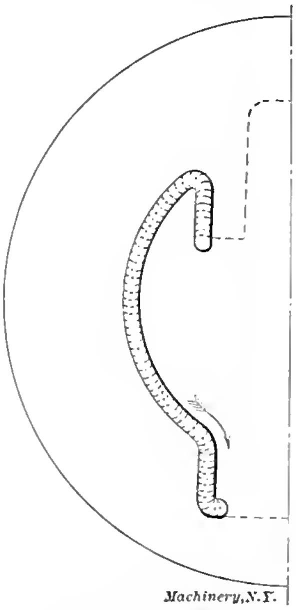

Machinery,N.Y.

Fig. 4. Half-view of a Templet, illustrating by the Dotted Lines the Successive Punchings.

Now the wise superintendent, if he has a machine of a given series to design, will give the draftsman the limits of the product to be turned out on that machine, possibly a few leading dimensions, and leave the rest to him. That

is, if he is a good draftsman—but a wise superintendent never has anything but a good draftsman. He may get the others a little cheaper, but they are expensive. The superintendent of the shop in question was a wise superintendent, for he did all of the above named things, but he was unwise inasmuch as he did not let it end there. He wanted to get into the detail of design too much. He wanted to see that a cam face was not ⅛ inch too wide when ¼ of an inch would have made no great difference. With this characteristic fully developed, it was his habit each morning during the hour devoted to the drafting-room, to change the diameter of a shaft ¼ inch, the width of a slide ½ inch, the diameter of a cam roller or its stud by some small amount until, by making a few changes small and inconspicuous in themselves, he had mapped out enough changes, erasures, moving of parts, etc., necessary to accommodate these minor changes, to keep the draftsman busy about all day. He also had a habit of impressing the draftsman with the fact that the changes must be made, and the changes were made. During the next week, however, things that had appeared too light, might, when changed, seem too heavy, thus necessitating another alteration.

Do you wonder that it was discouraging for the ambitious man to work there? Do you believe me when I say that the drafting force was continually changing and that it was hard to keep a good man?

There were in the drawing-room only a draftsman, tracer and blue-print boy—the latter two embodied in one person who seemed to be a fixture. The draftsman was, however, a transient: First, because the superintendent knew a good man when he saw him work and unless he was good would soon get rid of him; and, second, because the good men would not or could not stand the dictation of the superintendent and would leave. At last, along came a man, "the best man who ever pushed a pencil over a piece of paper," according to the statement of the superintendent. Not only was this man a good draftsman, but he was also a good reader of character. He seemed to size up the superintendent immediately, and, at the same time, seemed to know just how to handle the situation. I have seen him repeatedly lead the superintendent over the parts that he had been accustomed to change, to some minor part, usually something that would not affect the parts already designed, and discuss this with an energy that would make one believe that it was the only vital part of the machine. Over and over again would the two men study this part until the time came for the superintendent to go, or until he was called away. He usually went away with the remark that he would take that up the next time; and, under the artful guidance of the draftsman, he usually did. Thus did the draftsman guide the superintendent from part to part in such a way that the changes made did not affect the previous design. The draftsman was happy, more work went through the drawing-room, there was a more systematic progression in the designs, there were no changes in the drawing force, and there was a superintendent who was better satisfied, less anxious, and had a lighter burden to bear. I know the superintendent was better satisfied, for his visits to the drawing-room were less frequent, and I have once or twice heard him remark, "If there is anything you want to talk over with me on this design call me in, otherwise go ahead."

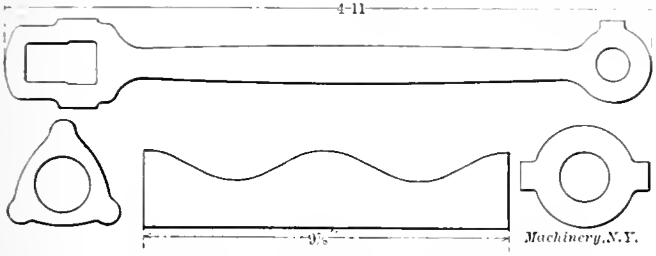

Fig. 5. Examples of the Work for which the Machine is Adapted.

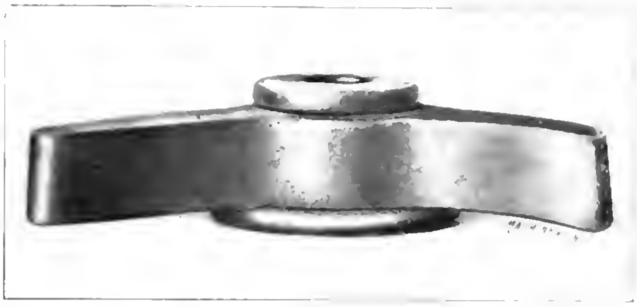
This confidence in the man was not due to his great ability as compared with those preceding him, but can be attributed only to the fact that the draftsman had educated the superintendent to the fact that minor changes are not necessary in machine design. The draftsman, too, was wise enough to call in the superintendent and discuss at length any of the essentials with which he was not familiar. At no time during the period in which the man was a draftsman, and up to the time he was made assistant superintendent, did he appear conceited or in any way pretend to know more than the superintendent. I believe this to be one of the greatest helps.

I want to be just to the superintendent and speak of his good qualities as I have of his weaknesses. He was a wonderful man as a shop superintendent, leaving the details of the several departments to his foremen, having the confidence and esteem of the workmen, and at the same time making dividends for the company every day. Had the drawing department been a large one with a chief and a number of men, I believe his attitude would have been the same as toward all other branches of the factory and that he would have left all details to the man in charge. He had but to learn that the small department could be handled in the same way.

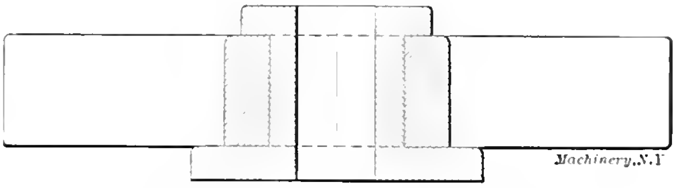


A Casting Puzzle—The Bushing with Flanges is One Piece and is a Loose Fit in the Pawl.

* * *

CASTING PUZZLE.

The accompanying half-tone illustration and line engraving illustrate a difficult piece of casting made by the Taylor & Fenn Co., Hartford, Conn. The casting is a brake ratchet pawl with bushing, used on street railway cars. Both the bushing and the ratchet are solid castings. It will be a puzzle, we expect, to most mechanics to figure out how this work is accomplished. The clearance between the two castings is only a few thousandths inch.



Cross-section of Brake Ratchet Pawl and Bushing.

* * *

An ingenious and simple method of cutting master plate cams to accurate lead, is used in the shops of the Windsor Machine Co., Windsor, Vermont. Suppose, for instance, it is desired to cut a plate or disk cam having a portion of its periphery formed with a uniform rise, at the rate of 1.360 inch to a revolution of the cam. The blank is mounted on a work arbor in the usual way, and a plain cylindrical cutter of sufficient length is clamped in place on the spindle. The indexing is set for a number of spaces obtained, for instance, by dividing the lead per revolution by 0.005. This gives $1.360 \div 0.005 = 272$. The blank is adjusted at the proper height for the cutter to machine the top of the desired rise. The dogs are set as when cutting gear teeth, and the slide runs back automatically, the work indexes and the cutter feeds forward again. During the indexing the work head is fed downward by hand 0.005, the number of thousandths agreeing with the number used for dividing the lead to get the indexing. This combination of the automatic feeding and indexing of the machine, and the feeding of the head down 0.005 inch at each indexing, is continued until the required cam outline has been completed. The working edge is then carefully dressed off with a file, after which the master cam is ready for use.

MACHINE SHOP PRACTICE.*

GASHING AND HOBBING A WORM-WHEEL.

In the construction of worm gearing, the distance from the center of the worm to the center of the worm-wheel may be fixed, or, in some cases, variations, within reasonable limits, may be permitted. When the center distance is fixed, which will be the condition governing the work under consideration, the mechanic may have the opportunity of testing the accuracy of his work by assembling the finished gear in its place, which is, of course, desirable. We shall assume, however, that in this case, such opportunity is not afforded.

The worm itself should first be accurately finished as it can be used advantageously in testing the center distance when hobbing the worm-wheel. We shall assume that this has been done, and that the wheel blank has also been turned, and will consider the method of hobbing the teeth in the latter in a universal milling machine. It is first necessary to gash the blank. This operation consists of cutting teeth, which are approximately the shape of the finished teeth, around the periphery of the blank, by the use, preferably, of an involute gear cutter of a number and pitch corresponding to the number and pitch of the teeth in the wheel. If a gear cutter is not available, a plain milling cutter, the thickness of which should not exceed three-tenths of the circular pitch, may be used. The corners of the teeth of the cutter should be rounded, as otherwise the fillets of the finished teeth will be partly removed. After the gashing operation, the teeth are finished to conform to the shape of the worm by revolving the blank and a cutter known as a hob, together, sinking the latter into the blank until the teeth are cut to the required depth. As the worm which meshes with and drives the worm-wheel, is simply a short screw, it will be apparent that if the axes of the worm-wheel and worm are to be at right angles to each other, the teeth of the wheel must be cut at an angle to its axis in order to mesh with the threads of the worm. The method of setting the work and obtaining this angle will first be considered.

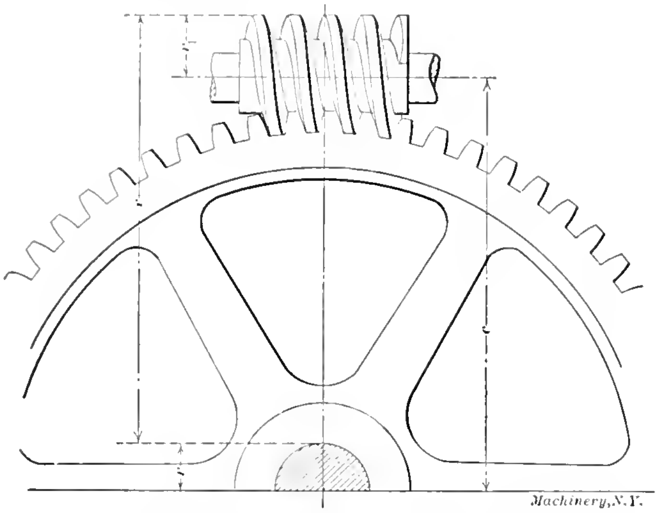


Fig. 1. Determining Center Distance between Worm and Wheel.

After the dividing head and tail-stock have been clamped to the table and the cutter has been fastened on its arbor, the table is adjusted until the point of the center of the dividing head and the center of the cutter lie in the same vertical plane. (See Shop Operation Sheet No. 1.) If the cutter used has a center line around its periphery, the table may be set by raising it high enough to permit the index head center to come in contact with the cutter; the table can then be adjusted laterally until the center coincides with the center line on the cutter. When the table is set, it should be clamped to the knee slide. The blank to be gashed is now pressed on a true-running arbor which is mounted between the centers of the dividing head and tail-stock as illustrated on Shop Operation Sheet No. 86, and the driving dog is secured, to prevent any vibration of the work. The table is now moved longitudinally until a point midway between the sides of the blank is directly beneath the center of the cutter arbor. To set the blank, place a square blade against it on first one side and then the other and adjust the table until the distances between the blade and arbor, on each side, are equal. Of course, if the diameter of the arbor were greater than the width of the blank, the measurements would be taken between the latter and the square blade. The table should now be set to the proper angle for gashing the teeth. This angle, which should be given on the drawing, may be determined either graphically or by calculation. The first method is illustrated in Fig. 2. Some smooth surface should be selected, having a straight edge as at *A*. A line *B*, equal in length to the lead of the worm thread, is drawn at right angles to the edge *A*, and a distance *C* laid off equal to the circumference of the pitch circle of the worm. If the diameter of the pitch circle is not given on the drawing, it may be found by subtracting twice the addendum of the teeth from the outside diameter of the worm. The addendum equals the linear pitch × 0.3183. The angle *a* is then accurately measured with a protractor, as shown in the illustration. The table of the machine is then swiveled to a corresponding angle which can be measured by the graduations provided on all universal milling machines. If the front of the table is represented by the edge *A*, and the worm has a right-hand thread, the table will be swiveled as indicated by the line *ab*; if the worm has a left-hand thread the table will be turned in an opposite direction. The angle that the teeth of the worm-wheel make with its axis, or the angle to which the table is to be swiveled, may also be found by dividing the lead of the worm thread by the circumference of the pitch circle; the quotient will equal the tangent of the desired angle. This angle is then easily found by referring to a table of natural tangents.

When the table is set and clamped in place, as many gashes are cut in the periphery of the wheel as there are to be teeth. If the diameter of the cutter is no larger than the diameter of the hob to be used, the depth of the gashes should be slightly less than the whole depth of the tooth. This whole depth may be found by multiplying the linear pitch by 0.6866. Before starting a cut, bring the cutter into contact with the wheel blank, set the dial on the elevating screw at zero, and sink the cutter to the proper depth as indicated by the dial. When the cutter is larger than the hob, the whole depth of tooth should be laid out on the beveled side of the blank, and a gash cut in to this line. The depth as indicated on the dial should then be noted and all the gashes cut to a corresponding depth.

When the gashing is finished, the table is set at right angles with the spindle of the machine, and the cutter is replaced with a hob which is practically a milling cutter shaped like the worm with which the wheel is to mesh. The outside diameter of the hob and the diameter at the bottom of the teeth, are slightly greater than the corresponding dimensions of the worm in order that there may be clearance between the latter and the worm-wheel. Before hobbing, the dog is removed from the arbor. The hob is then placed in mesh with the gashed blank, and, as the two rotate together, the blank is gradually raised until the body of the hob between the teeth just grazes the throat of the blank. After the work has made a few revolutions, to insure well-formed teeth, the hob and wheel are disengaged, and the finished worm is placed in mesh with the latter, as shown in Fig. 1, after the chips have been thoroughly removed from the teeth on which the worm bears. The worm is now turned along the periphery of the wheel until its axis is parallel with the

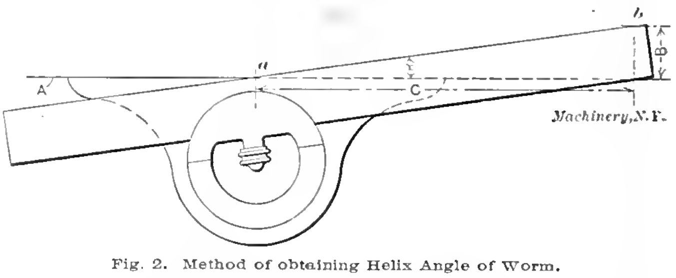

Fig. 2. Method of obtaining Helix Angle of Worm.

---

* With Shop Operation Sheet Supplement.

top of the table. It may be set in this position by testing the top surfaces of the threads at either end with a surface gage. Set the pointer of the gage so that it just touches the top of a thread and measure the distance x from the pointer to the arbor. Subtract from this dimension the difference between the radii r and r_1 of the arbor and worm, and the result will be the center distance C. If the worm is accurately made and the worm-wheel blank turned to the exact dimensions, this center distance should be very close to the distance required. If necessary, the hob may be again engaged with the wheel and another light cut taken. When testing the center distance, as explained in the foregoing, it is better to lower the knee sufficiently to make room for the worm beneath the hob, and not disturb the longitudinal setting of the table, as the relation between the wheel and hob will then be maintained, which is desirable in case it is necessary to re-hob the wheel to reduce the center distance.

When worm-wheels are made in large quantities, they are cut in machines especially designed for this purpose, in which the wheel blanks, instead of being mounted on a free-running arbor, are driven by gearing at the proper speed. This makes gashing the blank previous to hobbing unnecessary, as the change gears insure a correct spacing of the worm-wheel teeth.

BENDING STRESSES IN CAR TRUCK ARCH BARS.

W. E. JOHNSTON.*

The stresses occurring in bent and offset rods and bars appear to be underestimated rather frequently. A particular instance of this is met with in the design of the bottom arch bar shown in Fig. 1. Several of these gave indications of weakness in service with loads as indicated. The material in the bars was the usual grade of arch bar iron.

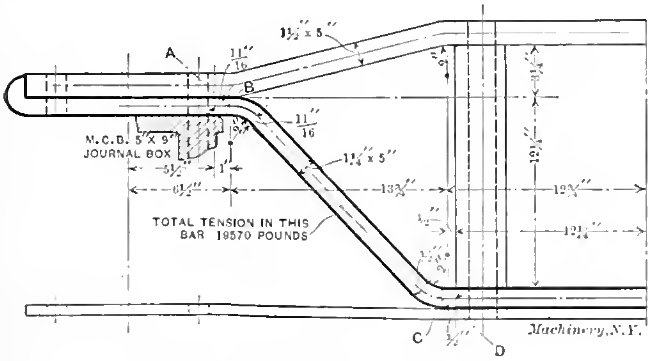

Fig. 1. Data of Railway Car Truck Arch Bar.

In calculating the stresses in this bar, the first step is to locate a center line so as to determine the amount of the offset, which is the lever arm on which the tension in the bar acts to produce bending moments and resultant stresses in addition to those due to direct tension. It is apparent that when the load comes on the bar, it will bend down over the edge of the journal box, and up around the edge of the column, and the two bends will straighten out slightly, as shown exaggerated for clearness in Fig. 2, which indicates the character of the stresses set up by these deflections. Assuming that the journal box bolts and column bolts are tight, so that the arch bar is held firmly to the journal box and columns, without deflection between the bolts, the portions of the bar extending out beyond the edge of the journal box at the top and the column at the bottom will act as beams, rigidly fastened at one end and loaded at the other, carrying the load out toward the adjacent bends to the points where the bending moment reverses. The bending moment reverses midway between the bends also. A line AD, Fig. 2, drawn through points B and C on the lines of reversal, will be the center line of the pull on the bar, and the length of a perpendicular to this line from any point on the center line of the bar itself, between the bearing on the journal box and columns, multiplied by the pull, will be the bending moment acting on the bar at that point.

Since the section of the bar is uniform, it will be sufficiently accurate for practical purposes to draw the line AD Fig. 1, so that the perpendiculars on it from the center line of the bar at the edges of the bearings on the journal box and columns, will be equal to the longest ones that can be drawn from the center line at the adjacent bends. In this case, these perpendiculars are 11/16 and ½ inch respectively, as shown in Fig. 1, and will be the lever arms on which the force P will act to produce bending moments. The total pull P is about 19,570 pounds. The area of the bar is 5 × 1¼ inch = 6¼ square inches. The stress, due to direct tension, is then $\frac{19{,}570}{6.25} = 3{,}130$ pounds per square inch. The greatest offset is 11/16 inch. The section modulus S of the bar for bending vertically is $\frac{bd^2}{6} = \frac{5 \times (1\frac{1}{4})^2}{6} = 1.302$. Consequently, the fiber stress on the inside of the bend below B is $f = \frac{Pl}{S} = \frac{19{,}570 \times 11/16}{1.302} = 10{,}333$ pounds, due to bending. The total tensile stress on the inside of the bend is evidently the sum of the stresses due to straight tension and to bending, or $3{,}130 + 10{,}333 = 13{,}463$ pounds per square inch, or about 4 1/3 times that due to the direct pull alone. As a matter of fact, the journal box and column bolts are seldom tight, and the consequent deflection in the bar above the journal box and below the columns will increase the offsets at the bends slightly, and the maximum stresses due to bending are actually a little greater than calculated above. However, since the upper arch bar and the tie bar are in more or less intimate contact with the bottom arch bar, and assist to some extent in keeping it straight, the difference is probably very small.

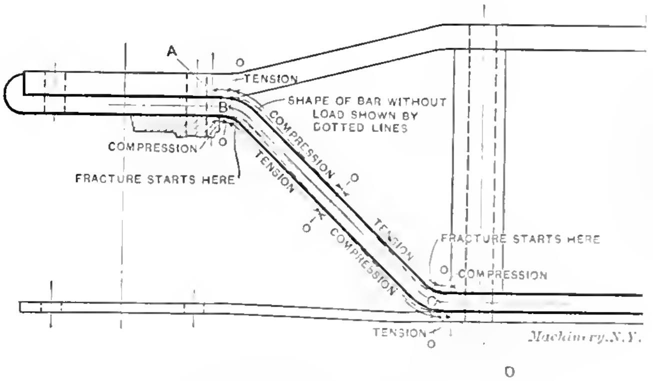

Fig. 2. Illustrating Character of Stresses in Arch Bar.

Examination of some of the broken arch bars confirmed the opinion that the breakage was due to excessive tensile stresses on the inner sides of the bends, as the fracture always started on the inner side at or near the point of greatest offset, some occurring at the top and some at the bottom. It seems, therefore, that large radius bends in arch bars are an element of weakness rather than of strength, unless they are made to fit the journal boxes and columns reasonably closely. By curving the edge of the bearing on the columns and making the radii of the bends in the arch bar a little greater than those on the journal boxes and columns, but with the centers on the same vertical line, probably the best possible results will be secured, the difference in the radii being made just sufficient to cover the unavoidable inequalities in the forgings and castings.

* * *

During the past few years the coinage of penny and half-penny pieces in England has been extraordinarily heavy, and the cause has been ascribed to the introduction of the "penny-in-the-slot" machines placed in the railway stations and public places. Last year an officer of the British mint estimated that not less than £250,000 ($1,250,000) is permanently locked up in these machines and withdrawn from circulation. A single company, it is stated, in twelve months, took no less than 33,984,671 pennies out of their machines.

NEW DEVELOPMENT IN STEEL CASTINGS.

Every mechanical engineer is familiar with steel castings, and probably every one has often employed them and wished that he could be justified in a much wider use; but difficulties of quick supply, of uncertainty of sound castings, of all too frequent hard spots, of rough surfaces, of washed cores, of obliterated finer details, of inability to get thin sections, of drawing and weakness at rib joints, have each or all compelled a resort to much heavier gray iron castings or to expensive bronze castings, or to even more expensive forgings.

When the engineer is told that he can get castings in steel within twenty-four hours, with no hard spots, with a surface as good as gray iron, with absolutely sound material one thin machining cut below that surface, without blowholes or coldshuts; that he can give himself a free hand in design even to the extent of committing the hitherto unpardonable sin of running a quarter-inch or even thinner rib into a two-inch or heavier section and with a fillet of a quarter-inch radius, and do that without fear of drawing or weakness in the corner—that engineer will shake his head incredulously.

When the engineer is further told that he can get all of this and practically make his own suggestions as to elastic and ultimate limit, elongation and contraction per cent, and can specify carbon, tungsten, nickel, manganese, vanadium and other alloys exactly as he would for bar stock or forgings—then that engineer may be pardoned if he considers that his informant is either trying to fool him or has himself been fooled. But such castings are here, and are shown in the accompanying illustrations.

The collection of steel castings shown in Fig. 1 is fairly comprehensive; at the bottom there are cranks, crosshead, propeller, auto truck axles, gasoline engine crankshaft, truck-wheel and worm gear. On the shelves above, a heterogeneous collection of sections of light walls, complicated corework, light ribs with almost feather edges and all with sharp details, present themselves. Modestly showing itself is a gear cutter, near the left-hand of the lower shelf, that is cast from high carbon steel, finished and hardened just as though it had passed through the blacksmith's hands instead of the molder's flask; better still, nothing in its behavior will ever let the user suspect its unorthodox origin. Near it is a hollow casting, with thin, circular heat radiating ribs; work of this character is considered creditable to the gray iron founder when as clean and sharp as this, but was not heretofore considered as even a possibility for the steel founder. On the next shelf at the extreme right the peculiar double crescent terminating in the cross-cored hollow stem involves walls of only one-eighth inch thickness; yet perfectly clean, sound, uniform material and as clean core surfaces as are ever found in gray iron are its characteristics.

Further along the clean work of the cast bevel pinions compels the admiration of those who know. That holds also for the tortuous snakelike exhaust manifold with its very thin cooling ribs to be seen on the same shelf at the left.

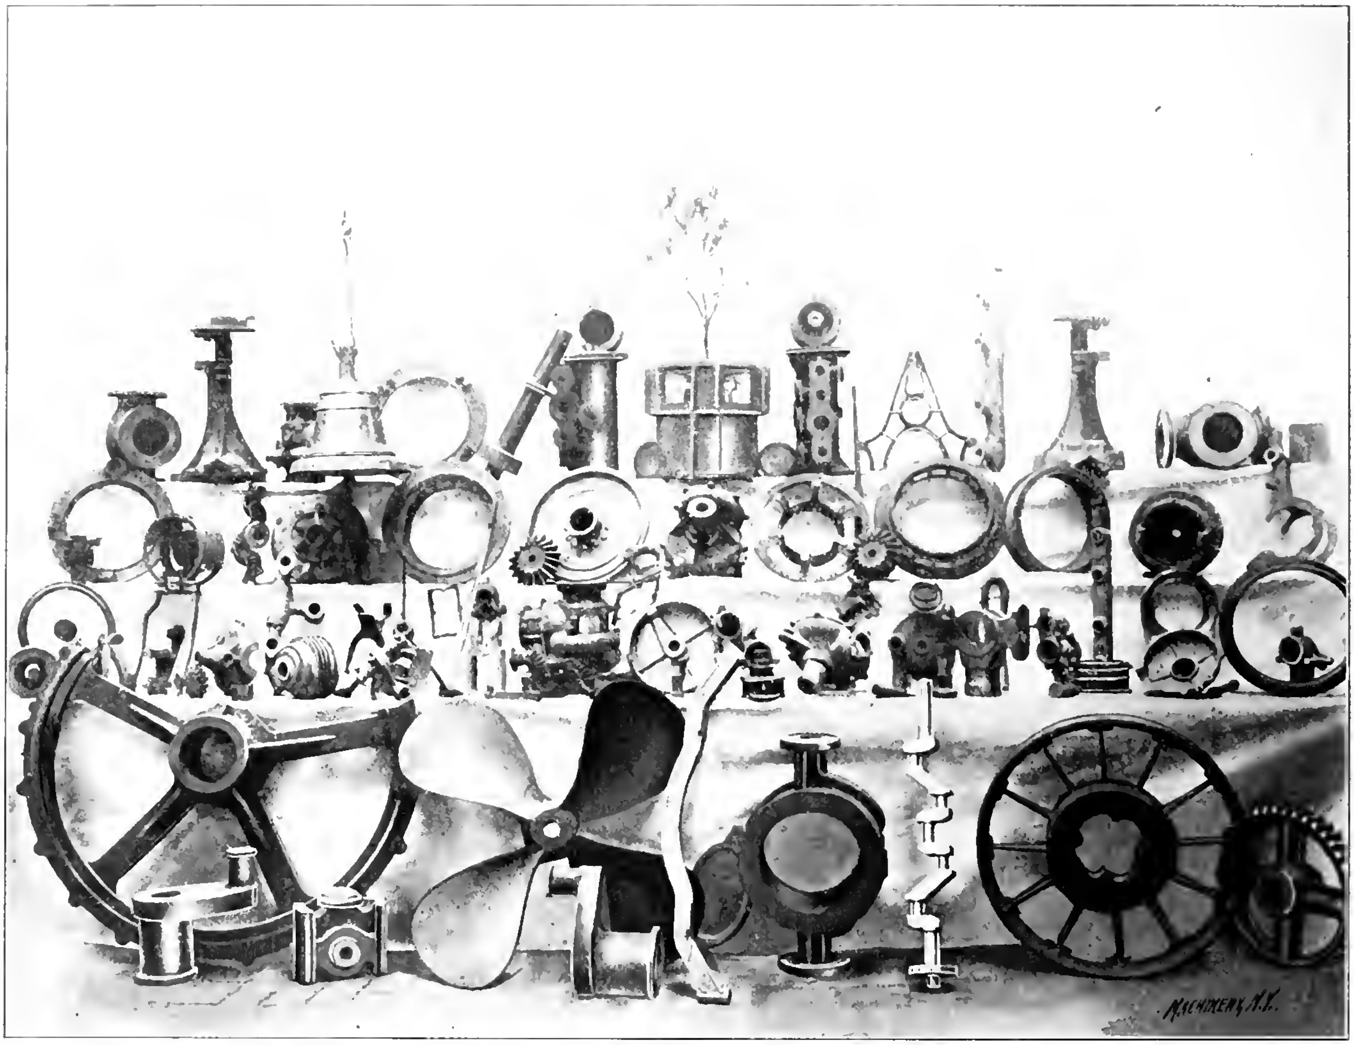

Fig. 1. Group of Steel Castings made by German process, illustrating Great Variety of Applications.

Passing by the ship's bell and other objects on the top shelf with a mere glance, the eye is held by the spray of oak leaves. The material would have made glad the heart of Tubal Cain, for the leaves are forged and shaped cold from cast test bars of soft steel, practically wrought iron, and the stems welded.

The wheel at the bottom right should have received more than mere passing mention; doubtless the designer had his own reasons for the extraordinary combination of light spokes and heavy rim; the maker of these castings has no fault to find, for being afforded this opportunity to show that light spokes joined to heavy hubs or rims, are all easy to him and that he could, as a matter of every-day work, surmount difficulties that are alike beyond the gray iron founder as beyond the steel founder not possessed of the new knowledge.

In Figure 2 the larger central piece is a valve used by the German Navy to withstand pressures of 2,250 pounds per square inch. The faces of the flanges all have a light cut

taken off in accordance with the specification. Most remarkable is the spidery support of the central stem guide hub. A critical examination of the line section of Fig. 3 of this casting disclosing its complicated coring and thin, quarter-inch, walls abruptly joining the three-quarter-inch heavy flanges, first creates distrust of the possibility of the production of this thing in steel, then surprise and admiration as the photograph and actual casting are viewed. Originally this piece was made of a light grade manganese bronze; even then a large percentage failed to pass the inspection pressure test. In this much cheaper steel casting wastes are altogether negligible.

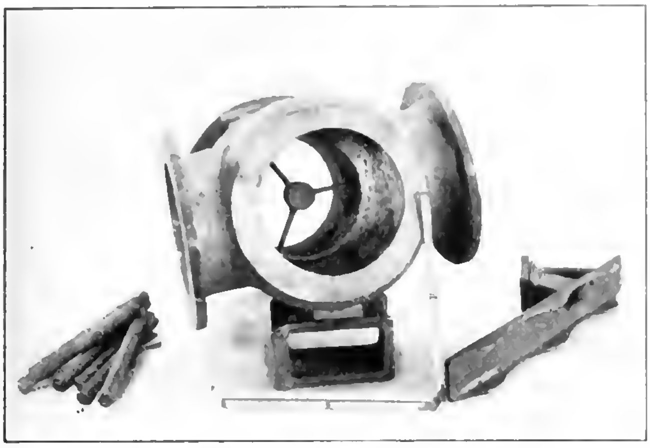

Fig. 2. Thin Steel Casting Valve Body for German Navy, carrying 2250 pounds Pressure.

Referring again to Fig. 2, the casting supporting the valve is a German railway truck detail. The piece to the right is not a carpenter's plane, but a portable yardsman's brakeshoe as used in German freight yards; it must be and is very light; the edges thin down to one-eighth inch. At the left is a bundle of cast test bars.

The group of Fig. 4 will interest the automobile engineer more particularly. The bevel gear housing, the steering gear details, the crank-shaft and the exhaust manifold all show clearly the clean-cut quality of the surfaces, the sharp definition of detail, the quality that makes a cast crank-shaft feasible, the remarkable coring and thin walls, that are all characteristic of this virtually new art of steel founding.

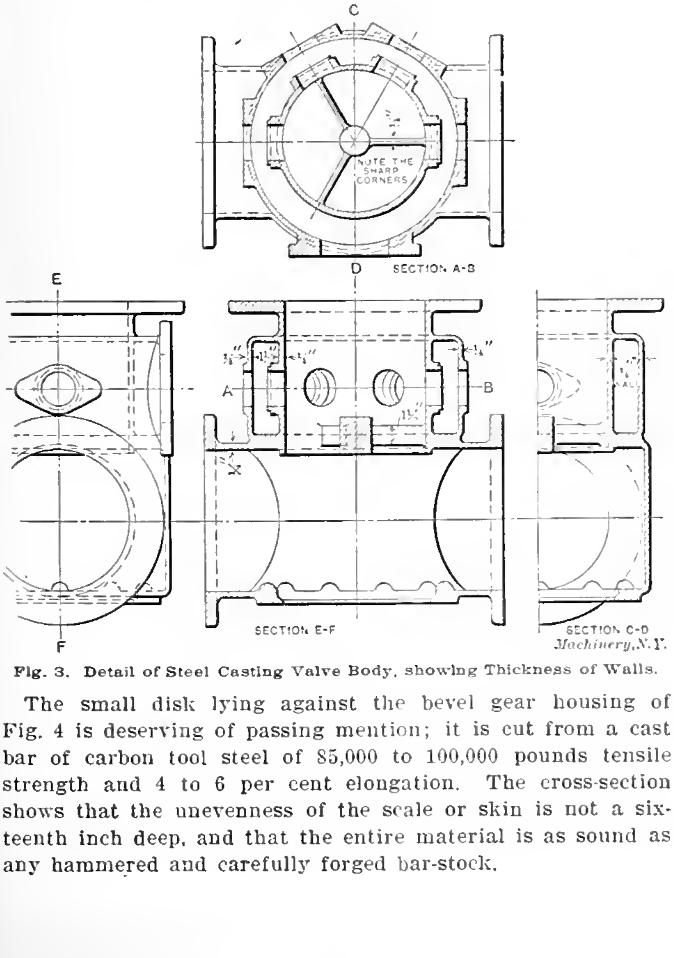

Fig. 3. Detail of Steel Casting Valve Body, showing Thickness of Walls.

The small disk lying against the bevel gear housing of Fig. 4 is deserving of passing mention; it is cut from a cast bar of carbon tool steel of 85,000 to 100,000 pounds tensile strength and 4 to 6 per cent elongation. The cross-section shows that the unevenness of the scale or skin is not a sixteenth inch deep, and that the entire material is as sound as any hammered and carefully forged bar-stock.

The majority of the castings shown in Figs. 2 and 4 are a standard composition known as extra ductile weldable; that has 25,000 to 27,000 pounds elastic limit, 49,000 to 53,000 pounds ultimate strength, 26 to 27.5 per cent elongation and 41 to 42 per cent reduction of area; these are qualities characteristic of only the best Swedish iron forgings. The next standard melt gives about 70,000 pounds ultimate strength, and after that about 100,000 pounds is frequently supplied.

Other special physical characteristics or desirable alloys are furnished as required. The minimum quantity must be one crucible charge of 200 pounds. The only limitation is that the specification must be one that is procurable in rolled or hammered bar-stock. Cutters in self-hardening or high-speed steel of simple or complicated shapes are a regular output. The usual heat treatments, as oil tempering, hardening, etc., that are employed with forgings and bar stock are applied to these steel castings also whenever they are of the corresponding composition.

As to the process itself, that is founded on the well-known crucible type. The novelty resides in the addition to the crucible charge compounded in accord with the specified analysis, of a "bomb" or "pill" that imparts the fluidity, smooth flowing and gas free qualities that make possible the avoidance of the various ills of the ordinary process. That suitable melting arrangements, molding methods, sand composition, facings and many other apparently minor matters go to the attainment of the final result, is evident enough to all familiar with the older processes. Further details that would interest the practical founder are not yet ready for publication.

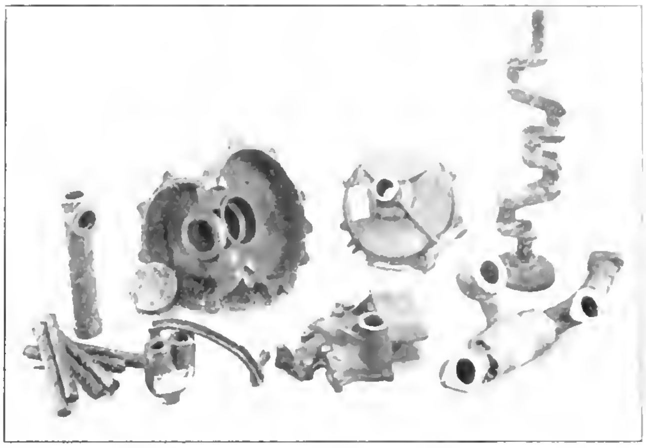

Fig. 4. Automobile Parts made in Steel by German Casting Process.

The process was originated in Germany where it has been worked near Berlin for four years on a fairly large scale. The various large electrical companies use certain grades for their field magnets because of the remarkable permeability and great density and freedom from blow-holes of the soft grades; Lahmeyer, f. i., uses certain mixtures for high speed turbine work. The locomotive builders are permitted to use these castings where the government that owns all the railways in Germany excludes all other steel castings. Automobile builders consume considerable quantities. Governmental as well as private naval establishments are heavy consumers. The general machine industries take up considerable in gear blanks, with cast as well as blocked-out teeth. Strange to say, even grate bars that are usually made of the very cheapest of cast iron, are an increasing product; this is because the very soft grade possesses a very high resistance to heat, does not warp or burn, and has a life so much in excess of the cast iron as to justify the higher first cost.

Mr. Henry Hess, president of the Hess-Bright Mfg. Co. of Philadelphia, Pa., has acquired the process for North America, and is preparing to establish the industry here. Castings will be imported during the interim until the American plant is at work.

* * *

The total length of street and interurban lines in the United States operated by electricity is now more than 38,000 miles. There are still 776 miles of street railway operated by cables, steam, or horses.

LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

IRONWORK ORNAMENTATION OF A MECHANIC'S HOME.

The accompanying half-tone illustrations show a city door yard in Greater Pittsburg, which is the result of the labors of a mechanic during Saturday afternoons and holidays for a period of two years. A helper was employed occasionally. The novelty of the work is that the greater part of the ornamental ironwork shown is waste from a machine shop and scrap from a scrap iron yard, even the fence being procured in a scrap yard, minus posts, hinges, scrolls, and other ornaments. The house is on the corner of two streets.

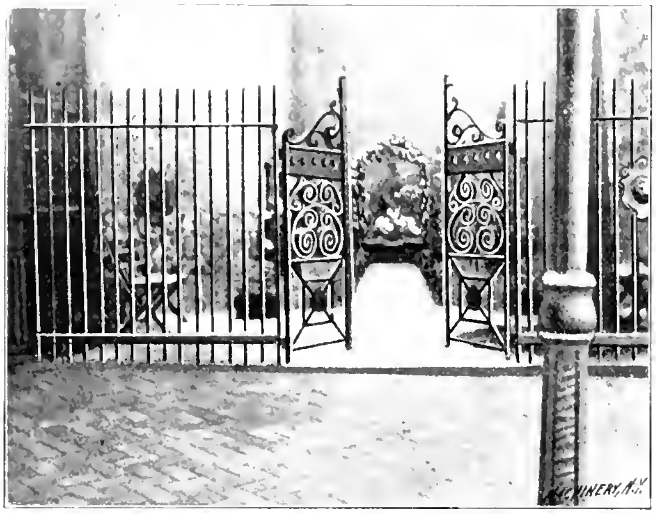

Fig. 1. Front View of Yard with Ornamental Fence and Gates.

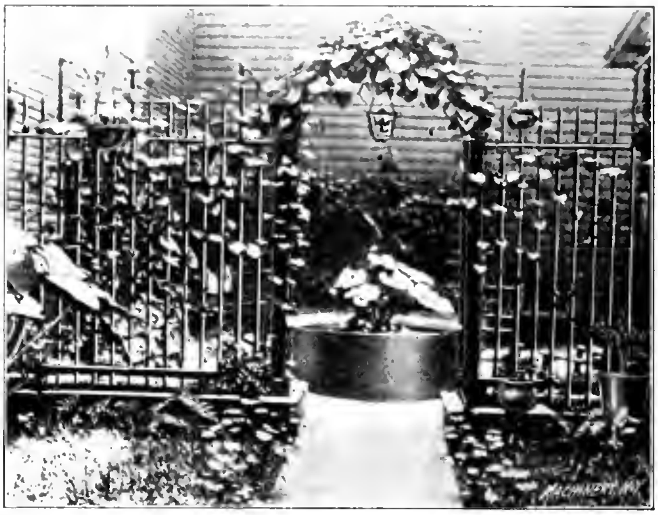

Fig. 2. Interior View of Yard showing Fish-Pond in Center.

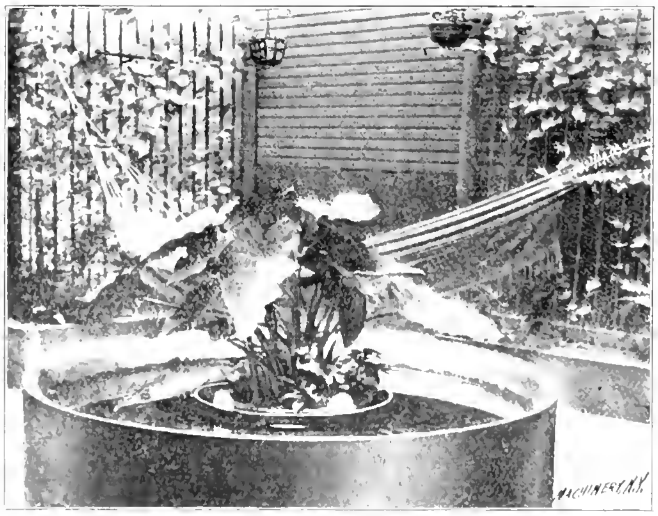

Fig. 3. Portion of Yard, with Fish Pond made from Cast Iron Pulley lined with Concrete.

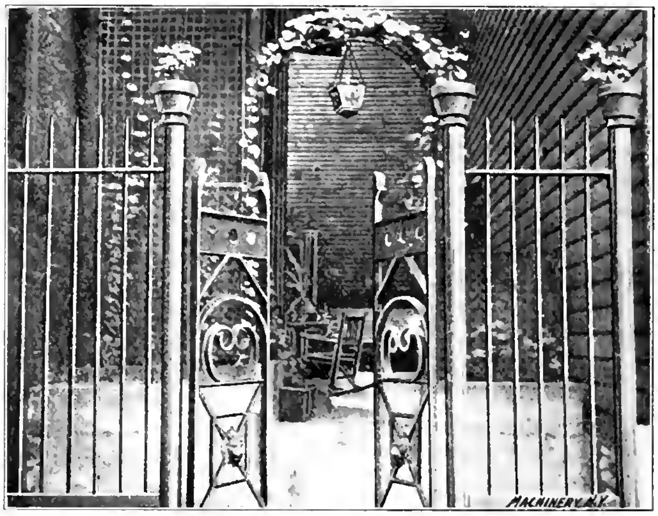

Fig. 4. Entrance from Side Street, showing Pipe Fence Posts and Cast Iron Flower Pots.

Fig. 1 shows a front view of the yard and the ornamental fence and gates. The hinges of the gates have ball bearings. The lions' heads and scrolls are made of iron, copper plated with a verde green finish. In the yard are a sunken garden, concrete flower pots, hanging baskets, lamps, and a fish pond in the center.

Fig. 2 illustrates this portion of the yard and shows the fish pond, which is made from a 5½-foot diameter gas engine pulley, 24-inch face, and weighing 865 pounds. The interior is lined with concrete and faced with cement. The center of the pond, in which the plants are growing, is a discarded fire pot of a furnace, 24 inches diameter, 24 inches high, and weighing 245 pounds.

Fig. 3 shows a near view of the fish pond. This view also shows a fence used as a trellis for vines, and concrete flower beds 8 feet long, 15 inches wide, with 3-inch thick walls reinforced by iron wire woven and laid in the mold before the concrete is poured. The fence posts are 3-inch iron pipe, imbedded 2½ feet in concrete and are amply strong to sustain the hammock.

The fence on the side street is illustrated in Fig. 4. This view illustrates the means for securing the fence to the post by angle brackets of iron. The flower pots on top of the posts were molded from a regular 8-inch flower pot, and are made of cast iron, weighing 11 pounds each. The tops of the posts are threaded, and standard 3-inch caps are riveted to the bottoms of the flower pots, and they are then screwed onto the posts. This view also shows the back porch, the lattice of which is made from an elevator car. The posts of the back porch are made from 3-inch iron pipe, imbedded in concrete. The sliding elevator door was also utilized, and a lock is provided which secures the door and protects the refrigerator and contents which are stored in the porch.

Pittsburg, Pa. W. A. PAINTER.

DEVICE FOR TESTING TRUTH OF CUT GEARS.

The illustration shows a device for testing the truth of cut gears used in the construction of gas and gasoline engines. All cut gears are tested after the machining is done, or if they are case-hardened, after the hardening process. Only gears that are absolutely true are put in the engines; however, a slight variation from truth will pass inspection. Gears that have been case-hardened will vary more or less, consequently a test must be made to see that no imperfect ones are used. In engines of this class, all gears are meshed closely to avoid any back-lash and to prevent as much as possible any noise in the running. If a pair of gears have become slightly oval in shape during the hardening process,

long and short diameters will exist which are not noticeable to the naked eye. Assembling gears of this kind will result in a "rattle" or a "bind" in each revolution, and to avoid such gears is the purpose of the test.

The device for making this test consists of a cast iron plate *A* ribbed at the bottom and machined on the top surface; a cast plate *B* with a projecting arm *C* in which is secured a shoulder stud-screw *D*; a cast-iron segment plate *E* drilled and reamed at one end to fit fulcrum stud *D*, and having at the opposite end a shoulder stud *F* on which revolves a master gear of the same pitch as the gears to be tested; an indicator pointer *G* drilled to pass down over fulcrum stud *D* and axle stud *F*; a graduated brass plate *I* secured to base *A*; and a shaft *J*, the lower end of which revolves in a step bearing beneath the plate *B*. To this shaft is secured a worm-wheel, and on the part which projects above this worm-wheel are placed, and rigidly secured by means of a key, the gears to be tested. The worm *L* is made of machine steel and case-hardened, and is driven by a ½-inch round belt passing over wheel *M*. A steel spring *N* is fastened to plate *B* and index hand *G*. The segment plate *E* is machined on its bottom face which rests and slides on the upper face of plate *B*. On the upper face of plate *E* rests the index hand, and on top of this is a steel washer around axle stud *F*. On this washer rests the master gear, which is perfect in every detail. The gear to be tested is revolved by means of the wheel and worm, and any irregularity in the diameter will show on the graduated plate.

Testing the Truth of a Cut Gear by revolving it with Master Gear and noting changes in Center-to-center Distance.

DETROIT.

MAKING AND HARDENING A DRILL FOR BRICK.

The accompanying illustration shows a cheap and serviceable form of drill for brick walls, which can be made from wrought iron, gas or steam pipe. A solid plug is welded in one end to close it up and serve as a head for the drill, and the other end is serrated after the same manner as a hollow mill or core drill, and slightly spread to give it clearance. As the drill is made from wrought iron, ordinary methods of hardening are of little use; but by heating the working end of the drill to a fusing temperature, along with a piece of thin cast iron, and allowing them to come in contact while in the fire, part of the cast iron will adhere to the wrought iron and can be pretty evenly distributed over the teeth by turning the drill. After a fair coating of the cast iron has adhered to the teeth, remove the drill from the fire, shake it or give it a light rap upon something solid to remove any surplus cast iron, and insert in a cold water bath. The teeth of a drill treated in this manner are so hard that they can not be touched with a sharp file, and will wear until the rest of the drill is completely worn out if it is not subjected to heavy hammering.

Brick Drill made from Wrought Iron Pipe.

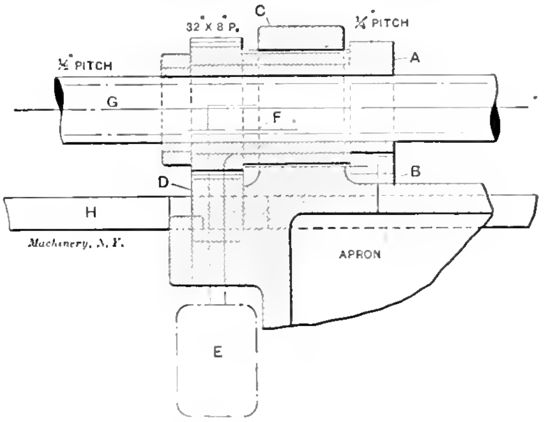
JAMES CRAN.

Plainfield, N. J.

CUTTING AN ACCURATE SCREW FROM AN INACCURATE LEAD-SCREW.

"We find, after testing, that the feed screws of the machines supplied by you to our order are not accurate enough for our purpose; before placing any further orders with you we should like your assurance that this matter will receive your attention."

Thus ran an epistle received by us from one of our best customers, and one of the first things done after reading it was the testing of the lead-screw of our precision (?) screw-cutting lathe. It was found to be about 0.090 inch out in six feet, so that our customer had just cause for complaint. A conference of heads of departments was held, and various methods of overcoming the difficulty suggested. One idea was to have a threaded bush to take the thrust of the lead-screw, arranged so that as the lead-screw revolved the bush was also turned by suitable gearing, pulling the lead-screw and carriage bodily with it as it screwed out of its bearing. This scheme, though a good one, was vetoed because, as one of the foremen pointed out, it could only rectify the aggregate inaccuracy; local errors would not be provided for. I then had a turn, and claimed that I had a scheme whereby *all* local errors were rectified. The idea of all the local inaccuracies in the lead-screw being corrected in the screw being cut, was deemed impossible and at first sight it does seem to be a rather difficult thing to accomplish, but after an explanation of the proposed method it was acknowledged that the scheme was practicable. We did not use it, however, as it was thought advisable to install a new lathe, and with this machine we got a lead-screw which was guaranteed to be within certain limits; however, it might be interesting and useful to readers of MACHINERY to know how we proposed to accomplish the seemingly impossible task of cutting an accurate screw from an inaccurate lead-screw.



Machinery, N.Y.

Fig. 1. Section in the Plane A—B, Fig. 2.

The first thing to do is to measure the pitch of the lead-screw at a number of places and find what the inaccuracy is. A large change gear is mounted at the end of the screw and, assuming that the lead-screw is ½ inch pitch, six turns of the change gear should move the carriage exactly 3 inches. Every 3 inches seems to be a convenient distance, though longer or shorter distances could be measured in exactly the same manner; of course, the lead-screw would have to be turned a larger or smaller amount. After the change gear has been revolved, we will say 6 times, a vernier or micrometer is used to measure the actual movement of the carriage. By this means we can tell how much the actual movement differs from the theoretical movement, or, in other words, how much the pitch of the screw is out. This difference or error, for every 3 inches of the whole length, is tabulated, care being taken to also record whether the pitch is large or small. When the screw has been measured throughout its length, the next operation is the correction of the errors. The method whereby this is done is shown diagrammatically in Figs. 1 and 2.

Referring to Fig 1, a special lead-screw nut *A* is screwed directly onto the lead-screw and kept from revolving by the pin *B*. On the outside of the nut revolves the 32 × 8 pitch gear, the shank of which is threaded externally and screwed into the bracket *C* which is screwed to the apron. Meshing

with the 32 × 8 pitch gear, is a rack *D* upon the top of which presses the weighted lever *E* pivoted at *F*. At the lower end of the rack is fixed a runner *J*, as shown in Fig. 2. It will be seen that if rack *D* be moved either up or down the carriage will be moved independently of the lead-screw *G*, and a simple calculation will show that 0.050 inch movement of the rack will move the carriage 0.001 inch, so that if we can arrange some means of raising and lowering the rack at the right time and the right amount, we shall be able to cut a screw which will not be a copy of the lead-screw because it will not have its errors. At the front of the bed and directly under the runner on rack *D* is a fence-like structure *H* made of wood. This consists of a number of boards, joined together by battens at the back, and arranged so that the runner may work on the end of the grain of the wood. Knowing what the errors in the screw are, and also knowing that to raise or lower the rack 0.050 inch gives a carriage movement of 0.001 inch, it is quite an easy matter to reckon up how much the vertical movement of the rack must be to compensate for the errors we have previously tabulated; so that if we divide the board *H* into 3-inch spaces by vertical lines, we are in a position to mark out the profile required to meet our particular needs. Suppose that in the first 3 inches the pitch of the lead-screw was 0.003 inch short; we should know then that the *fall* between the first and second 3-inch marks *K* and *L* would require to be 0.150 inch. Proceeding in this manner, the whole of the profile is marked out. Then, if care is used in cutting to the marks and in mounting the board in position, we are ready to get to work on our screw, knowing that the errors in the lead-screw will be corrected by our automatic compensating gear. Of course, when cutting the corrected screw, the counter-shaft will have to be reversed, as the lead-screw nut must not be disengaged. I forgot to mention that it would, perhaps, be advisable to take the measurements of the lead-screw after the solid nut *A* has been put into position, as the conditions then would be more like the conditions when actually cutting the screw.

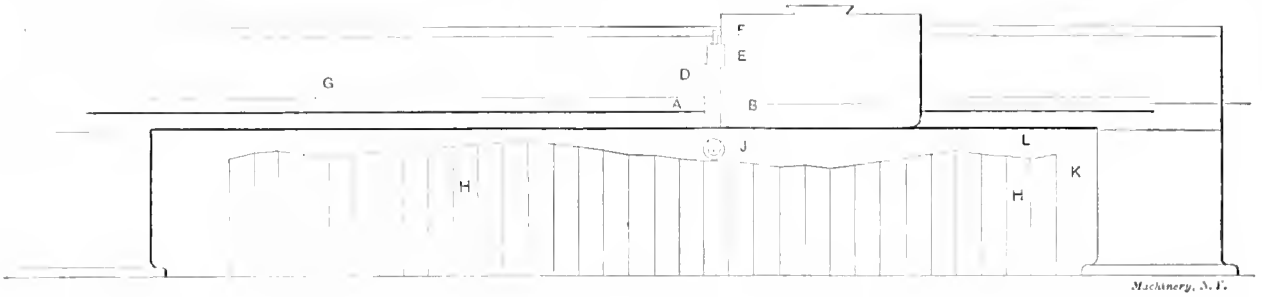


Fig. 2. Device for Correcting Inaccuracies in the Lead-screw by an Automatic Movement of the Carriage regulated by the Rise and Fall of Roller J.

As mentioned before, we didn't have to operate on our old lathe, but if I am ever placed in similar circumstances, and a new machine is out of the question, I should have no hesitation in trying this method of making the inaccurate lead-screw cut one that is accurate.

RACQUET.

INTERMITTENT CAM—CAM ROLLERS.

The writer recently had occasion to give a shaft an intermittent motion with an angular movement of 90 degrees, the shaft to revolve in one direction and the power to be obtained from a parallel shaft having a speed ratio of 4 to 1. A pair of intermittent gears would have done the trick perfectly, but were not used as excessive shock was feared on account of the high speed to which they must be run.

On one end of the shaft to be rotated, a disk with four cam rollers *A* spaced to 90 degrees, was placed, and working over this plate was the cam *B*, as shown in Fig. 1. The development of this cam is shown in Fig. 2. Though originality is not claimed for the design, it may be of interest. The cam imparts the regular crank motion, as shown further on, and the action is, therefore, quiet and easy. To lay out the cam, a circle *AHGB* is chosen for the path of the cam rollers of the driven shaft, and divided into four parts. The cam action is to take place on the line *AB*, which line is perpendicular to the center line of the centers *M* and *D*. Upon *AB* the semi-circle *ACB* is drawn and divided into any number of equal parts, and the points thus found projected onto the line *AB*. Radial lines *DE*, *DF*, etc., are then drawn from the center *D* through these points to the circle *AHGB*, transferring the harmonic motion to the path of the cam rollers. The arcs *OT*, *EU*, *FX*, etc., are then drawn. The outermost position of the cam roller with respect to the cam, will be seen at *A*, likewise the innermost at *O*. Arcs are drawn through these outer and inner positions of the roller centers. A distance *JS* is chosen, depending upon the time required for the action. This time must not be too long, else interference of the cam and rollers will result, and if too short, a sharp point at *O* is developed. *JS* is divided into the same number of parts as the arc *CB*, and radial lines drawn to the center *M*. At the intersection of these lines and the arcs *OT*, *EU*, *FX*, etc., which have been previously drawn, we have the centers which the cam rollers must successively occupy. Three arcs are then approximated to cut these centers, giving the cam track desired. One-half only of the cam is shown developed, as the other side is symmetrical.

In order that the cam slot can engage the next roller, either a pawl must be used to hold the roller plate (using only the effective part of the cam by cutting away the dwell), or notches cut into the side of the cam itself to admit the next roller into the track. These notches *C*, Fig. 1, can be laid out at the time the motion is plotted, but the method used in this instance for determining the shape and position of the slot was a more natural one, as a lay-out of both cam and roller plate was made on cardboard and the parts cut out and pivoted on thumb tacks; then by revolving the disks, having previously blacked the rollers, the shape of the notch developed itself. It will be seen that two rollers are engaged in the track at the dwell of the cam, thus making a more rigid stop than is obtained with intermittent gears.

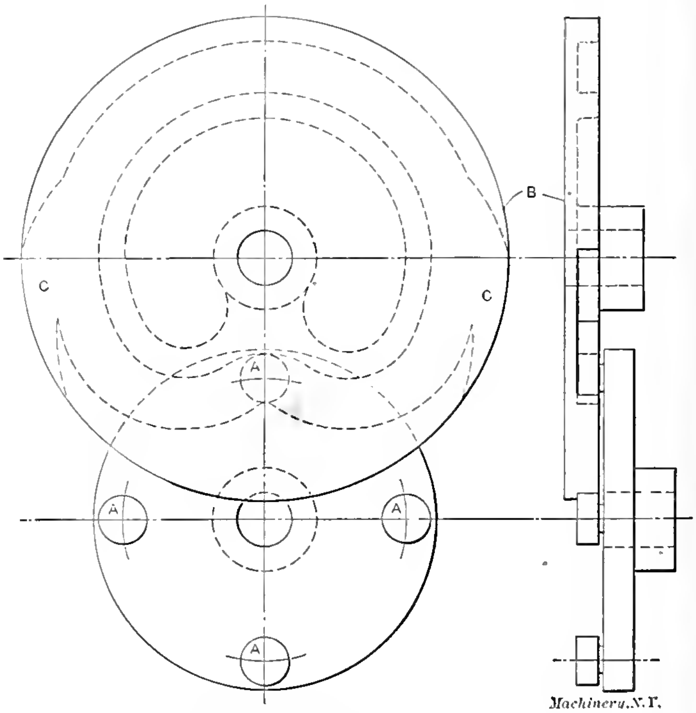

Fig. 1. Cam, and Disk with Rollers, by which an Intermittent Movement is Imparted to the Driven Shaft.

As a rule, cam rollers belie their name, in that they do not roll; they stick once, then a flat soon appears on the

periphery, or the stud wears thereby, destroying the true cam action. The ball bearing rollers shown in Figs. 3, 4 and 5, overcome these difficulties and from experience I know that these rollers roll, require little attention, and insure the true cam action being maintained. Fig. 3 is a somewhat heavy type, the two bearings being contained in a sleeve which protects them from dirt and dust. This roller has the advantage of being supported from each side. The bearings used are an article of manufacture. Fig. 4 illustrates a roller designed to overhang its point of support. The cam arm should be rather heavy to keep the roller true, especially if designed for a movement that is heavy, or if at times subject to very quick action; otherwise the roller may cant a bit, as shown exaggerated by the dotted lines. This is a point that is often overlooked in the ordinary roller, and while it is desired to avoid this overhung style, at times this type is by far the most convenient. In Fig. 5 a light type of roller is shown. As this type is small, the design is changed slightly, the internal ball race being removed. As will be seen, this race is cut in the stud which holds the roller to the arm or plate.

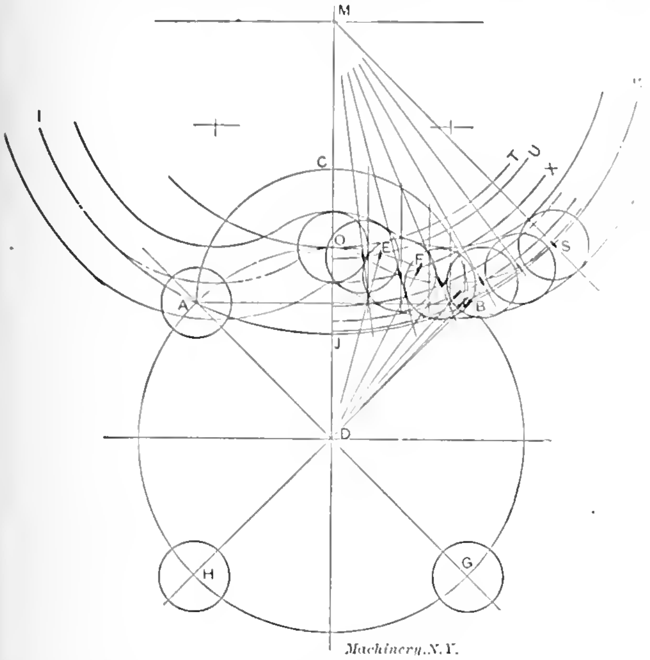

Fig. 2. The Development of the Cam shown in Fig. 1.

CYRUS TAYLOR.

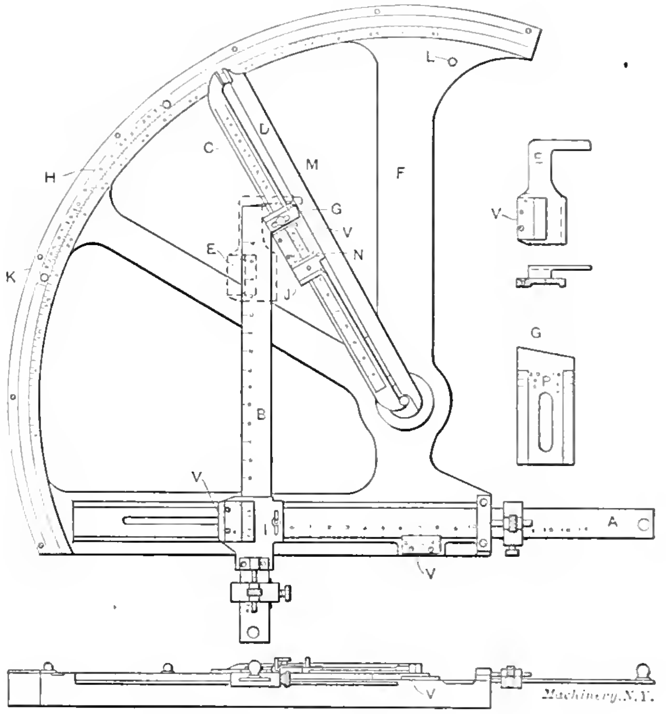
London, Eng.

A BEVEL GEAR GAGE.

In order to overcome the necessity of calculations for bevel gears, the gage illustrated in the accompanying engraving was constructed. The range of this gage will permit calculations of bevel gears from 1½-inch to 24-inch pitch diameter to be readily made. The frame *F* is a brass casting reinforced by ribs not shown in the engraving. It is finished and graduated on the rim to half degrees. The rim is also grooved to receive a vernier slide *H*, which reads to minutes. This slide is retained in place by the strip *K*, allowing the vernier to slide with slight friction. The lower part of the frame is planed to receive a scale *A* running in a groove with a good sliding fit. The head *I* is fastened tightly on the end of the scale *A* and forms a slide for the scale *B*. On the end of scale *B* is a small arm, not indicated, which carries a hardened bushing receiving the taper pin *M*. This latter is driven tightly into the slide *J* and its center is exactly on the radial line from the center of the arm *C*, and the index at the arm's recording end is at the rim of frame *F*. The slide *J* is of a channel shape, sliding freely on the radial arm *C*, but can be lifted off the arm entirely. The scales were made to order by the Brown & Sharpe Mfg. Co., and are graduated to fiftieths of an inch. Each scale is provided with a vernier, reading to 0.001 inch.

Given this arrangement, it will be seen that if the scale *B* is slipped down until the zero mark on this scale is opposite the zero on the vernier at *V*, the radial arm *C* will be parallel to the scale *A*. In this position, scale *A*, scale *B*, and slide *J* can be moved as one piece in the longitudinal direction of scale *A*, the radial arm remaining at zero on the degree scale on the rim of the frame. When the scale *B* is moved from its zero, the arm *C* will register the angle accordingly. The arm *D* is called the face-angle arm, and is moved independently from arm *C*. It is provided with a hardened straight edge on a line exactly radial from the center where the arm is pivoted. This arm is used for determining the face angle and the depth of cut, as will be referred to later.

The piece shown in detail at *E* is the diameter increment gage, more commonly called the blank diameter gage. It is made to slide on scale *B* and is used only when face-angle arm *D* is moved away. At *G* is shown one of the addendum and depth of cut gages. These gages are shown in detail, so as to show more clearly the lines and figures by which they are graduated, the gage *G* being also enlarged. The addendum and depth of cut gages are hardened and ground to fit the slide across the top of slide *J*. Owing to the fact that the pitch lines would come too close together if all were marked on the same piece, there may be different blades for different pitches and depths of cut. One of these blades can be seen in place in the assembly drawing, with the corner extending beyond the center of the pin *M*. If the gear was a four-pitch gear, the amount of extension would be one-quarter inch; if a 6-pitch gear, 1/6 inch, etc. The blades are set by bringing the pitch lines opposite the zero mark on slide *J*. The gages can be used at either end of slide *J*, the point *N* becoming the working point when it is necessary to get closer to the center for small bevel gears. When the gage is set, if the arm *D* is brought up against its point, the face angle is thereby determined.



Gage facilitating Bevel Gear Calculations

As an example, we will assume that we are to make bevel gears like samples furnished us. We find in the larger bevel gear of the samples furnished 40 teeth, and in the smaller 20 teeth. The larger gear measures roughly about 10 inches pitch diameter, and we therefore decide that it must be 4-pitch. To get the correct size of the larger gear, set scale *B* to one-half the pitch diameter of the large gear, or 5 inches,

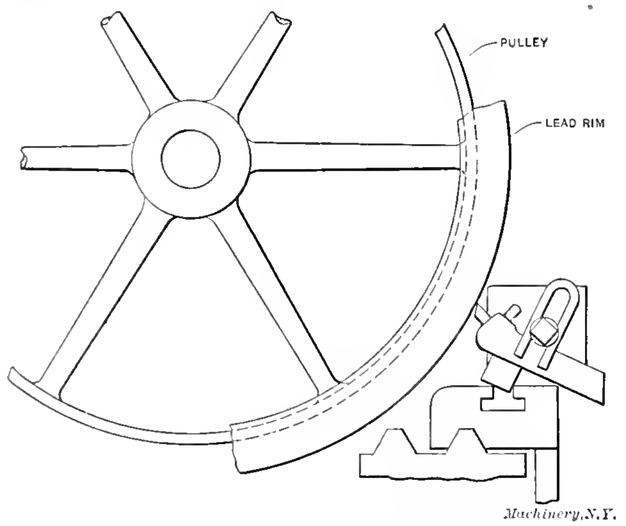
and set the scale *A* to one-half the pitch diameter of the small gear, or 2½ inches. Lock the scales by means of the wing nut on the head *I*. Take an addendum gage for 4-pitch, and set the 4-pitch mark in line with the zero on slide *J*. Bring the arm *D* up to the corner of the blade of the gage, and read off the angle to which it points on the protractor, using the vernier *H* if necessary. The angle read off the scale is the face angle of the blank. Now move the arm *D* around against the stop pin *L*, place gage *E* on scale *B* and slide it down until the extending arm touches the addendum gage on the corner. Then take the reading of the gage *E* at the vernier. Twice the amount of this reading, plus the reading at the *B* scale vernier, equals the outside diameter of the blank. This whole operation is done in less than five minutes. It simplifies the method of getting the sizes of bevel gear blanks, and particularly for the repair shop, is a great convenience.

The gage may also be used as a right angle triangle computor. Scales *A* and *B* may be considered as the sides including the right angle, and the scale on the arm *C* will give the length of the hypothenuse, registering one of the oblique angles on the protractor at the same time. By setting the slide *J* to a unit radius and the arm *C* to a known angle, the reading on scales *B* and *A* becomes the sine and cosine, respectively. By setting scale *A* to a unit length and arm *C* to a known angle, the reading on scale *B* becomes the tangent of the angle, etc.

W. A.

GRINDING WHEEL FOR LEATHER SPLITTING KNIVES.

From a mechanical standpoint, the most exacting as well as the most interesting process in the manufacture of fine leather is the cutting of the tanned hide into thin sheets or "splits," which are worked up into a multitude of products, ranging from watch fobs to automobile cushions, and varying in thickness according to their respective uses. As the allowable deviation is but a few thousandths inch, the splitting machine must be kept in perfect condition, and the cutting knife be maintained with almost a razor-like sharpness to prevent dragging or crowding the hide and leaving a thick spot. There are two types of splitting machines in general use, one of which has a cutting knife ⅜ inch thick, 4 inches wide, and about 6 feet long. This knife is sharpened at the top and bottom, with the ground edges extending back nearly 2 inches, forming as sharp an angle as is practicable. The grinding is done with fine, sharp sand applied to a lead wheel, across the face of which the knife is passed.



Machinery, N.Y.

Turning a Large Pulley with Lead Rim in a Small Lathe.

One of the "annual" jobs is the preparation of a new grinding wheel. A 24-inch pulley with a number of one-inch holes drilled in the rim is put in a sand mold and lead poured in, completely surrounding the rim. The pulley is then turned off to a diameter of 27 inches and the edges chamfered. Our largest lathe will not permit the tool-post to pass the pulley, so we used first a tool that extended out 7 inches which, though made of heavy stock, left fine chatter marks. Before the chips fell from the tool, they would also rub against the finished surface, and produce straggling grooves. The wheel as finished, though passable, did not present a neat appearance, so I decided to have it done in another way, as shown in the illustration. An angle plate was bolted to the lathe carriage, and to it was clamped the tool suitably blocked. In this position the tool is rigid, and its slant is sufficient to let gravity carry the chips away, and the completed wheel is perfect. It might be asked why such a wheel is used in place of an ordinary abrasive stone of proper grade. There are two reasons: First, in order to have the cutting edges of the knife as little concave as possible, a large grindstone wheel must be used, the cost of which does not compare favorably with the lead wheel method; second, the lead and sand method heats less, leaves less "feather," and a better edge than other wheels that have been tried for the purpose.

Middletown, N. Y. DONALD A. HAMPSON.

SPECIAL HOB FOR WORM-GEARS.

The accompanying half-tone and line engraving show a hob made by the writer several years ago for facilitating the cutting of worm-gears. It is well known that if a hob is not provided with relieved teeth, it is an unsatisfactory tool for removing stock, and can only be used for the last finishing touches on the worm-gear after it has been previously gashed. The gears which were to be cut in this case were commonly made of cast iron, and to first gash these worm-gears and then hob them was rather expensive. There were no facilities for making ordinary hobs with relieved teeth, but there was a lathe in the shop fitted with a relieving attachment whereby it was possible to relieve single cutters. In order to overcome the necessity of using hobs with relieved teeth, we proceeded to make a special form of hob, as shown in the accompanying half-tone and line engraving. On this hob, teeth were cut of the same form as the cross-section of the worm thread, but instead of giving a lead to the hob thread, the teeth are simply circular ridges around the tool, and the threads are circular grooves. The hob is then fluted in the ordinary way. When in use, the hob or cutter, as it would be more properly called, is set at an angle with the axis of the worm-wheel in order to produce the proper angle of the teeth in the latter. The outside of the hob is turned to a conical shape toward each end, the cutter being full size in the center, and the angle of the taper being equal to the angle to which the cutter is turned or rotated for cutting the worm-teeth. This angle, of course, is the same as the angle to which the saddle of the milling machine is turned when hobbing. When using this tool for hobbing, instead of indexing one tooth at a time, it is common to index around a number of teeth at a time, so as to give the cutter a chance to cut nearly an equal amount on both sides of the center. This obviates any tendency of crowding caused by a heavier cut on one side than on the other. Finally, of course, the worm-gear is finished by indexing one tooth at a time.

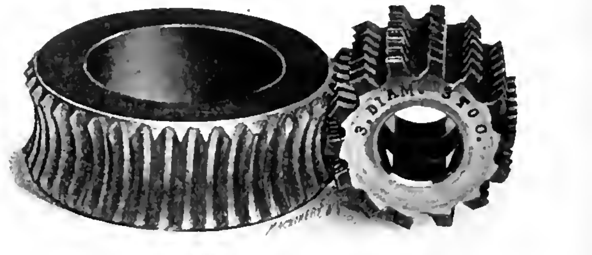


Fig. 1. Worm-gear and Special Hob by which it is Cut.

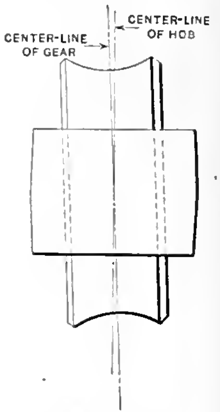


Machinery, N.Y.

Fig. 2. Diagram Illustrating the Setting of the Hob.

It should be stated here that originally there was no thought of making the gears without hobbing, but it was found that it was possible with a cutter of this form to cut

a fairly good-looking gear without hobbing. Of course, the gear will not be theoretically correct, but it will be nearly enough correct for the commercial purposes for which it is intended. It is evident that both right-hand and left-hand cutters can be cut simply by turning the table on which the index centers with the worm-wheel are mounted, in opposite directions. **Francis P. Havens.**

Waltham, Mass.

TURNING SOFT RUBBER.

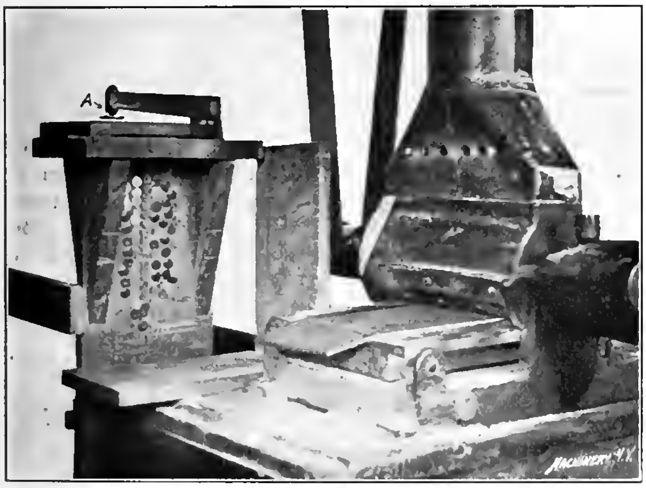
In the How and Why column of the December issue of Machinery a question regarding the turning of soft rubber was submitted. The writer has turned soft rubber with an ordinary wood-turner's gouge, about ½ inch wide, and it works very well. The gouge must be ground hollow and kept very sharp. The shavings resemble band rubber. No lubricant is used. **F. A. Ross.**

Beloit, Wis.

In regard to "L. M.'s" question as to a method of turning soft rubber in a lathe, the following procedure will be found to give good results. Rig a small grinding wheel on the tool-post, driven by a drum from overhead or by a small motor attached to the carriage. If a grinder of suitable size is available, more accurate results will be obtained. This is the method used for turning the soft rubber couch rolls used on paper machines. No lubricant is necessary.

Bay City, Mich. **H. J. Mastenbrook.**

In reply to the question submitted by "L. M." in the How and Why section of the December issue of Machinery as to the best method for turning soft rubber, the writer would suggest the use of an abrasive wheel. It would be well to write to one of the large firms making such wheels, stating plainly the kind of rubber to be turned; in this way exactly the right kind of wheel for the purpose can be obtained. The lathe should then be rigged up for exactly the speed recommended by the wheel makers. It is important that the correct speed be employed, as a difference of a few hundred revolutions per minute may cause difficulties. If a grinder is at hand, it is, of course, better to use this machine than to rig up a lathe for the purpose.



Machine for Grinding Soft Rubber Sheets to Correct Thickness.

The accompanying half-tone shows a grinder used in a rubber stamp factory for obtaining a uniform thickness of thin sheets of vulcanized soft rubber which is provided with letters on one side. Such a sheet is shown in the front of the enclosed emery wheel. The dust is carried off through a hood by the suction of a fan. A gage for showing the thickness of the sheets in thousandths of an inch is shown at *A*. While the grinder shown is not likely to be one that "L. M." could use, it illustrates the principle of the only satisfactory way of machining soft vulcanized rubber—that is, by grinding. **Ethan Viall.**

Decatur, Ill.

In the December issue of Machinery, "L. M." asks for information about turning soft rubber. The writer submits a little of his own experience which may be of service as an answer.

Provide first a tool of almost razor-like keenness; then, rubber-turning is practically a repetition of similar work on other soft materials run at a high speed. Fig. 1 shows a rubber turning tool used for feeding from right to left, with the point ahead. The noticeable feature about it, distinguishing it from other turning tools, is its lack of clearance. The elasticity of rubber renders clearance unnecessary; in fact, it is objectionable. The tool shown is set above center, and the lower side of the cutting point is flared out to give stiffness to it. A tool to cut when feeding in either direction is made with a double cutting point like the section in Fig. 2.

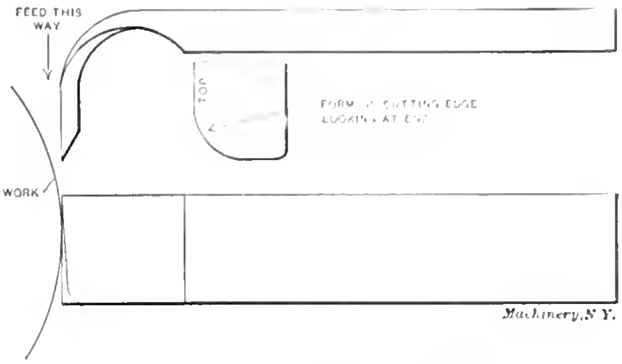


Fig. 1. Tool for Turning Soft Rubber.

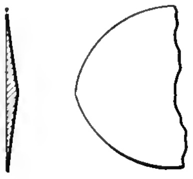

Fig.2

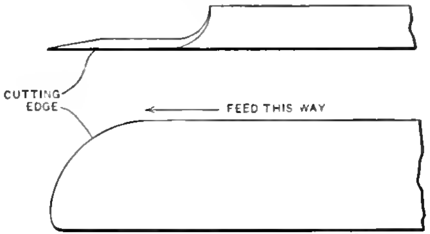

Fig.3

Fig. 2. Double-edged Tool for Turning Soft Rubber. Fig. 3. Cutting-off Tool for Soft Rubber.

On one occasion some rubber compression springs for file cutting machines were finished. The stock came in "bars," three inches in diameter, with a one-half inch core running through the center. The pieces were cut off on a bandsaw to approximate length, and then faced off in the chuck with the tool shown in Fig. 3.

For blanking out stock, round or otherwise, a bandsaw is quicker than any other method, but the operator should use great care or provide himself with suitable guides or clamps to prevent personal injury through the work catching and the latent spring in the rubber knocking the hands against the saw.

Contrary to the kink which so many know of wetting a knife before cutting rubber, the writer found it best to work it dry. The "dust" from the cut and the surfaces over which the tool passes will have a brownish hue—much darker than the stock as it regularly comes; to restore to the original gray or to remove finger marks, rub it on powdered soapstone in the lathe after the cut surfaces have been smoothed with sandpaper. **Donald A. Hampson.**

Middletown, N. Y.

SAWING CAST IRON UNDER WATER.

Regarding the question in the How and Why section of the December issue submitted by the "H. M." Co., the writer would say that if it is necessary to saw cast iron under water, a coarse-toothed saw should be used to minimize clogging, and some form of positive feed employed to force the saw into the cut. If the saw fails to cut for even one forward stroke, wet cast iron will tend to glaze, no matter whether the slip is caused by clogged teeth or insufficient pressure. Dulled or clogged teeth will soon polish the slot so that even a new saw will not cut. The same tendency to glaze is noticeable in filing or drilling wet cast iron, and it is necessary to keep the tool constantly cutting and not permit it to slip. The same condition is met with in drilling unannealed tool steel.

If the cutting of cast iron under water is undertaken with the idea of obtaining more speed, the procedure is inadvisable for obtaining the object desired. If speed in cutting is wanted, a metal-cutting bandsaw will give the best results.

Decatur, Ill. ETHAN VIALL.

DRILLING HOLES IN GLASS.

Many people think that it is a very hard job to drill holes in glass, but this is not so. It requires, of course, more time and more care than drilling in metal, because there is greater danger of breaking the glass.

The drill is made of a steel rod or an old three-cornered file. One of its ends is ground to a long tapering triangle-shaped point. It is placed in a swiftly revolving chuck (lathe or electric hand drilling machine), and the glass pressed against it very gently.

The work should be held in the hands in order to feel the pressure against the drill. As a lubricant, turpentine is used.

North Tarrytown, N. Y. JOHN INGBERG.

SLIDE RULE FOR ADDITION AND SUBTRACTION OF FRACTIONS.

The slide rule illustrated herewith, will undoubtedly meet with great favor among draftsmen and engineers in general, who have occasion to check up long lists of dimensions on drawings. This operation can be performed with speed and perfect accuracy, all chances of error are entirely eliminated, and such work becomes a pleasure instead of a task by the aid of this simple slide rule which any draftsman can make in a few hours. Of course, it is understood, in performing operations in addition or subtraction on this rule, that the operator has a pencil and pad to keep account of the units and whole numbers.

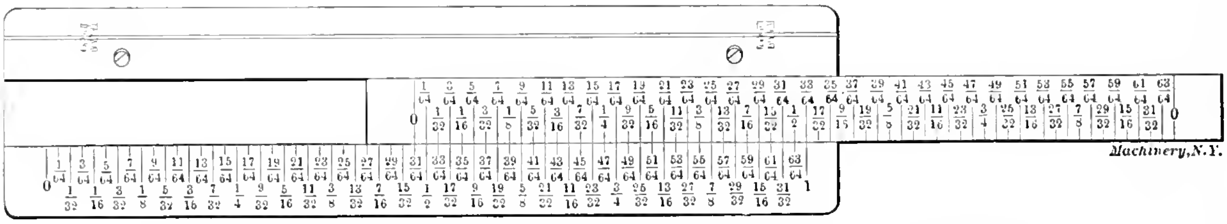

Fig. 1. Slide Rule set to add 31-64 to any of the Fractions on the Runner up to and including 33-64.

Assume that we wish to add 31/64 to 13/32: First set the left-hand zero mark of the runner to 31/64 on the lower scale, as shown in Fig. 1, and opposite 13/32 on the upper scale (or runner) read 57/64 on the lower scale for the answer. Assume that we wish to add 5 39/64 to 16 47/64: First write down 21 on the pad, then set the right-hand zero mark of the runner to 47/64 on the lower scale, and opposite 39/64 on the upper scale (or runner) read 1 11/32 on the lower scale for the answer. This added to 21 = 22 11/32 for the final answer. Assume that we wish to subtract 51/64 from 1⅝: First set the right-hand zero mark of the runner to 51/64 on the lower scale, and opposite 1⅝ on the lower scale read 53/64 on the upper scale (or runner) for the answer.

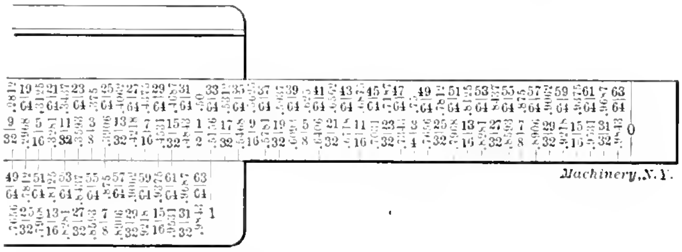

Fig. 2. Slide Rule Illustrated in Fig. 1 with Decimal Equivalents Added.

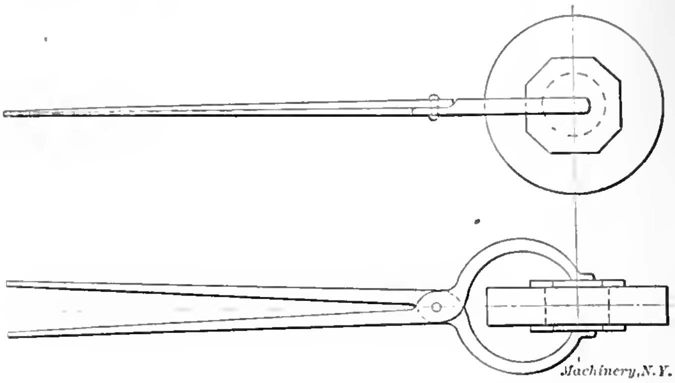
The operations for addition on this rule are identical with those for multiplication on the ordinary slide rule, only the latter employs a logarithmic scale instead of scales of equal parts. WM. C. MICHAEL.

Claremont, N. H.

[The addition of the decimal equivalents of fractions to the slide rule, as indicated in Fig. 2, would increase its value considerably, though there might be some confusion because of the multiplicity of numbers. The decimal equivalents would make it possible to add decimals and common fractions without changing the form of either, and the rule could also be used for checking drawings dimensioned with decimals.—EDITOR.]

REDUCING THE SIZE OF HOLES IN PARTLY FINISHED WORK.

In rough boring solid steel gears and similar work, it sometimes happens that the hole is made a little too large to permit a finishing cut to be taken. This may be done accidentally or through carelessness on the part of the workman, but, in any case, the bored piece is useless for the purpose for which it was intended unless the size of the hole can be reduced. The easiest way to do this is to heat the piece to an even temperature, and cover each end of the hole with a shield of some kind; sheet asbestos placed under iron plates, or two pieces of wood, one on each side, can be used.



Method of holding Protective Shield over the Center of the Heated Piece.

The covers are held in place with a pair of tongs as shown in the accompanying illustration. The work and covering is now plunged in a bath of cold water. The shields protect the center from the water. As all the cooling is done from the outside, the hot stock is forced toward the center as the outside shrinks. When fairly well cooled off, remove the piece from the bath and anneal it all over. The piece is then ready for the inside finishing cut.

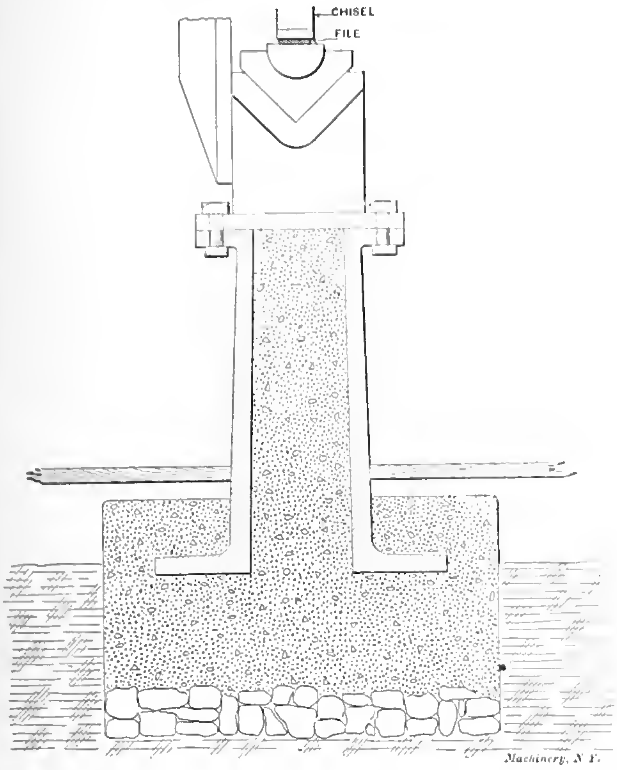
Plainfield, N. J. JAMES CRAN.

BASE AND FOUNDATION OF FILE CUTTING MACHINES.

In the manufacture of files, after the more preliminary operations, such as forging, annealing, grinding, and stripping, have been performed, the blanks go to the cutting shop where the teeth are formed on special machines. The blanks are held on a composition metal bed set in the table, which latter is driven longitudinally by a screw at a rate proportionate to the grade of the cut, and the teeth are cut thereon by rapid blows from a chisel secured in a holder or the chisel head. This chisel head or hammer, as it is commonly called, weighs, complete, from 8 to 12 pounds and makes from 2,000 to 3,000 strokes per minute. The machines for this purpose, subjected as they are to this constant jarring, should be well built and firmly mounted, not only to insure long life on their part, but also to enable the operator to turn out the best class of work; he must follow the cut with his eye so as to detect and immediately rectify any irregularity in the cut. A bench or a pedestal resting on the wood floor, found in some factories, will not answer for a foundation.

Some file cutting machines constructed by the writer were mounted as shown in the accompanying line engraving. The

foundation was built in the usual manner, the pedestal with the top perfectly level being supported from the floor until the concrete had set. In this case the pedestal was an octagonal casting, though a round or square one would have served quite as well. It will be noticed that as an aid to greater stability the inside of the pedestal is filled with concrete up to the base of the machine proper. As built, the foundations give perfect satisfaction.



Cross-section of a File Cutting Machine Concrete Foundation.

Middletown, N. Y. DONALD A. HAMPSON.

BENDING DIE.

The die herein treated was designed and made for the third and last bending operation on the piece shown at *A* in Fig. 1. The metal is 1/16 inch thick, of soft composition, and easy to bend. The first and second operations are performed in a like number of dies; the blanking or cutting from strip stock being done in one die, and the bending of the blank to a U-shape, as shown at *B*, in another. No description of these tools will be given here as they are of simple construction and readily understood by the average tool-maker who is at all familiar with die designing and die making.

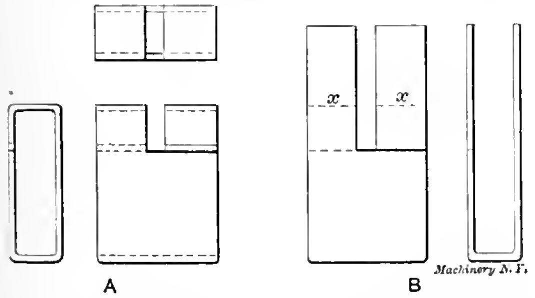


Fig. 1. Appearance of the Work when Finished and before the final Bending Operation.

The tool under consideration shown in Fig. 2, has, of necessity, several moveable parts in order to make the four bends required to complete the work. All the members are of simple outline and easy to make and assemble; therefore no detailed description of the methods of machining each part will be given. The holder *A* is of cast iron and is machined on the bottom, top, and sides to receive the several steel parts. The bending slides *B* and *B* are located in finished seats in the holder and secured in place by plates ¼ inch thick, each of which is, in turn, fastened by four 5/16-inch countersunk screws. The slides *B* have a close running fit, and are forced in to make the right and left bends by the cams *K* on the punch; their opposite or outward movements are made to take place by four compression springs *C*, located in the holder and acting against the pins *D* which are tightly driven into slides *B*. The third slide *E*, which has slotted holes to allow it to move in and out a limited distance, begins to operate after the other two have done their work; the object of this latter slide is to hold the steel form *F*, upon which the work is mounted, down, and free the formed piece from the punch on the up stroke. Springs hooked to the right-hand end of the press bolster and to pins *J*, return the slide *E* when the ram ascends. The four steel pieces *H* are adjusted, when the die is first set up in the press, to properly locate the form *F* which holds the work. The hardened rectangular steel piece *K* gives bottom to the work when in place to be formed. Hardened steel pieces *L* and *L* support the punch parts *K* and prevent their spreading when acting on the bending slides *B*.

The work having been bent U-shape previous to the finishing operation, is put on the former *F* which it pinches sufficiently to hold its own weight, and is carried to the die. On the down stroke the punch parts engage the inclined faces of the bending slides *B* and force them in, causing the right and left horizontal bends to be made at points indicated by the dotted lines *x* in Fig. 1. Further downward movement of the press ram permits these two slides to move out. The cam *L* forces the slide *E* inward until the inner ends extend over the bending form *F*, holding it down until the final bends are made by the former *M*, and the punch ascends sufficiently to free itself of the work. As the press slide continues to go up, the bending slides *B* make another in-and-out movement, thereby striking the formed piece a second time and setting the bends. The finished work is removed from the form by dropping the latter in a yoke secured to the press in a convenient position, and giving a slight pull. We have found it a good plan to taper the forms slightly from the section where the work is located, to the rear, to facilitate the removal of any material, after it is bent, that has a tendency to hug and not spring away. A suitable handle should be on the front end of the form for the comfort and convenience of the press-man, and it should extend to the front of the die sufficiently to make it absolutely unnecessary for the operator to incur any danger of accident by putting his hands between the working parts of the tool. We usually run this type of die in the press at about 100 strokes per minute, and have a slide movement of three or four inches. Several sizes have been made and all are giving good satisfaction. The tool herein described is of medium capacity. ENGINEER.

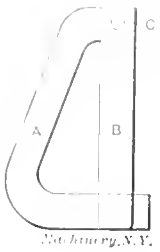
SHOP KINKS.

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

ADJUSTABLE ERASING SHIELD.

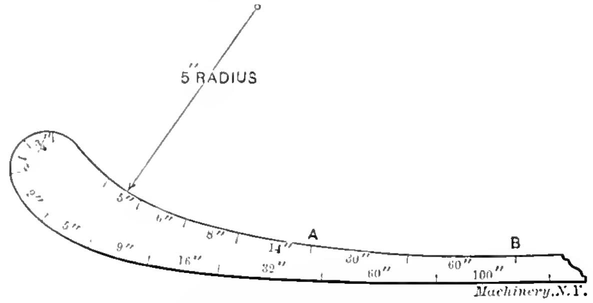


The engraving represents an adjustable erasing shield. It consists of two parts, *A* and *B*, which are hinged at *C*. By moving arm *B*, any size space can be had. Its advantage over the ordinary shield is that a very narrow space can be had at any time, while with the ordinary kind the spaces grow larger each time it is used. The shield is made of thin sheet brass.

Aurora, Ill. **JOHN B. SPERRY.**

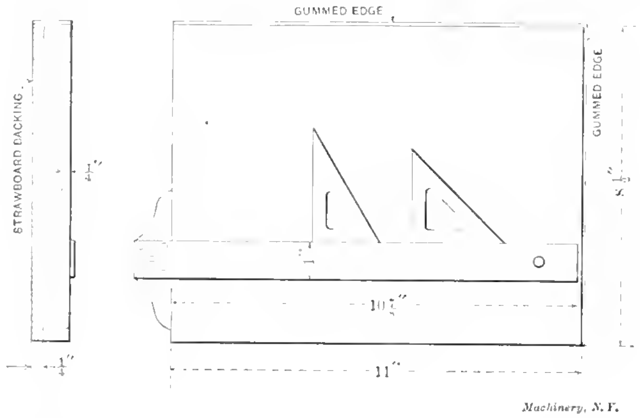
DRAFTSMAN'S GRADUATED CURVE.

The use of curves in the drafting-room has become almost as necessary as the use of the angles. While their use may facilitate the drawing and designing of shapes of irregular curves, it often puts the pattern-maker to more or less trouble in producing the exact forms in wood. A drawing without dimensions is of but little use to the workman; the same may be said of many outlines that are laid out in the manner mentioned. In most cases approximate outlines are good enough, but for particular exactness the radii should be given; and they can be obtained directly if the curve is graduated as the one shown above. **WINMAC.**



SKETCH PAD ARRANGEMENT.

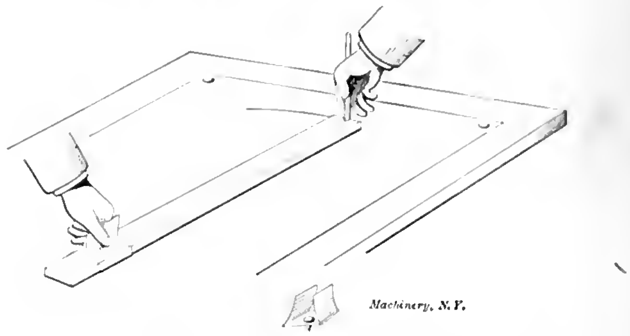
The accompanying engraving shows a very satisfactory scheme for saving time and making accurate sketches without the necessity of hunting for a drafting board and thumbtacks. Ordinary letter paper, or paper with a business heading, is blocked on an extra thick straw-board back, which should be at least 3/16 inch thick. The top and right-hand edges of the pad are gummed to hold the paper absolutely true. A small-sized T-square with a head no thicker than the straw-board backing, and the blade about 1 inch wide and slightly shorter than the length of the pad, is used. This combination gives a simple and compact means of making small sketches, and is always ready. Its great advantage lies in the fact that it can be kept on the desk or slipped into a drawer, and takes up but little room. If a carbon copy is desired, one side of the top sheet can be loosened, and the carbon paper easily placed in position.



C. C. M.

DRAFTSMAN'S TRAMMEL SUBSTITUTE.

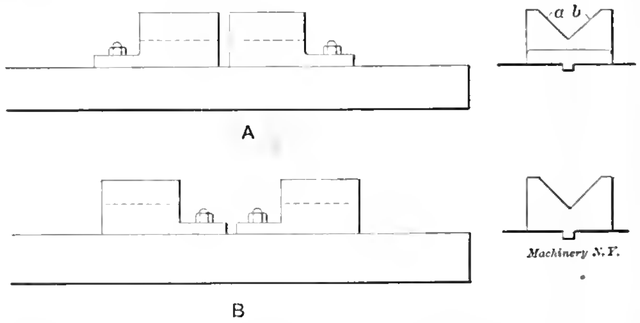
Occasionally circles or arcs of large radii are required when a trammel is not at hand. Substitutes, which are more or less clumsy and impractically contrived and which are intended to give relief in such emergencies, are, at times, described in the mechanical magazines. The accompanying engraving illustrates an arrangement which, with proper manipulation, is capable of producing results equally as good as those obtained with the most expensive instrument, and it has the added advantage that the necessary materials are always at hand with a moment's preparation. A straightedge is provided with a small notch in one end and a thumbtack, as shown by the dotted lines, inserted near it. A postal card having a thumb-tack point projecting from its center is creased over the stick; then the device is ready for use. Lay off the required radius on the paper and prick the center; insert the tack point and grasp the card flaps firmly with one hand while the other guides the pen or pencil in the notch as the curve is struck. The head of the thumb-tack which is near the notch, acts as a shoe which glides smoothly over the paper, and prevents blurring in case ink is used. A little practice makes the adjustment of the notch over the radius extremity a simple matter. **W. F. MOODY.**



Denver, Colo.

PLANING ACCURATE V-BLOCKS.

In planing a pair of V-blocks that are to be used on the planer platen for heavy keyway work, etc., the following method will be found to be a most accurate one, and the style of cast iron V-blocks, shown in the engraving, extremely well adapted for general use. First, the castings are planed on the bottom and the tongue made to fit the slot in the platen on which they are to be used, and, as there are various sizes of slots in planer platens, it is necessary that the succeeding operations be done upon the planer that the V-blocks are being made for.



After being drilled for the bolts, the blocks are placed on the platen as shown at *A*, and the tool-head is set to an angle of 45 degrees. A roughing cut is taken down side *a*, then the blocks are reversed as shown at *B*, and another roughing cut taken down the opposite side *b*. The foregoing operations are then repeated for the finishing cut, without disturbing the angular setting of the tool-head.

If this method is adopted for planing V-blocks, the user will find that the V is always in the center of the slot, regardless of the position of the blocks; but if they are planed by the old method of setting the tool-head first to one side and then the other, the V-blocks are only in line when set in slots as originally planed, and the workman, especially if he is a new one, is liable to get them placed the wrong way about, resulting in error and delay. **R. S. F.**

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

WHITCOMB-BLAISDELL SINGLE-SPEED PULLEY, GEAR-DRIVEN LATHE.

We present herewith a complete description with illustrations of a new 18-inch lathe, built by the Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass. This lathe is of the single-speed pulley type with speed changes obtained through geared connections. The principal feature of the design is the new form of clutch used in making the speed changes. This is of very ingenious construction, and involves a principle on which the builders have obtained a basic patent, though the idea is so simple that it is strange no one has previously patented it. Besides this one particularly novel feature, there are so many other points of originality in the design that the amount of space we have allowed for describing it is fully justified.

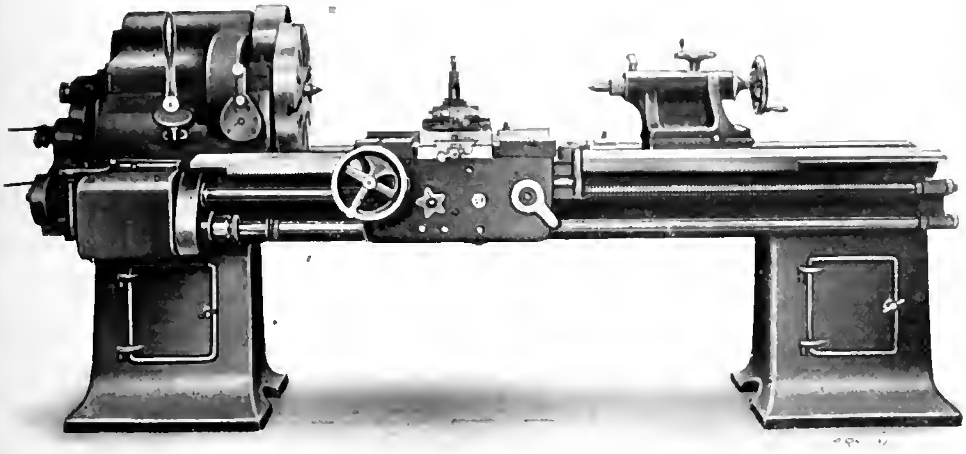


Fig. 1. The Whitcomb-Blaisdell Single-speed Pulley, Gear-driven Lathe, 18-inch Swing.

Driving Mechanism.

The geared head-stock is shown in elevation and detail in Figs. 1, 2, 3 and 5. Power is received at the driving pulley *A* (see Fig. 3), which is keyed to shaft *B*. This shaft revolves in fixed bearings in the head-stock and carries pinions C_1 C_2 and C_3 keyed to it, and has pinion teeth cut on it at C_4. These four pinions mesh with corresponding gears D_1, D_2, D_3, D_4, which normally revolve loosely on friction shaft *E*. Either one of clutch bodies F_1, F_2 and F_3, and gear *H*, may, however, be engaged with the corresponding gear D_1, etc., by means of clutches G_1, etc., whose construction will be described later. It is thus seen that four rates of speed may be given to shaft *E* when pulley *A* is running at constant speed.

Shaft *E* carries gear *H* keyed to it, and has pinion teeth cut in it at *J*. *H* and *J* mesh with gears *K* and *L*; *K* is keyed to clutch member *M*. *L* and *M* may be connected by clutches N_1 and N_2 respectively, with clutch bodies O_1 and O_2, which are keyed to the spindle *P*. The four speeds, which may be given shaft *E* are thus doubled, giving eight speeds for the spindle.

The construction of clutches *G* and *N*—the main point of interest in this drive—is best seen in the detailed views at the right of Fig. 3. The peculiarity of this form of clutch may be expressed by saying that it is a positive friction clutch —that is to say, its engagement takes a measurable amount of time and allows some slipping of the engagement surfaces, thus obviating the severe shock met with at high speeds in positive clutches. On the other hand, it avoids the uncertain driving power and excessive slippage met with in friction clutches, and obviates as well, the necessity for frequent or even occasional adjustment.

In the upper clutch, the expansion ring Q_1 is hung on a pin R_1, which is, in turn, fast to the revolving gear D_1. This ring is thus always rotating when the driving pulley is in motion. The open end of ring Q_1 has pivoted to it a lever S_1, which through the medium of strut T_1 may be made to spread the ring open, engaging the inner diameter of F_1, and thus connecting D_1 and *E*. The movement of the lever for thus operating the clutch is effected by the sliding spline V, which has keyed to it a series of cams U_1, U_2, etc. When this spline is shifted axially on shaft *E* to bring cam U_1 in the path of the revolving lever S_1 (the direction of revolution being immaterial), the latter, as soon as it strikes U_1, is forced outward, spreading ring Q_1 and engaging the clutch. Supposing, for instance, that clutch ring Q_1 and lever S_1 are revolving in the direction of the arrow, and that shaft *E* is being started from a state of rest; it is evident that the rotation of the ring and lever will cause the latter to ride up on the cam until the clutch is fully engaged, when, since *E* is rotating at the same rate as Q_1, the relative movement of S_1 and U_1 will cease so that the clutch will not be tightened more than is necessary to carry the load. If slippage occurs at any time, this will simply cause lever S_1 to ride still further over the cam, tightening the clutch still further. Any slippage thus tightens the clutch the exact amount required to carry the extra strain.

One of the interesting points in the design of this clutch relates to the matter of relieving the face of the clutch ring for the oil, where the driving surfaces come together. As is well known, clutch surfaces which run in oil must be grooved so as to allow the parts to come quickly to a bearing. In the case of this clutch, it was found necessary to groove the periphery of rings Q_1, etc., to such an extent that the bearing area was divided into about ¼-inch squares, separated by oil channels. This permits the lubricant to be squeezed out almost instantly. If larger undrained areas had been permitted, the squeezing out of the oil would have taken some time, and as long as it remained, the full driving force would have come from the engagement of lever S_1 and cam U_1; as these parts, with the acute contact surface between them, could not have been made strong enough to stand the strain of the full driving power, this complete grooving is necessary for the operation of the clutch. The builders advise the use of a thin free-flowing oil for the headstock mechanism.

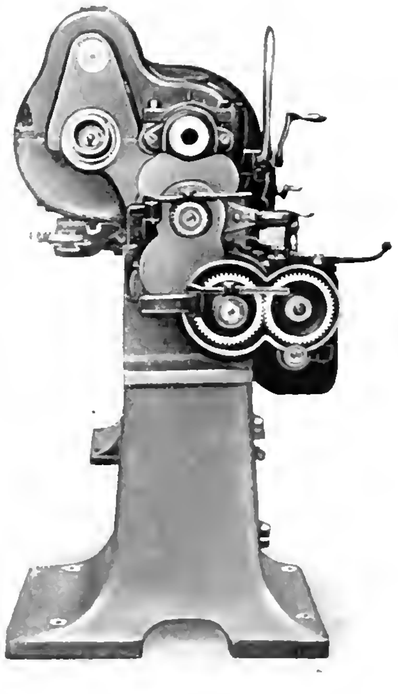

Fig. 2. End View of Lathe showing Feed Gearing Connections.

It will be noted that no adjustment is required, the clutch adjusting itself, each time it is used, to the amount required by the load. It may also be seen that the amount of slippage that takes place before the clutch is engaged is predetermined by the shape of the acting surfaces of the lever and cam, as there is no possibility of the parts ever slipping for more than the merest fraction of a revolution. The wearing surfaces are far more durable than in the ordinary type of friction clutch. This durability is still further enhanced by the

method of mounting rings O_1, etc. These, it will be seen, are provided with circular tongues at a, entering corresponding grooves in members D_1, etc. In their open positions, these tongues closely fit the small diameter of the grooves, thus centering the rings in members F_1, etc., and holding them entirely free from these members, so that there is no rubbing of parts not in action. When the rings are spread open to engage their respective members, the free fit on the outside diameter of tongue a permits them to engage freely and without restraint.

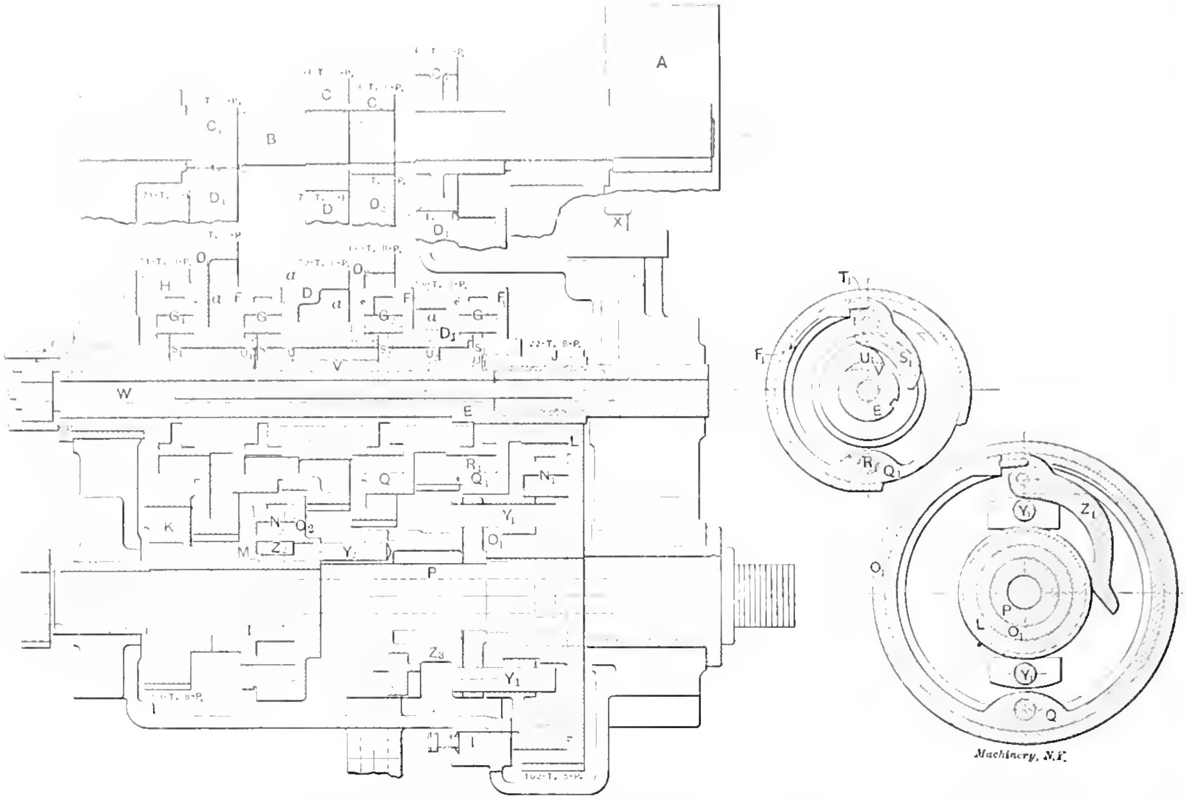

Fig. 3. Head-stock Spindle for Whitcomb-Blaisdell Lathe showing the Gearing, and the Positive-action Friction Clutches which control the Speed Changes.

Spline V carries four cams U_1, U_2 etc., which engage corresponding arms S_1, etc. In the position shown, a movement of spline V to the left will bring U_1 out from under lever S_1, allowing it to drop and thus releasing the clutch. Continued movement brings cam U_3 under lever S_3, thus engaging this clutch. A further movement to the left carries U_3 beyond S_3 and engages U_2 with S_2. The position farthest toward the left brings U_4 and S_4 in engagement. In the reversed motion, the same sequence is gone through in reverse order. This movement of spline V is effected by its connection at the left-hand end with sliding rod W, which passes through shaft E. This rod has pinion teeth cut on its extreme right end, engaging a pinion on stud X, which is in turn connected by gearing with the crank shown at the front of the main bearing of the head-stock in Figs. 1 and 5. The four positions of the spline and the four corresponding speeds are indicated by the dial pointer shown.

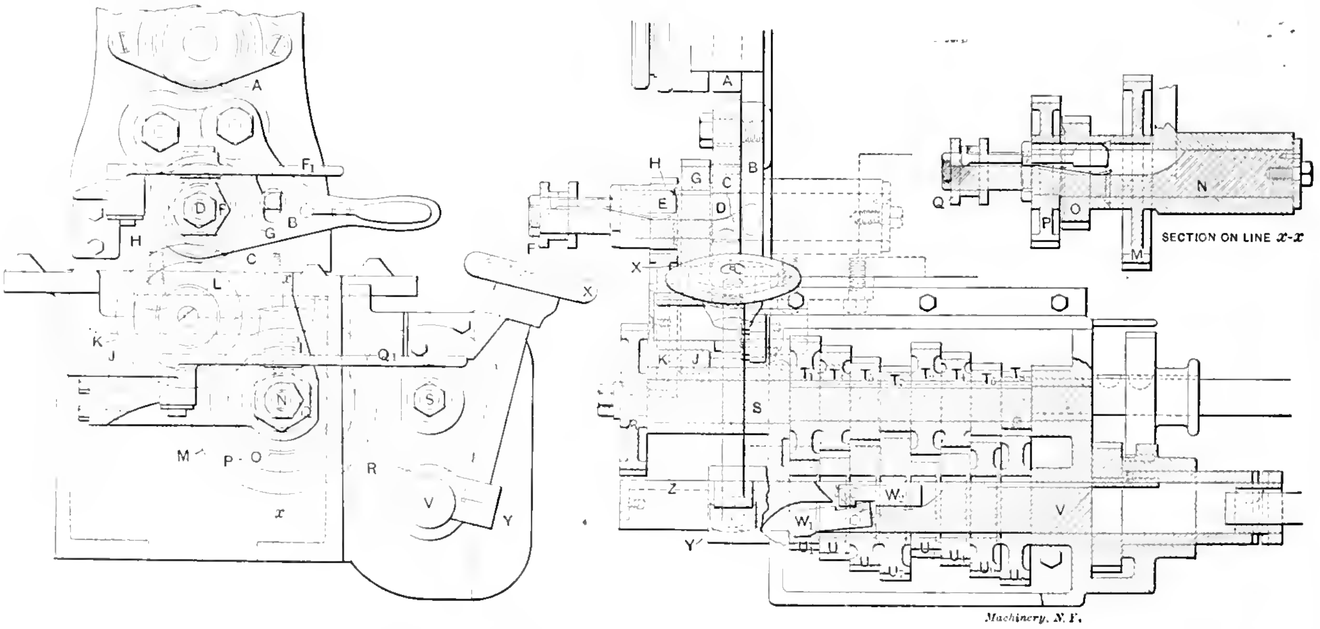

Fig. 4. The Feed Change Mechanism; note the Double Sliding Key for the Gear Box.

Clutches N_1 and N_2 are identical in principle with clutches G_1, G_2, etc., though they differ slightly in construction, as shown in the lower face view at the right of Fig. 3. In these clutches cams U_1, etc., are replaced by pins Y_1 and Y_2, which engage levers Z_1 and Z_2. These pins are fast in the sliding collar Z_3, which is shifted by means of the vertical lever shown at the front of the head-stock in Figs. 1 and 5. Owing to the comparatively slow motion of gear L, two pins Y_1 are provided, while but one pin Y_2 is used. This insures rapid action in the clutch even at slow speeds.

The only criticism that came to the writer's mind in examining and operating these clutches related to the possibility of trouble from a faulty engagement of cams U_1, etc., with their corresponding levers. Such a faulty engagement might take place, if U were brought under S at just the time the

latter came around, so that the engagement took place on the corner. It appears that this sometimes happens, without ill effects, however. If the corners of the engaging surfaces are new and sharp, *U* may easily be pressed into complete engagement. If the corners of these surfaces should be rounded from long usage, they disengage themselves and the operator throws them in again immediately.

A detail in the construction of the head may be noticed at *I*; this is a spring plunger which may be pressed into engagement with corresponding notches in the face of member O_1 which is keyed to the spindle. It is thus possible to lock the spindle for unscrewing chucks, faceplates, etc., from the nose.

The Feed Changes.

Provision is made in this lathe for thirty-two changes of feed for turning or threading, without removing or changing the gearing. Figs. 2, 4 and 5 show how this is effected. The feed driving gear *A* on the spindle is connected through the usual reversing tumbler gearing on sector *B*. Gear *C* is keyed to shaft *D*; this shaft is slotted for sliding key *E*, operated through collar *F* by horizontal lever F_1. Key *E* may be set to drive either of gears *G* and *H*; these are separated by the hardened internal collar shown, which withdraws the key from one before it engages with the other. Gears *G* and *H* mesh with corresponding gears *J* and *K* keyed to the hub of pinion *L*, which thus may be given either of two rates of speed. *L* and *K* engage gears *M* and *O* on shaft *N* (seen best in the detail at the upper right-hand of Fig. 4) through a sliding key arrangement exactly similar to that in the shaft *D*. Either of gears *O* and *M* may be engaged to *N* by the shifting of collar *Q*, and the horizontal handle Q_1 attached to it. Shaft *N* thus has four rates of speed, which are transmitted through gears *P* and *R* to shaft *S*, in the feed box proper.

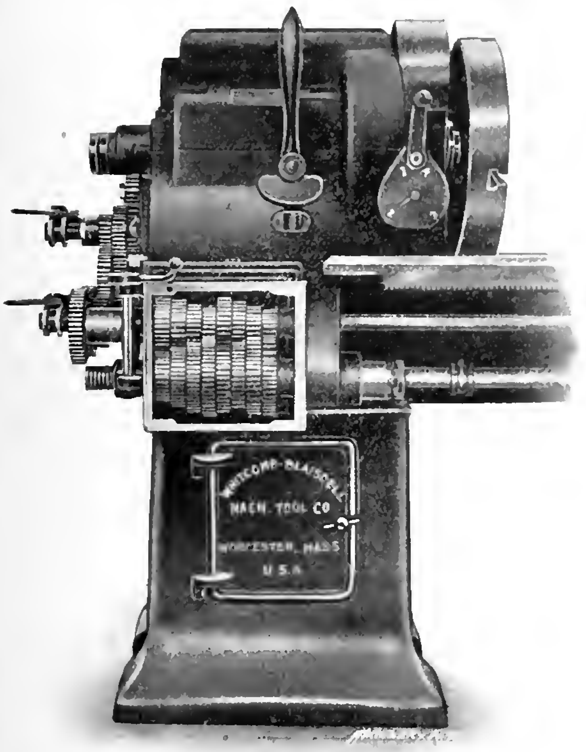

Fig. 5. View of Head-stock End of Lathe, with Gear Covering Removed.

This feed box is of the sliding key variety, but differs radically from the usual type in the details of its construction. This will be inferred from the arrangement of the gears, as shown in Fig. 5, where it will be seen that they are disposed in the form of a double cone on each axis. The reason for this will be apparent in the line drawing, Fig. 4. Gears T_1, T_2, T_3, etc., are keyed to shaft *S*, which, as explained, can be connected with the spindle in four different ratios. These gears mesh with mating gears U_1, U_2, U_3, etc., on sliding shaft *V*. These gears are engaged with *V*, in turn, by keys W_1 and W_2, which are pivoted to *V*, and are connected with each other by the spring and interlocking surface shown, so that when one moves into engagement the other drops out, and vice versa. This alternate movement in and out of engagement is effected by the hardened washers placed between each of the gears. As *V* in Fig. 4 is shifted to the right, the washer between U_1 and U_3 throws key W_1 out of engagement and puts a tension on the spring connecting W_1 and W_2, so that the latter is thrown into engagement with the spline in gear U_2, as soon as it comes into position to do so. A further movement of *V* disengages W_2 and throws W_1 into engagement with U_3. The order of engagement as *V* is shifted to the right is thus, U_1, U_2, U_3, U_4, etc.

V is shifted by means of a sleeve *Z* attached to its outer end, which has rack teeth cut in it meshing with pinion *Y*, at the lower end of the vertical rock shaft shown in Figs. 2, 4 and 5. This shaft has a handle or knob *X*, and carries a dial with figures corresponding with the pair of gears engaged. Referring to the feed and thread plate at the front of the head-stock, the operator may find the number of threads per inch given by each of these eight positions, in combination with the four changes effected by the horizontal levers. The feeds are five times as fine as the threads.

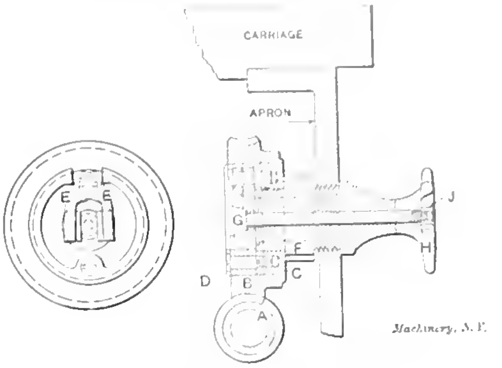

Fig. 6. Adjustable Friction Drive for Apron Feeds.

The advantages of this form of gear box lie in the short axial movement required for the sliding keys, and the correspondingly compact arrangement of the controlling mechanism for the eight changes. It should be noted also, that, owing to the fact that when one of the keys is in engagement the other is withdrawn, there is little wear on the hardened washers separating the gears. A much better selection of threads has been provided in this box than usual, owing to the fact that the gears have not been limited to even pitches. Where it was necessary in the gear box, in obtaining a desired ratio, to employ fractional pitches, this has been done without hesitation, so that the pitches of different gears vary, though they are most of them about nine diametral. Each of gears U_1 and U_2 has six splines in its bore, so that they engage quickly. Provision is made for disconnecting either the feed rod or the lead-screw from the feeding mechanism, by means of the sliding gear and sliding clutch shown at the right of Fig. 4.

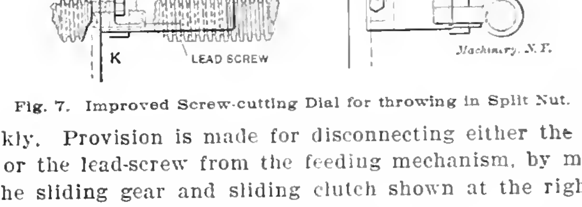

Fig. 7. Improved Screw-cutting Dial for throwing in Split Nut.

The Carriage and Apron.

The details of the carriage construction follow the standard practice of the builders in most particulars. There are, however, two points of improvement which are worth mentioning. One of them relates to the friction drive for the feed. This is shown in section and plan in Fig. 6. The worm *A*, keyed to the feed rod, engages a wormwheel *B* which normally revolves

loosely on clutch body *C*. Split friction ring *D*, pinned to *C*, may be spread apart by the double levers *E*, so that the worm-wheel drives *C* and the pinion *F*, to which, in turn, *C* is pinned. Levers *E* are spread apart by turning bolt *G* so that the circular portion of its head, instead of the flat portion, is brought around between the ends of the levers. Bolt *G* is turned by knob *H* on the outside of the carriage. The improvement in its construction lies particularly in the method of adjusting the clutch from the outside. This is done by nut *J*, which draws in bolt *G* against the pressure of the spring under its head. Owing to the conical shape of the round portion of the head of *G*, the axial movement operates to spread the levers further part, and thus adjustment is made for wear.

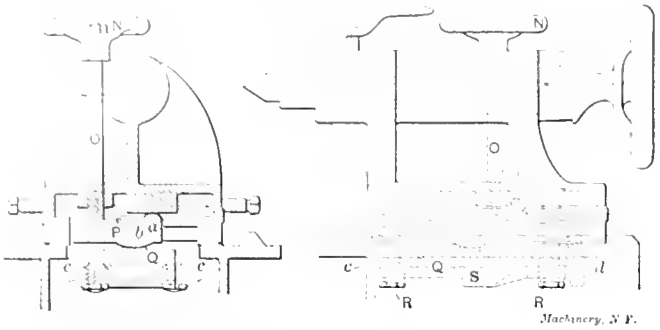

Fig. 8. Tail-stock, showing Method of Clamping at the Four Corners with Single Hand-wheel.

Another improvement in the construction of the carriage relates to a threading device which has been provided. This is shown in Fig. 7. The principle of the arrangement, it will be observed, is the same as that employed on other makes of lathes for indicating the points at which to throw in the half-nut to "catch the thread" when running the carriage back by hand for a new cut in threading. Worm-wheel *K* meshes with the lead-screw and is always in engagement with it. This is connected by gearing in the ratio of 2 to 1 with the vertical shaft *L*, which carries at its upper end a revolving dial having graduations indicated by a stationary pointer. The improvement consists in providing three concentric circles for these graduations, one for even pitches, one for odd pitches, and a third for half pitches. This provision makes it possible to catch the thread much quicker on even pitches than would otherwise be the case, while the cutting of half pitches is provided for. This is not usually done. The pointer is moved toward or away from the center to agree with the circle of graduations it is desired to read. It is evident from the dial that the wormwheel *K* has a pitch circumference of 4 inches.

The Tail-stock, Taper Attachment, Etc.

The tail-stock clamping arrangement is original with this lathe. It is shown in Fig. 8. The tail-stock is clamped to the bed at the four corners by means of hand-wheel *N*. This is keyed to the threaded stud *O*, which may thus be screwed down against the hardened plate bearing in lever *P*. This latter is fulcrumed at *a* against the under side of the tail-stock, and has a spherical boss at *b*, which bears against a hardened plate on clamping lever *Q*. This latter is hung from spherically seated nuts on studs *R*, which form a fulcrum for it. The outside ends at *c* bear on the under side of the ways of the bed, clamping the tail-stock at the front end. Pressure is also transmitted from lever *P* through lever *Q* to the outer end of lever *S*, which in a similar way through similar bearing points *d*, clamps the rear end of the tail-stock. Springs near bearing points *c* and *d* throw the clamping surfaces out of engagement when hand-wheel *N* is screwed back to relieve the pressure.

The advantages of this arrangement lie in the very firm clamping which can be obtained, and in the handiness of the operation, it being necessary to make but one movement to clamp the tail-stock. Ordinarily there are at least two, and sometimes four nuts to be tightened. The workman is often careless about this, tightening only one. With this arrangement, the clamping action is simultaneous at the four corners with but one movement. Of course in adjusting the tail-stock, it is necessary to so set the nuts or studs *R* that the clamping action is evenly distributed.

Among the advantages of this lathe is that common to all lathes of the single pulley constant speed type, namely, that of delivering the same horse-power through all the changes of spindle speeds. In addition, this lathe never has to be slowed down to make any change in speeds or feeds, all of which may be effected by an unskilled operator, at full speed, or under the heaviest cuts. All the gearing in the head runs in oil, and it has been found to require no attention after many months of continuous operation, and then the only requirement was that of refilling with oil. The construction will thus be seen to possess marked advantages from the standpoints of both operation and maintenance.

DIAMOND MACHINE CO.'S FACE GRINDER.

The accompanying engravings show the general features of a large face grinder which has been designed by the Diamond Machine Co., of Providence, R. I. While this machine was planned with reference to the particular work of grinding locomotive guide bars, its construction is such that it will be found useful for the general run of surfacing operations in the ordinary machine shop.

The machine consists, as may be seen, of a reciprocating work-table, sliding on a long bed, which carries the work back and forth before the face of a large ring emery wheel, held in a steel-bound adjustable chuck, which so supports the wheel as to make it entirely safe at any reasonable speed. The bearings are of ample area, and are lined with a high grade of babbitt; they are ring oiled, and protected from dust. The end pressure is taken by a ball thrust bearing. The longitudinal table movement is obtained by an open and cross belt reversing mechanism, connected to the table rack by heavy gearing. The mechanism used is similar to that found on the planer. It is regulated for any desired length of stroke by the shifting of adjustable dogs. When it is desired to operate the table by hand, the clutch is thrown in to connect, with the table gearing, the hand-wheel shown at the front of the bed. The cross feed is effected by adjusting the spindle head axially along the rearward extension of the bed on which it is

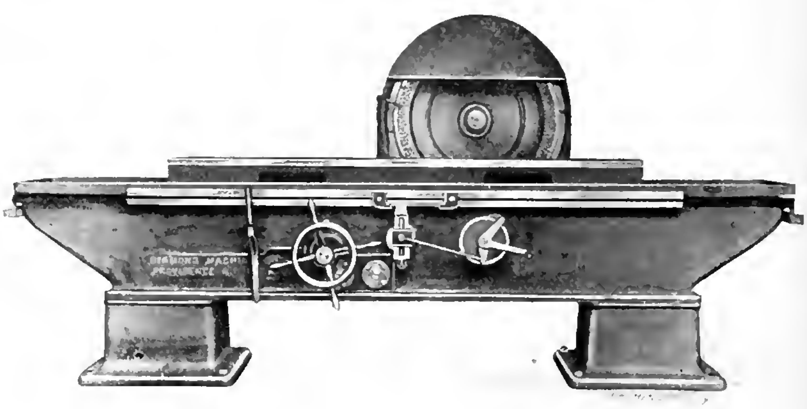

Fig. 1. Face Grinder for Finishing Guide Bars and General Work.

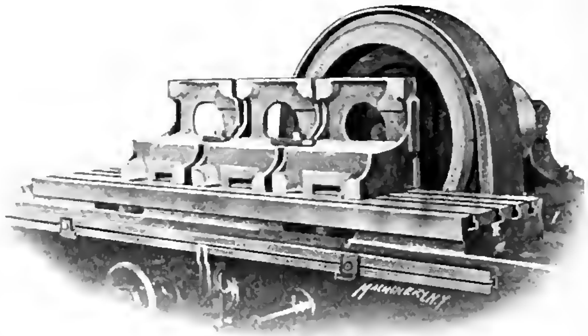

Fig. 2. Facing Machine Parts on the Grinder.

mounted. This cross feed is shown connected for automatic control in Fig. 1. It is capable of very fine adjustment.

One of the advantages claimed for this machine in the work of finishing flat surfaces, is the fact that it works with equal facility on hard or soft iron, or may even be used for hardened steel. The work does not need to be so rigidly fastened as on a planer or milling machine. The movements of the mechanism are of great rapidity, as compared with those of other machines for this class of work. It has been profitably applied to such miscellaneous operations as the finishing of machine columns, water meter cases, water pipe flanges, lathe legs, floor plates, etc. It is shown in Fig. 2 grinding a casting of a form often met with in machine shop work.

This machine is built in either 7-foot or 9½-foot lengths, and for belt or motor drive. Longer machines can be made if desired. On the 7-foot machine the clamping surface of the platen is 7 feet long and 17½ inches wide. The table travel is at the rate of 20 feet per minute. The wheel is 30 inches in diameter and runs from 350 to 700 revolutions per minute, depending on the nature of the work. The wheel spindle bearing is 3½ inches in diameter and 10 inches long. The floor space required for operating is 18 feet 4 inches long by 7 feet wide. The weight complete, with counter-shafts, is about 8,000 pounds; with a motor drive which is self-contained, the weight is about 10,000 pounds. An automatic pump with suitable attachments for wet grinding is furnished on all machines.

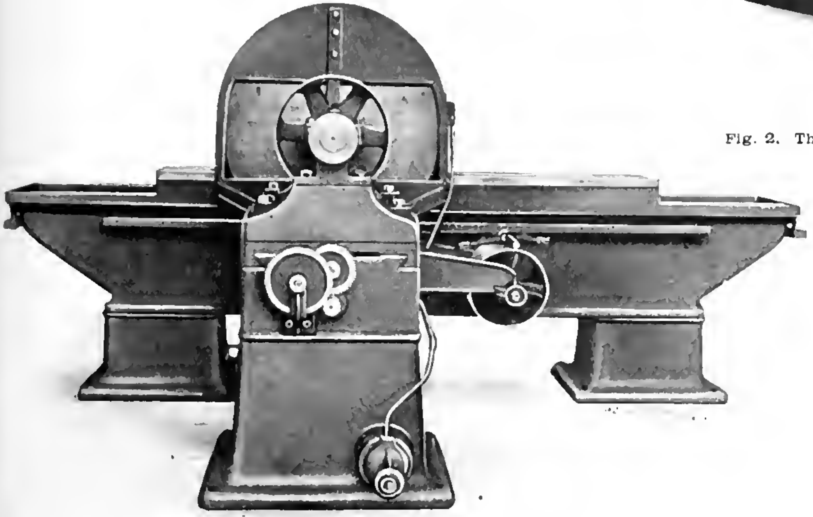

Fig. 3. Rear View of Diamond Face Grinder.

SCHELLENBACH-HUNT UNIVERSAL MICROMETER AND SURFACE GAGE.

The four half-tone engravings published herewith give a very good idea of the range of usefulness offered by a new micrometer measuring instrument, made by the Schellenbach-Hunt Tool Co., Cincinnati, Ohio. It is intended to be used as a widge-range micrometer caliper in either of the two positions shown in Fig. 1 or Fig. 2, as a height gage (see Fig. 3), or as a micrometer scratch gage for laying out work as shown in Fig. 4. All these various applications are possible with very little change in the instrument itself.

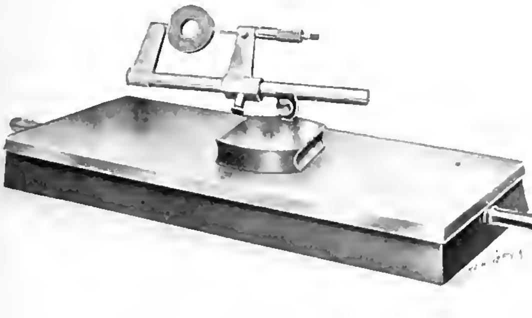

Fig. 1. Schellenbach-Hunt Measuring Instrument arranged as a Bench Micrometer.

As may be seen in Fig. 1, where the instrument is arranged as a bench measuring instrument, the micrometer head is carried by a sliding jaw, which is adjustable to eight different positions on the bar or beam of the caliper. The bar can be shifted endwise to any desired position in the base clamp, and by a quarter turn backward, the instrument can be lifted out of the clamp and be placed inside or outside of the jaw, as may be necessary to permit it to be moved to the desired location as indicated by the graduation on the bar. These locations, of course, are for even inches. The length of the jaws is such that round work up to 4 inches in diameter, and flat work up to 7 inches in length, can be calipered to thousandths of an inch.

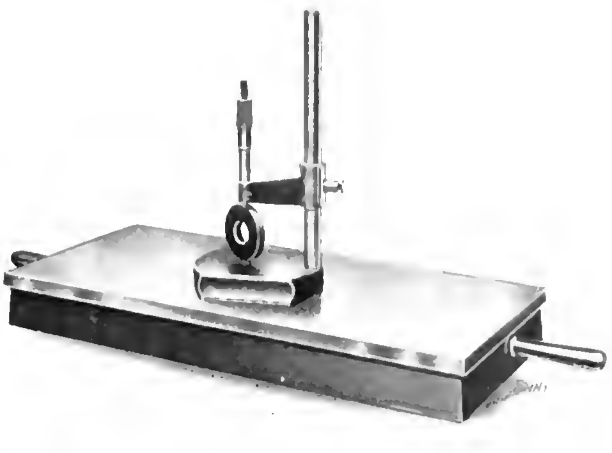

Fig. 2. The Same Instrument used as a Micrometer on an Anvil Base.

The location of the sliding jaw on the bar is determined by conical holes in the center of the flattened side of the latter. To set the jaw, it is only necessary to slide it to approximately the desired position and then screw the locating pin down until its conical end seats itself in the bar. This both positions and clamps the jaw rigidly at the same time. The bar, as well as the locating pin and the bushing which guides it, are hardened, ground and lapped.

In Fig. 2 the instrument is seen with its fixed jaw or anvil head removed, and with the bar clamped in position on the base, with the point of the measuring screw over an anvil point in the latter. A 2-inch reference disk is shown held between the measuring points, as in Fig. 1. The capacity of the tool when used in this way is the same as before. The bar is drawn to its seat in the base by the same screw used in connection with the anvil head.

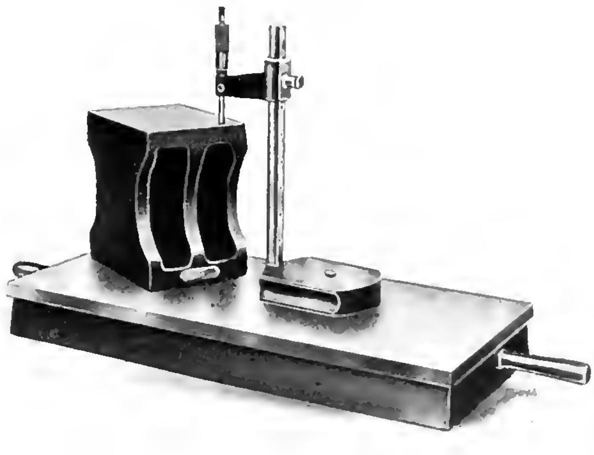

Fig. 3. Arranged as a Height Gage, whose Capacity may be Increased by Height Blocks such as shown.

In Fig. 3 the instrument is arranged for use as a micrometer height or surface gage. The change from Fig. 2 is merely that of turning the bar half way around. In this position any distance from 0 to 8 inches in height can be measured. By the use of cast iron height blocks, such as shown in place under the measuring screw, the range can be extended. The makers

furnish these blocks 6 and 12 inches high; with them, the instrument has a range of from 0 to 26 inches by thousandths of an inch. They are useful in setting the tables of milling and boring machines to exact position in relation to the centers of their spindles, and in connection with measuring the various heights of planed and milled surfaces, the location of jig bushings, etc.

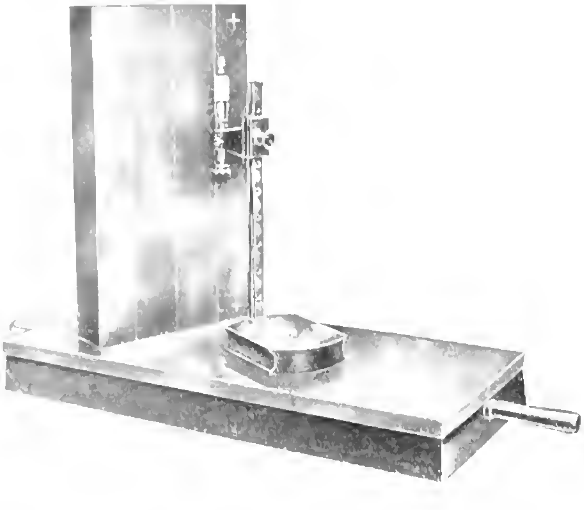

Fig. 4. The Tool arranged as a Micrometer Scratch Gage—laying out Centers for Boring.

In Fig. 4 the instrument is shown with a special circular scribing tool attached to the end of the measuring spindle. When so arranged, it becomes a precision scratch gage—a tool which should be appreciated by any one having to do with the laying out of holes and machined surfaces in work requiring fine measurement. The lower face of the scribing disk is ground at right angles to its bore, while the upper side is ground at a slight angle and to a sharp edge, which is notched. The points formed by the notches are the scribing elements. The lower side of the disk is drilled and tapped for a screw, the head of which projects over the edge of the bore, and locates the scribing lines in the plane of the end of the measuring spindle. The disk is slotted, and is clamped to the spindle by means of a tightening screw. The cutting points are kept sharp by grinding, in the same way that a formed gear cutter is ground. As the face of the disk is a plane surface, grinding the notches to keep the scribing points sharp can be continued indefinitely, without destroying the accuracy of the cutter.

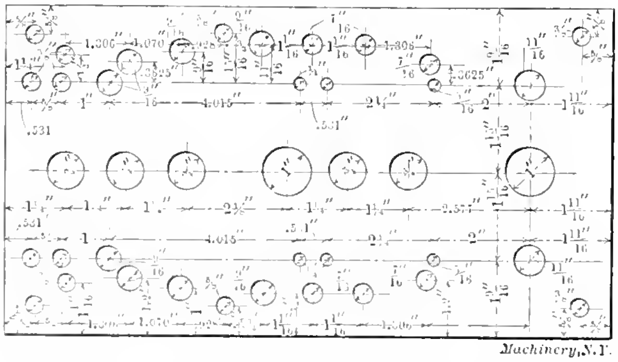

Fig. 5. Diagram of Work being Laid Out in Fig 4.

The particular piece of work which is being laid out in Fig. 4 is shown in Fig. 5, with the measurements of the various holes which are to be drilled in it. The locating of these, it will be seen, involves the taking of a great many measurements, which are made with facility and accuracy when this instrument is used. The measurements from one edge are first made and then the work is placed on its other face and lines scribed for measurements at right angles to the first. The intersections locate the various holes. When used in connection with the height blocks, such as the one shown in Fig. 3, lines may be drawn on work from within 1/16 inch of the base surface to the full range of the instrument, which is 26 inches, as described. It is, of course, understood that the micrometer spindle should be locked before the scribing is done. The provision of a scratch gage which can be set to thousandths of an inch should materially assist the workman in producing good work, in the many operations for which the tool is adapted.

SPECIAL SKINNER CHUCK FOR HOLDING GAS ENGINE CYLINDERS.

The two engravings shown herewith illustrate a special chuck made by the Skinner Chuck Co., 94 N. Stanley St., New Britain, Conn. It is designed for holding gas engine cylinders, and is especially adapted to the work of automobile factories. In the operation for which it is used, the cylinders are bored and faced, and practically finished at one chucking.

The chuck is of the two-jawed universal type. The jaws work together when operated by either screw, being connected by rack and pinion gears which are completely enclosed. Special jaws are used to fit the exterior of the casting which is to be machined. To prevent the possibility of the work's loosening and chattering in jaws at the extreme outer end of the work, they are connected at this point, as shown, by two swing bolts, one on each side. This ties the work and the chuck together, making it practically a solid piece, and permitting heavy cuts to be taken, with the special tools usually provided for such work.

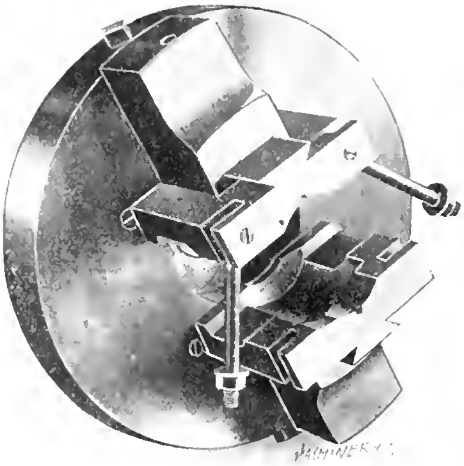

Fig. 1. Special Chuck, provided with Jaws for Holding Gas Engine Cylinders.

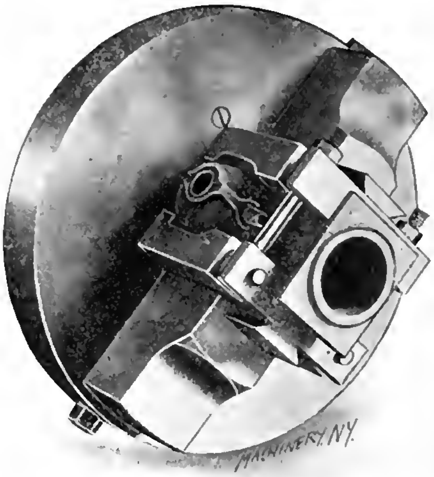

Fig. 2. Work in Place in Chuck. Note the Swing Bolts at Outer End of Jaws.

The chuck is of particular interest on account of its size. The diameter of the body is 24 inches, and the width of the adjustable jaws is 6 inches; the adjusting screw nuts are 1¼ inch square, and the net weight of the device is 490 pounds.

OSTER PIPE THREADING DIE-STOCK.

The Oster Mfg. Co., of Cleveland, O., has added a die-stock for threading pipe from 1 to 2 inches diameter, to its line of pipe-threading tools. This die-stock is so designed that the chasers automatically recede from the work while cutting, thereby forming a standard taper thread; the chasers are controlled by a cam for this purpose. On the face-plate of the die, graduations are provided by means of which special guide posts are set so as to obtain the exact size required to be cut; these guide posts, in turn, drive the cam which operates the chasers or dies. When the die has been set for cutting a certain size, the guide posts are locked by a nut at the bottom of the posts, and the setting remains unaltered as long as threads of a given size are cut. One feature of this die-stock is the universal

gripping chuck which can be adjusted to all sizes by revolving it by means of a handle. This takes the place of all bushings, and makes the die-stock entirely self-contained. The gripping jaws of the chuck are made of hardened tool steel, and consequently will not wear appreciably even after a long period of use.

AMERICAN 36-INCH TRIPLE-GEARED LATHE WITH TURRET ON SHEARS.

The unusually heavy turret lathe shown in Figs. 1 and 2, is built by the American Tool Works Co., Cincinnati, O. It is provided with the regular carriage, tail-stock, center and follow rests, etc., being in this respect identical with their 36-inch heavy pattern engine lathe. The chief point of novelty lies in the turret slide itself, and in the separate feed mechanism provided for controlling it.

The hexagonal turret is indexed by a bolt located at the front of the slide, which brings the locking point very near the tool. This is superior to the usual construction, which locks it at the back, in which case slight wear of the turret locating surfaces is multiplied several times at the tool point. The turret can be indexed automatically, or by hand, or the mechanism can be set so as to be operated, if desired, to run the slide back to the extreme limit without withdrawing the locking pin and revolving the turret. This is done by the small lever shown near the large pilot wheel in Fig. 1.

A unique construction of the turret slide itself, gives it support at the outer end by a gibbed bracket, which travels along the ways of the lathe. This support eliminates any tendency to spring at the extreme travel of the slide. For work which requires the turret slide to pass over the carriage, this bracket can be removed. The turret slide base is moved along the bed by the small pilot wheel shown in Fig. 1. This base is clamped to the lathe bed by two eccentrics, one at each end. It is further secured from slipping under severe end thrust by a bolt which engages a ratchet toothed rack which is cast in the center of the lathe bed, and is used in the same manner, also, for supporting the tail-stock.

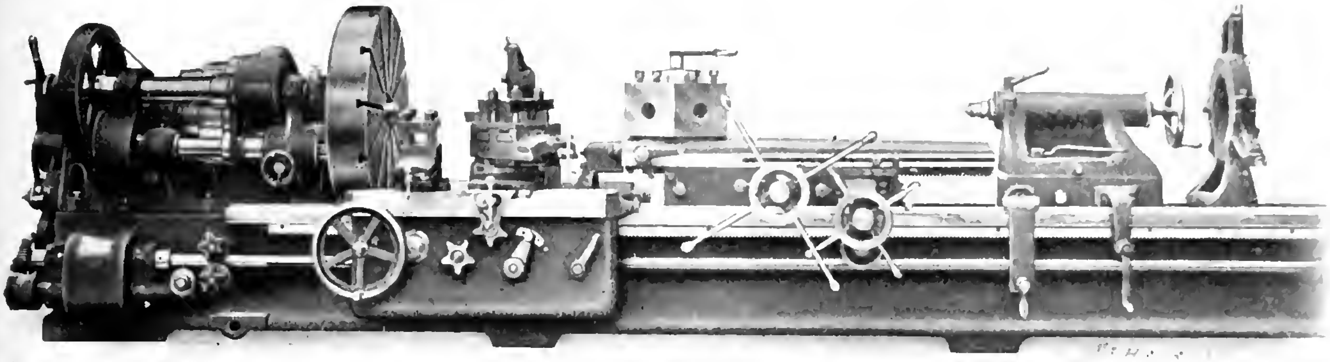

Fig. 1. Front View of Heavy "American" Lathe, with Turret mounted on Independent Slide on Shears.

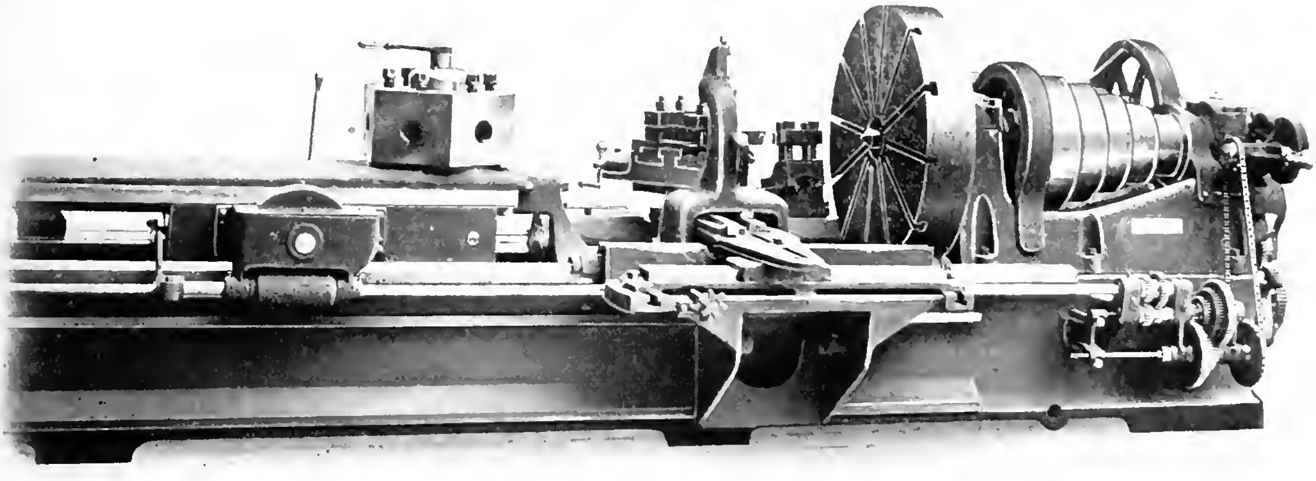

Fig. 2. Rear View of Lathe, showing Special Feed Mechanism for Turret Lathe.

Fig. 2, taken from the rear side of the lathe, shows the supplementary feed mechanism provided for the turret slide. This is driven through reverse gearing, sprockets and chain, from the rear end of the spindle, as may be seen. By means of a sliding key arrangement, eight changes of feed are provided, operated by the knobs shown at the front of the bed, beneath the head-stock. These feeds range from 0.005 to 0.162 inch per revolution, and are entirely independent of the regular carriage and apron feeds. This feed mechanism is provided with a protecting cover which is shown removed in the engraving. The reversing of the turret feeds is a convenient feature in such operations as back-facing and back-counterboring.

Provision is made for attaching the turret slide on the regular tool slide of the carriage, if desired, in work in which it is advantageous to employ the carriage feeds for the turret. This occurs in large tapping operations, for instance, where it is advantageous to give the taps a positive feed through the regular screw cutting mechanism. This arrangement is also of value in the ordinary work of chasing internal threads with the tool.

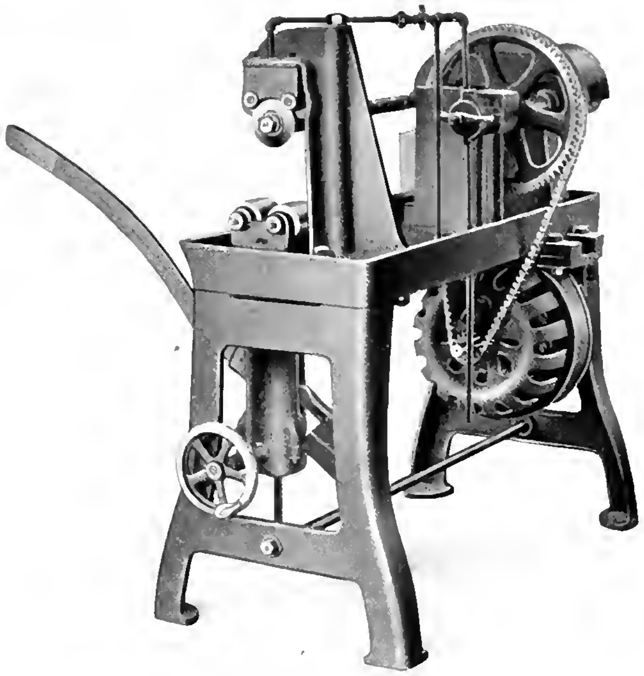
The taper attachment, shown plainly in Fig. 2, is of heavy and substantial construction, and is designed to eliminate all cramping tendencies of the moving parts. It is supported on the bed, though the entire attachment is bolted to and travels with the carriage. It may be quickly engaged or disengaged without disturbing the taper setting. For setting the taper, a vernier arrangement is provided, with a very fine adjustment.

The general features of the lathe are well known. The head-stock is triple back-geared, the regular back-gearing being automatically disengaged when slipping the pinion into mesh with the face-plate gear, and *vice versa*. Three changes of feed or lead are provided for turning and threading, with

each setting of gears. The compound rest is provided with a tool-holder of the four stud type; a serrated base is provided for the tool. The apron is tongued and gibbed firmly to the carriage, extending its entire length. It is double, giving all the shafts a double bearing. Both the longitudinal and cross feeds are reversed from the front of the apron. All the gears and pinions are of steel of wide face and coarse pitch, cut from the solid with special cutters; they are bronze bushed where they run loose. The studs are of crucible steel, hardened and ground, and provided with convenient means for lubrication from the front. The tail-stock is strongly proportioned, with large continuous bearings on the ways; and it can be adjusted rapidly by crank and gear. It is secured against movement by a pawl engaging a rack cast in the center of the bed. The regular equipment of this lathe consists of steady, follow and full-swing rests, counter-shaft and wrenches.

MOTOR-DRIVEN PIPE AND TUBE CUTTER.

In the accompanying illustration is shown a No. 6 Fox pipe or tube cutter equipped with a No. 3 Westinghouse motor, the machine being manufactured by the Fox Machine Co., 815-825 N. Front St., Grand Rapids, Mich. The motor is applied to the machine in a manner permitting of a very compact arrangement, and is mounted on the machine in such a way that practically no change from the standard design is required, except that the bed is provided with two pads onto which the motor is bolted. Instead of the regular tight and loose pulley, a large sprocket is placed on the driving shaft, power being transmitted from the motor to this shaft by a Morse silent chain. From the driving shaft power is transmitted to the cutter shaft by a train of gears. The action of the machine itself is simple. The flue to be cut off rests on two rollers shown in the foreground of the engraving, directly under the cutting disk. The position of the rollers is adjustable for different sizes of pipe, the adjustment being obtained by the hand-wheel shown. The cutting-off operation is accomplished by pressing down on the lever at the left which raises the rollers and brings the flue against the cutting disk. As an example of the capacity of the machine, it may be mentioned that a $1\frac{1}{2}$-inch standard wrought iron pipe can be cut off in about three seconds, and a 4-inch boiler flue in about eight seconds. The machine is regularly equipped with an oil pump and tank for supplying lubricant to the cutting disk.



Fox No. 6 Motor-driven Pipe and Tube Cutter.

As it is often required to place machines for cutting off pipe or boiler flues in places where a line shaft is not available, a motor driven flue cutter should be of especial advantage, and will undoubtedly prove of interest to those requiring machines of this character.

NICHOLSON INSERTED BLADE PIPE TAP.

In Fig. 1 is shown an inserted blade gas pipe tap made by W. H. Nicholson & Co., Wilkes-Barre, Pa. These taps are made regularly in sizes from 1 inch to 12 inches in diameter—an example of the latter size being the one shown. The blades are made of a special grade of tool steel, which is machined with a gib on the lower edge, fitting into a corresponding groove in the body of the tap. The tap body and shank is made of steel accurately finished. After the blades have become worn, the tap can be returned to the makers, who will fit it with new blades at a small cost, making practically a new tool.

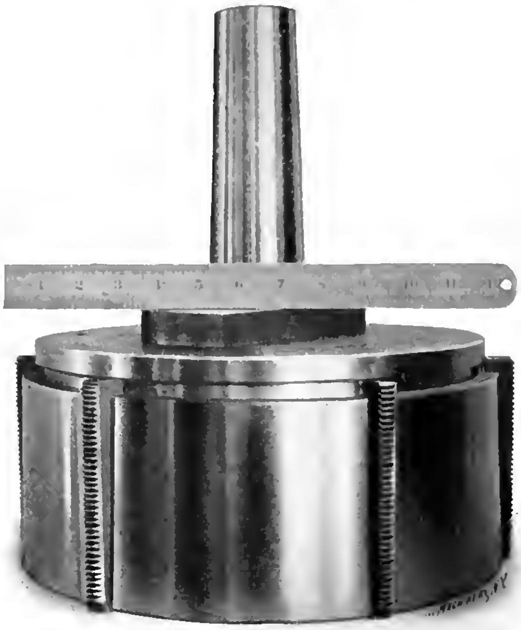


Fig. 1. A 12-Inch Nicholson Inserted Blade Pipe Tap.

This tap is made with shanks of different forms for use in different machines. The example shown in Fig. 1 is intended to be used in a tapping machine, being provided with a taper shank and a driving tongue or tenon, to fit a corresponding slot milled in the face of the machine spindle. These tools may also be conveniently used in the lathe or turret machine. For use in the lathe, the end of the holder is enlarged and bored out to fit the outer end of the tail-stock spindle, thus giving much greater holding power than is ordinarily obtained

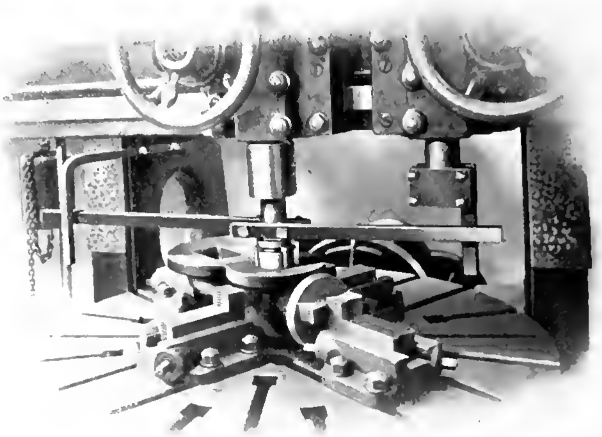

Fig. 2. Using the Tap in a Boring Mill.

for tapping in the lathe. When used in the boring machine or in turret machines, the tap is provided with a cylindrical shank, as usual.

Fig. 2 shows the tap in use on the boring machine. For this work and for the lathe, a squared section is provided on the shank, to which a holding clamp or wrench is attached to prevent it from turning.

HART'S "BUCKEYE" DIE-STOCK OF LARGE DIMENSIONS.

In the April 1908, issue of MACHINERY, an extended description of the design and operation of the Buckeye die-stock manufactured by the Hart Mfg. Co., 10 Wood St., Cleveland, Ohio, was given. The principal feature of this construction of die-stock is that the chasers which cut the tapered thread on the pipe, and which are inserted into the die body, are not as wide as the length of the thread; but by a mechanism which permits the chasers to recede from the work as they progress along the pipe, a full length thread of correct taper is cut. Another of the features of the die is that the chasers release automatically when the full length of tapered thread has been cut. A third feature, wherein this die differs from the ordinary die-stocks for pipe threading is in the adjustment of the dies. A wide range of sizes may be cut with the same chasers by simply loosening a screw and setting a stop to the required graduations. For a more extended description of how these features are accomplished mechanically, the description in the April, 1908, issue of MACHINERY, mentioned above, may be referred to. In adapting the Buckeye die-stock to the threading of pipe as large as 4 inches in diameter, it was found advantageous to provide the outside of the body with a large spur gear which meshes with a small pinion placed on the shaft squared on one end and which can be easily turned by a ratchet wrench of special design which is also supplied with the die-stock. The die-stock can also be operated by the ordinary die-stock handles as shown in Fig. 2. When the gear drive is used, the pinion has a planetary movement about the large gear, and its teeth are held in mesh with the gear when the body slides in and out of the frame by a member fastened to the pinion and engaging in the groove at the inside edge of the gear, this member at the same time acting as a guard for the pinion.

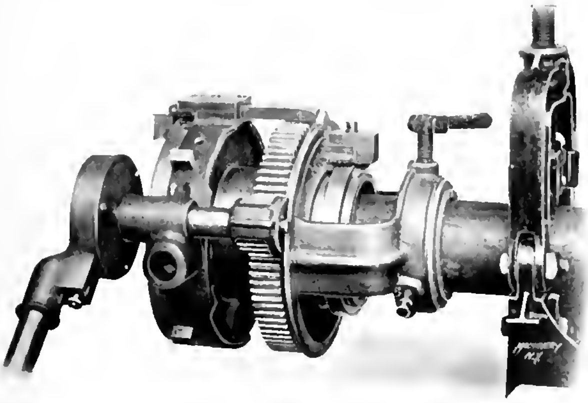

Fig. 1. Buckeye Die-stock for Cutting Taper Pipe Threads up to 4 Inches in Diameter.

The ratchet wrench furnished with the die-stock can be adapted to both right-hand and left-hand threading, by removing the latch pin shown in the engraving Fig. 1 and turning it. In Fig. 2 the cutting-off attachment provided with these die-stocks is shown in operation. The cutting-off tool is fed inward by the knob on the feed screw at the outside end, while the die-stock is turned around in the same way as when cutting threads. Back rests are provided, shaped in the same way as the chasers, but having blank end surfaces. These rests support the die on the pipe during the cutting-off operation.

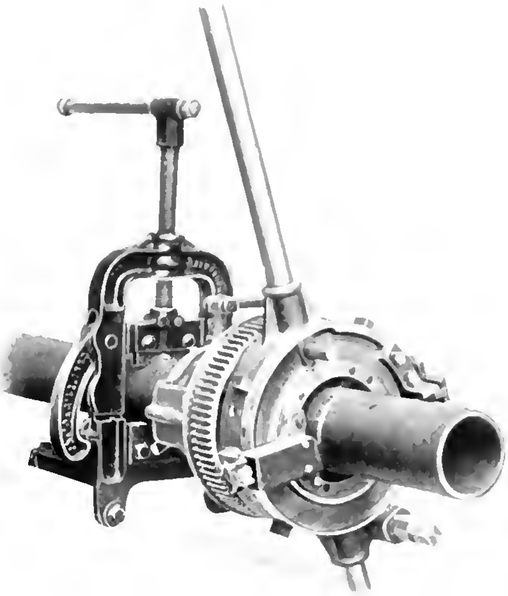

Fig. 2. Cutting-off Attachment mounted on Large Size Buckeye Die-stock.

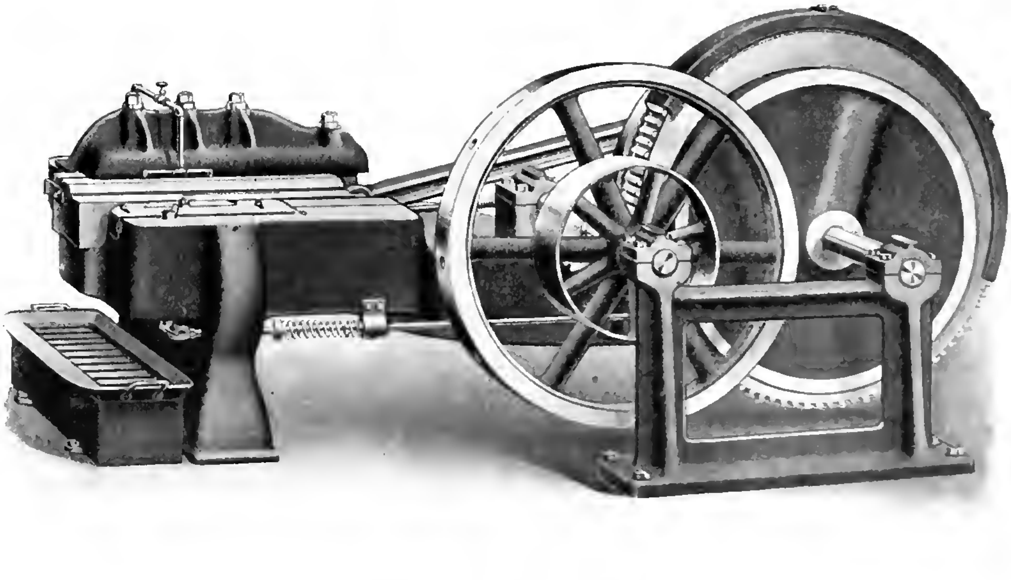
NATIONAL MACHINERY CO.'S THREAD ROLLING MACHINE.

The National Machinery Co., Tiffin, Ohio, has recently placed on the market an improved thread rolling machine, of which we show an illustration herewith. The machine is of the reciprocating type, in which the blank is started at the commencement of the stroke between flat reciprocating dies, grooved to agree with the thread it is desired to form on the bolt or screw. The movement of the die, on the forward stroke, rolls the blank through it between the grooved plates, forming the desired thread. Aside from having been redesigned throughout from the standpoints of greater power and durability, this machine has incorporated in it specific improvements in construction. One of these relates to making the slide which carries the reciprocating die, of unusual length, and backing it by a bank of hardened steel rollers, which greatly



Improved Thread Rolling Machine.

reduce the wear and the power required to operate the machine. This slide is operated by a crank having a quick return movement, so that the machine can be operated at a high rate of speed, and still allow the operator the maximum time for feeding.

The machine has a capacity for bolt and screw threads of all sizes up to 1 inch in diameter. It operates at a speed of 35 strokes per minute, and its net weight is 18,000 pounds.

IMPROVED ADJUSTABLE REAMER.

An improved reamer with inserted adjustable blades has been brought out by R. M. Clough, Tolland, Conn., this reamer being known as the Style B adjustable reamer. The improvement over previous designs consists in the shortening of the reamer as compared with adjustable reamers as commonly made. On sizes over 2 inches diameter the bodies of the reamers have been made one-half, and on sizes under 2 inches, one-third the total length. The advantages gained by doing this, outside of the decreased cost, are, in the first place, that on large reamers the shortening of the body decreases the weight so that when they are used in a horizontal position the weight does not cause the reamer to run out of true; in the second place, the shorter bodies permit the bottom of the slots for the blades to be given a greater amount of taper so that practically double the amount of adjustment as compared with ordinary inserted blade reamers can be obtained. The blades are fitted in dove-tail shaped slots and adjustment for wear can be made without regrinding the blades, which is necessary when the blades are clamped by screws or nuts. These reamers are regularly made in sizes from 3/4 inch to 6 inches diameter, and provided either with a straight or taper hole for a shell reamer arbor, or with a solid, straight or tapered shank.

COATES POWER ERASER, DRAWING CLEANER AND PENCIL SHARPENER.

The Coates Clipper Mfg. Co., Worcester, Mass., has brought out an electrically-driven flexible shaft device for drawing-room use which can be applied for many different classes of work. As shown in the accompanying illustrations, Figs. 1 to 4, a small motor, which receives its power directly from a lamp socket, is fitted on a pedestal with an independent switch. The motor is provided with a 3-foot long No. 11 Coates flexible shaft and is provided at the end with a clamp for holding circular erasers. It is a very handy instrument to use for extensive erasing on drawings or tracings, and there is less liability of injuring the surface of the paper or cloth than is the case when erasing by hand.

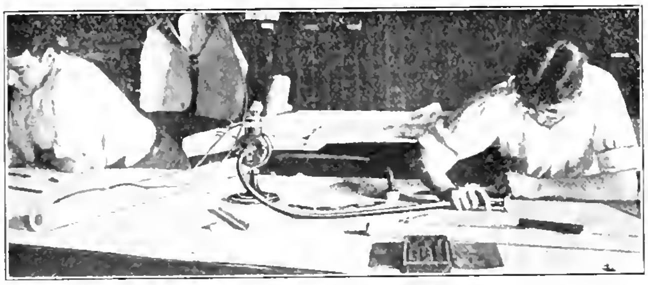


Fig. 1. Coates Electrically-driven Flexible Shaft Device for Drafting-room use, fitted with Ink or Pencil Eraser.

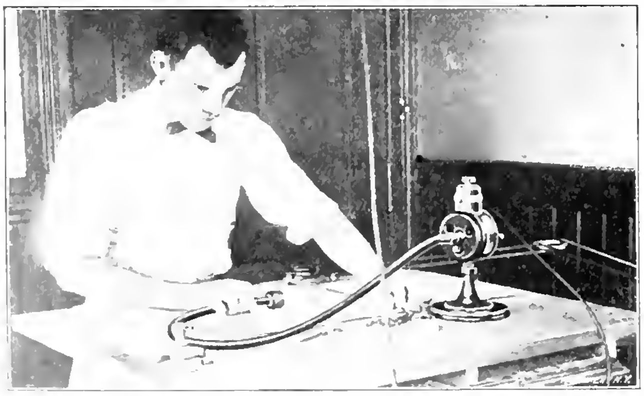

Fig. 2. Soft Rubber Roll fitted to End of Flexible Shaft for Cleaning Tracings.

The end of the flexible shaft can also be fitted with a small soft rubber roll for cleaning drawings when completed. In this way the right pressure can easily be applied to the soft rubber and the drawing is quickly cleaned without affecting the ink lines. A sandpaper disk for sharpening pencils can also be mounted on the end of the flexible shaft. This attachment is very satisfactory for the sharpening of pencils, because as soon as the sandpaper is worn out it can easily be replaced and the pencil sharpener thus always kept in first-class condition.

Fig. 3. Sharpening Lead Pencils on Sand Paper Disk mounted on End of Flexible Shaft.

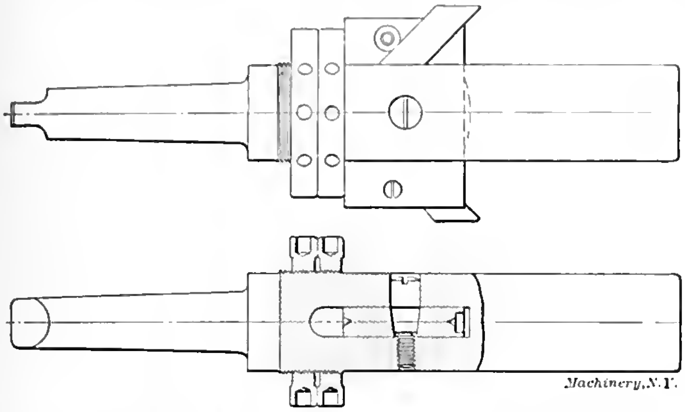
Fig. 4. Polishing Drawing Instruments on the Coates Flexible Shaft Device.

If it is required to polish or burnish drawing instruments, a small crocus cloth wheel can be mounted on the end of the flexible shaft. When ink spots have been left on drawing instruments and allowed to harden, or when rust spots have commenced to form, they can be easily and quickly removed by polishing with such a wheel. The needle points can be sharpened and the tools, in general, kept in good condition. These various erasers, sandpaper disks, crocus wheels, etc., are furnished with the device.

KELLY CYLINDER REAMER.

In the July, 1908, issue of MACHINERY three applications of the Kelly adjustable reamer were illustrated and described. The accompanying illustration shows a new cylinder reamer brought out by the Kelly Tool Co., of Cleveland, Ohio, known as the type C reamer. Referring to the engraving, it will be seen that the reamer is mounted in a heavy boring bar, a slot being milled through this bar into which the reamer is inserted; it is held in place by a screw passing through the bar and the reamer body, the hole in the latter being tapered in order to get a proper clamping action. By tightening the screw, a solid boring tool is obtained. In finishing reamers the screw is slightly loosened, thereby allowing the reamer body to "float" sidewise in the slot provided in the boring bar, so as to compensate for any discrepancy in the alignment of the machine. A few thousandths inch, or in extreme cases 1/64 inch, is sufficient "float" to enable both blades of the reamer to locate themselves centrally with the bore, and each blade will have an equal amount of work to do, a uni-

form diameter of the hole throughout being ensured. It will be noted that the cutter or reamer body itself is made of one sold flat piece of steel and is hardened, and into this the cutters are tightly fitted, being ground to fit 10 degree dove-tailed slots in the body. Hardened gib-bushings with a 10 degree taper, supply pressure on the outer side of the blade and force it against the inner wall of the dove-tailed slot. At the back of the tool is placed a hardened adjusting screw of fine pitch, which insures that the reamer will cut its exact calipered size.



Kelly Adjustable Reamer mounted in Boring-bar for Cylinder Boring.

For more detailed description of the reamer itself we refer to the article published in the July, 1908, issue of MACHINERY, mentioned above, the present illustration showing merely an interesting arrangement of the tool for boring cylinders and similar heavy work.

ALFRED BOX & CO.'S MULTIPLE DIE, BOLT AND PIPE THREADING MACHINE.

Alfred Box & Co., Philadelphia, Pa., have recently devised a bolt cutter of unusually convenient construction, being so arranged that it carries a number of dies ready in place to be used. The machine shown provides for eighteen of such dies, which may be for pipe threads, United States standard threads, or special straight or taper threads. The machine may thus be equipped for all of the regular run of work in a shop, making it possible to do odd jobs or manufacturing operations with equal facility.

The separate dies are mounted at the front ends of short quills, carried in bearings in the large face turret. This face turret is locked by a projection on a steel spring handle, shown at the left of Fig. 1, which engages notches in its periphery. The quills are driven by clutch members at the inner end, which are given the form of gears, as is shown in Fig. 2. The gears form clutch teeth, which engage with similar internal projections at the front end of the hollow spindle of the machine. This spindle is driven by a large gear, meshing with a pinion on the cone pulley shaft, as shown.

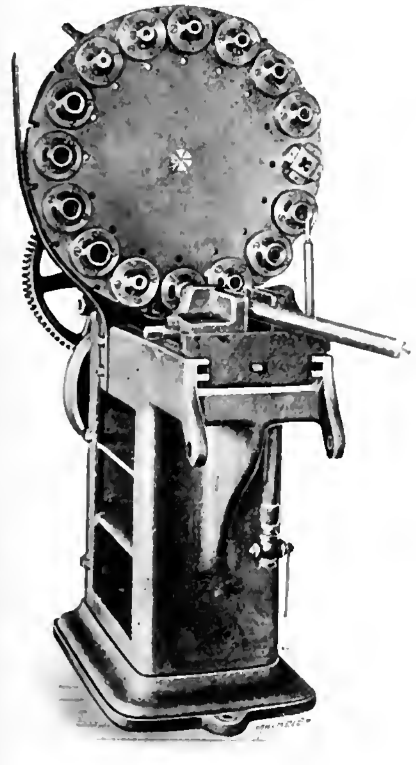


Fig. 1. A Bolt or Pipe Threader, with a Variety of Dies ready for Use.

In indexing to change from one die to another, the lever in back of the turret head in Fig. 2 is raised, bringing the turret forward until the clutch driving the die is disengaged The turret may then be rotated until the locking handle drops in the proper notch to agree with the die it is desired to use. The lowering again of the handle at the back of the turret connects that die with the driving spindle.

Provision is made for using dies of various forms. In the engravings, these dies are shown provided with guiding collars, for leading the work into the cutting edges, exactly central with the threads, thus insuring accurate results. The fact that the die quills and the driving spindle are hollow, makes it possible to work on bars of any length. The work is held from revolving by a vise, as shown.

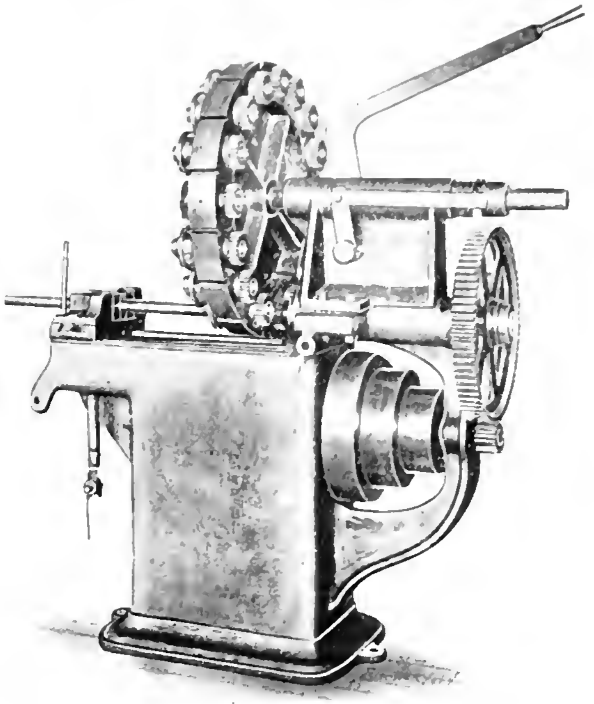

Fig. 2. Rear View of the Multiple Die, Threading Machine.

This machine should save much time in threading bars, pipes, rods, etc., especially in shops where there is much of this work to do in small lots of varying sizes.

HIGH-SPEED UNIVERSAL ATTACHMENT FOR WHITNEY MILLING MACHINE.

Figs. 1 and 2 show a high-speed universal milling attachment designed for use with the well-known milling machine made by the Whitney Mfg. Co., Hartford, Conn. The purpose of this attachment is to provide for the presenting of cutters to the work at any required angle in two planes; and to drive the cutter at a high speed for use with comparatively small cutters and end mills. This high-speed drive, however, is stiffly driven, and will bring out the full capacity of any tool likely to be used with it.

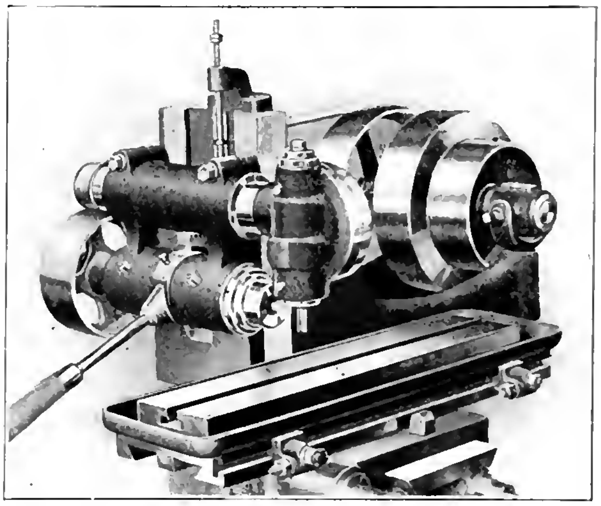

Fig. 1. Vertical Attachment for Whitney Hand Milling Machine.

The attachment, it will be seen, is mounted in the seat provided for the overhanging arm in the cutter slide. It may be revolved in this seat for swiveling the cutter about a horizontal axis. It carries on its outer end a cutter spindle, mounted in a head, which is itself adjustable about a bearing on the arm, on an axis at right angles to that of the latter. This gives the universal adjustment mentioned. The drive is by belt, from the regular driving pulley, over a small pulley at the end of the shaft passing through the center of the arm. At the spindle head, the motion is transmitted from this shaft to the spindle through a train of bevel gears, which permits the universal adjustment. Fig. 1 shows the cutter spindle vertical, while Fig. 2 shows it set at an angle with the horizontal.

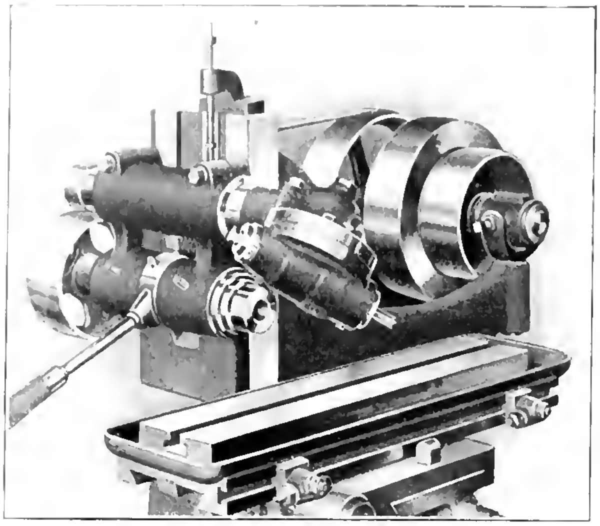

Fig. 2. Spindle of Attachment set for Angular Milling.

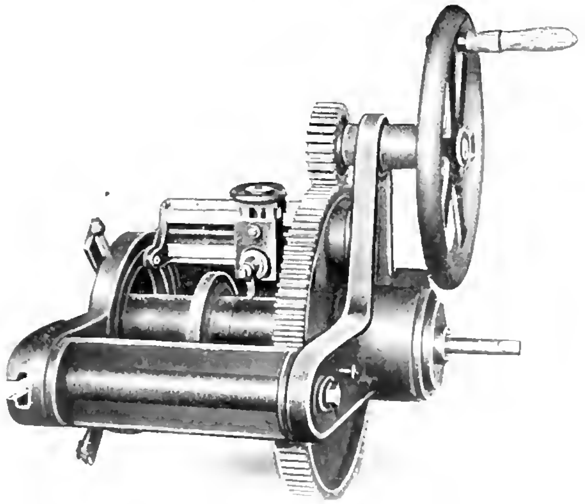
This tool was originally designed by a customer of the builders of this machine, the Porter-Cable Machine Co., of Syracuse, N. Y. The Whitney Mfg. Co. was so pleased with its usefulness in adding to the wide range of work to which the machine is adapted, that they have made arrangements to place it on the market.

STOW CRANK-PIN TURNING TOOL.

We show herewith an improved design of the crank-pin turner made by the Stow Flexible Shaft Co., Philadelphia, Pa. This device is of the type which permits the re-turning of a crank-pin while it is in place on the engine. It is supported at the back end by four jaws which center the tool against the flange of the pin. At the front end, a center is provided, which is screwed into the center hole of the crank pin, thus locating the device by the axis of the pin. When located in this way it is held firmly in place by any suitable clamping device.

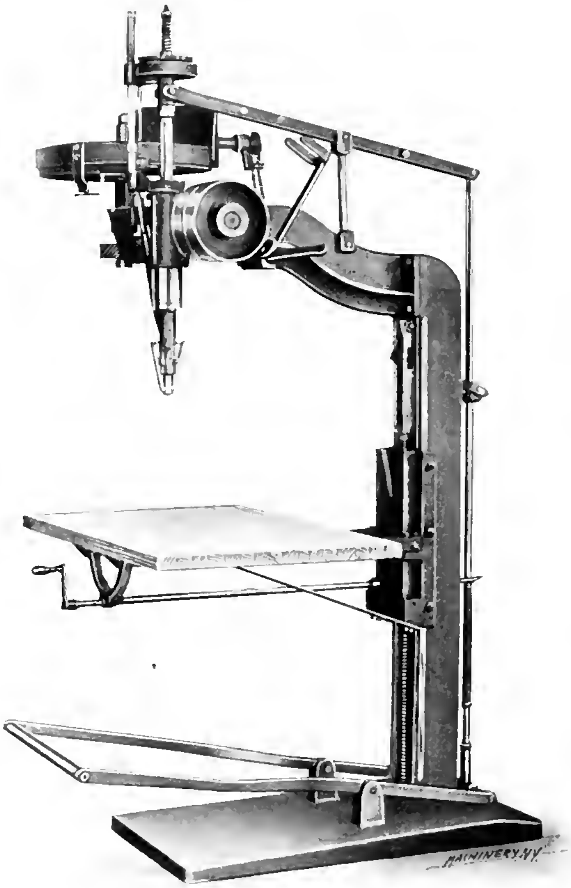


Portable Crank-pin Turning Machine, with rigidly supported Tool Slide.

A particular feature of this tool consists in an improved method of supporting the outer, or free end of the tool slide. This tool slide, it will be seen, is carried by a large gear, driven by the small pinion and hand-wheel shown. The free end of this slide is clamped to a ring, which is a running fit in a seat at the inner end of the frame. The tool slide bracket is thus supported at both ends, and is capable of doing much more rapid work than is possible with the usual unsupported construction. The various adjustments and movements of the tool can be readily understood from the engraving.

REYNOLDS AUTOMATIC SCREW DRIVING MACHINE.

A new design of power driven automatic screw driver has been added to the line built by the Reynolds Machine Co., Rock Island, Ill. In this line of machines the screws to be driven are dumped into a hopper or magazine, from which they are taken by a feeding mechanism which brings them into position for driving, at the end of the vertical spindle. There they are held by a pair of jaws, until the driver descends and engages the slot in the head of the screw, and forces it down into the work. The spindle, which is friction driven, runs as high as 1,000 or 1,500 revolutions per minute on the smallest sizes, so that the screws are driven in a fraction of a second. The capacity of these machines is limited only by the ability of the operator to get the work under the spindle, and he has both hands free to do this. Owing to the fact that the spindle is friction driven, the tightness of the drive may be limited to any desired amount.



An Automatic Screw Driving Machine for Large Work.

The particular form of the machine here shown is of larger capacity than anything previously made by the builders. It will set screws to the center of a 48-inch circle, and the table has sufficient vertical adjustment to take in work 30 inches high. The table is automatically raised, just as the screw is started, by means of a cam connection with the foot treadle and spindle operating lever at the top of the machine. The treadle is so arranged that the operator can reach it from any position about the table.

In addition to the usual features of magazine feed, adjustable friction drive for the spindle, etc., the machine has a positive stop which allows screws to be merely started, or set so that the head projects any uniform height desired.

This is effected by providing a braking device for the spindle and a release for the friction drive, which become operative at any desired point in the travel. The first machine of this type was built for the U. S. Arsenal at Rock Island.

NEWTON HEAVY FOUR-SPINDLE MILLING MACHINE.

A four-spindle milling machine of unusally massive construction is shown in the accompanying engravings. It was built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., for the Altoona Shops of the Pennsylvania R. R. The machine is of the planer type, with two side horizontal spindle heads on the face of the housings, and two vertical spindles on the cross-rail.

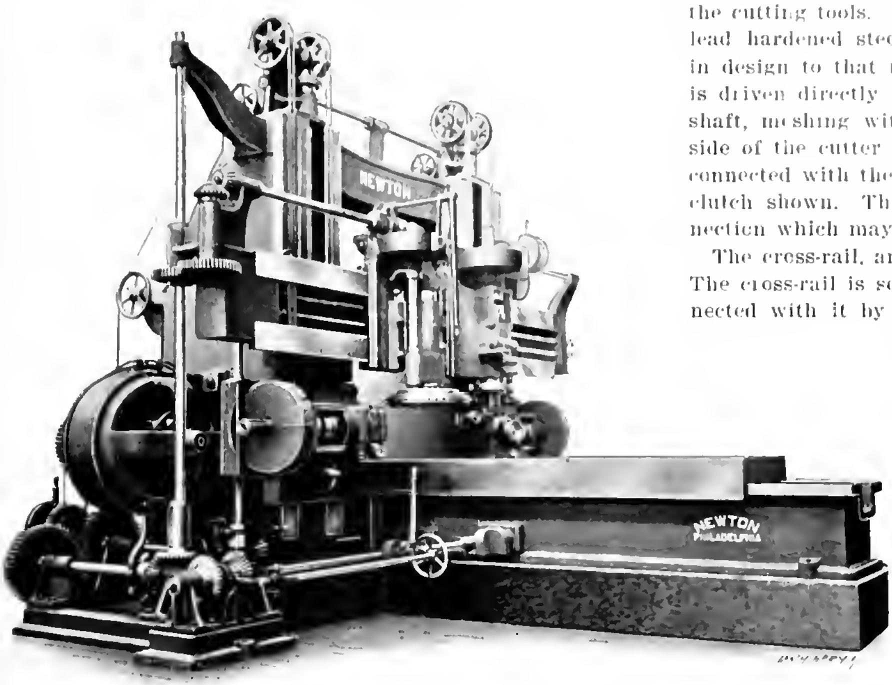


Fig. 1. Heavy Four-spindle Milling Machine, built for the Altoona Shops of the Pensylvania Railroad.

The machine is driven by a 50-horse-power General Electric motor, having a variable speed range from 560 to 1,120 revolutions per minute. As may be seen best in Fig. 2, this is connected through a rawhide idler pinion and idler gear to a cross shaft, from which is taken the motion for the feed and fast traverse of the two vertical heads. As is better seen in Fig. 1, from a smaller pinion on the hub of the second idler, motion is taken through a back gear drive for the vertical shafts driving the two side heads. Motion for the fast traverse and feeds is transmitted through to the working side of the machine, where it is connected with a feed box of the builders' standard design, giving nine changes. The arrangement of feeds and speeds provided makes available individual drive or simultaneous drive for the heads and feed; and fast traverse for the table, for raising and lowering of the cross rail, and for the cross adjustment of the heads on the rail.

The construction of the two side heads and of the right-hand cross rail head is similar. The spindles are 5⅜ inches in diameter and have a bronze bushed bearing 17 inches in length, with a double taper bearing 8¾ inches long at the end of the adjusting sleeve. The ends of the spindle have an external thread, on which face cutters can be fitted; they are provided, as well, with a No. 5 taper for holding end mills. The spindles are provided with through holes for retaining bolts. In addition there is a broad slot milled across the end of the spindle to fit the tenoned drive of large mills and arbors. All the spindle wormwheels are approximately 26½ inches in diameter, and are provided with hardened steel worms having roller thrust bearings. These parts are all encased and run continuously in oil. The rack sleeves in which the spindles are mounted have sufficient length to permit an independent adjustment of 12 inches for the spindle on the saddle by means of the rack and pinion and worm gear mechanism shown.

The left-hand cross-rail head is of somewhat different construction. The spindle is mounted in a slide which has an independent vertical adjustment The spindle carries a solid cast steel rotary planing head 26 inches in diameter over the cutting tools. This cutter head is driven through a steep lead hardened steel worm and a bronze worm-wheel similar in design to that used on the other heads. The cutter head is driven directly by a pinion on the end of the worm-wheel shaft, meshing with an internal gear fastened to the upper side of the cutter disk. This head may be connected or disconnected with the driving mechanism by the hand lever and clutch shown. The right-hand head has a back geared connection which may be thrown in or out, as required.

The cross-rail, and side heads as well, are counterweighted The cross-rail is so arranged that the side heads may be connected with it by swing bolts, and thus elevated or lowered by power when so attached. The elevating screws have roller thrust bearings both at top and bottom, to permit pulling the cutters into the work when sinking in to depth, without putting the screws in compression. The table feed is by a spiral gear and rack, similar in design to the well-known Sellers drive for planers.

The table of this machine is 42 inches wide and 18 feet long, and the feed movement permits the taking of cuts 16 feet in length. The maximum distance between the ends of the horizontal spindles is 60 inches and the minimum distance is 36 inches. The maximum distance between the end of the horizontal spindle and the top of the work table is 66 inches. The minimum distance between the centers of the vertical spindles is 32 inches. The table feeds available at the high speed of the motor range from 0.789 to 8.150 inches per minute. At the slow speed of the motor, these feeds are cut in half. A quick return of about 22 feet per minute is available

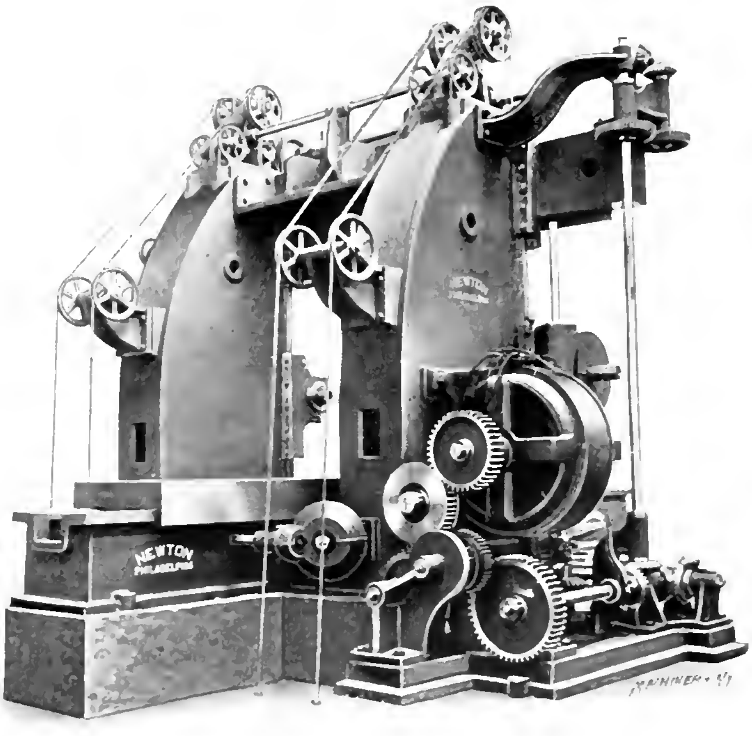

Fig. 2. Rear View of Four-spindle Milling Machine, showing Driving Gearing.

in both directions. The maximum feed of the rail vertically and the saddles on the rail is 1½ inches per minute, with the motor on the high speed.

"STAYIN" POSITIVE DRILL SOCKET.

The G. R. Lang Co., of Meadville, Pa., is placing on the market a drill socket which is intended to obviate the difficulties arising in high-speed drilling from the insufficient driving power of the ordinary taper shank drill with a tang. Under modern conditions this tang is much given to twisting off, rendering an otherwise good drill practically useless. Various appliances have been devised for using such broken drills effectively. The device here shown is intended not only for using such broken drills, but for preventing them from breaking in the first place.

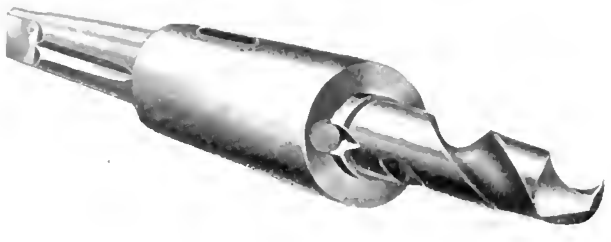

Fig. 1. A Drill Socket which relieves the Tang of all Stress

Fig. 2. An Old Drill Ground for use in the "Stayin" Socket.

Fig. 1 shows a socket of this design which has, as may be seen, a round driving key set in the taper hole. This driving key engages a V-groove milled in the taper shank of the drill. The driving is done by the frictional contact of the taper surfaces, and by the positive action of the round key mentioned. The tang is thus relieved of all strain, and is of use only in driving the drill from the socket. To provide, however, for drills that have had their tangs twisted off, the key slot is made unusually deep. In fixing up old drills to be used in this socket, the shank is ground flat, as is shown in Fig. 2, to give a driving surface for the key. A new and an old drill are shown separately in Fig. 3.

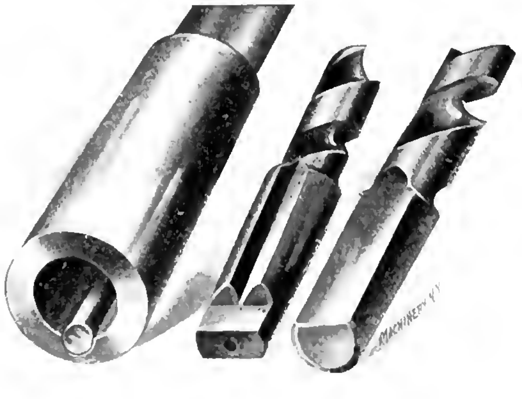

Fig. 3. The Socket and the Drills.

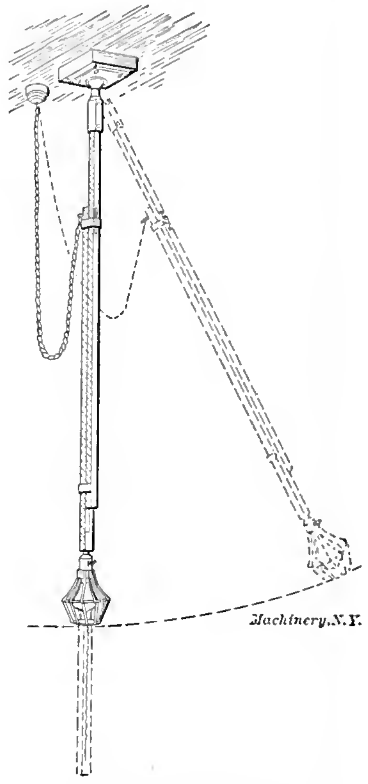
An advantage of this socket as compared with others for the same purpose lies in the fact that it not only holds the drill in the socket but holds the socket in the drill press, as well. The makers will furnish the jig for drilling a keyway in the drill press spindle for inserting the hardened steel rods which are furnished for the purpose. The sockets are made slightly heavier than the standard type, and the key is pressed in. They are all drilled by special jigs, which bring the keys parallel with the axis and central with the drift pin hole. Being accurately finished in the lathe, the taper fit is of the highest order. The makers keep all sizes in stock at practically the same price as the old style sockets.

ADJUSTABLE ELECTRIC LIGHT HOLDER

The Harley Machine Co., 92 Hayden Ave., Springfield, Mass., has brought out an adjustable electric light holder suspended from the ceiling and intended particularly for shop use. As shown in the accompanying line engraving, the holder consists of a ball and socket joint, the socket being fastened in the ceiling, and two wooden bars having a sliding adjustment. The lamp is fixed to the lower end of one of the bars. The socket consists of a steel plate pressed out in the center to fit the ball and fastened at the extreme corners so as to obtain a spring action. The upper end of the ball works in a wooden block fastened to the ceiling, and ample friction is thus provided so that the holder with the light at the lower end will stay in any position radially in which it may be placed, even though there be considerable vibration. The two sliding rods, being made of wood, provide sufficient friction so that the light can be pushed up or pulled down and still remain stationary in any position desired longitudinally. It will be seen that by this combination of movements it is possible to bring the holder to any position in a large circle about its socket and also to raise or lower the light according to the requirements. The difficulties of obtaining light in various positions, as required in machine work, recommend the use of an adjustable holder for the light, and any device providing adjustment will undoubtedly be of interest to mechanics in general.



Adjustable Electric Light Holder made by the Harley Machine Co.

TWO WILLEY ELECTRICALLY-DRIVEN GRINDERS.

Figs. 1 and 2 show two new designs of the Willey grinder as made by James Clark, Jr., & Co., Louisville, Ky. These machines are of the regular construction of this well-known line of tools, in having the motor built into the machine itself, making an unusually neat and satisfactory arrangement.

Fig. 1 is a floor grinder for general purpose work. The motor frame and pedestal are one casting, and the starter is contained in the frame, where it is out of the way and well protected. This starter is made for this particular machine, and is not a commercial product. The armature shaft, which is also the wheel spindle, is very stiff. The motor is especially designed for grinder service, being completely enclosed from emery dust. The tool rests are so supported that they can be adjusted to any desired position. The surface grinding attachment shown over the left-hand wheel is furnished when desired at extra cost.

The addition of a self-contained wet grinding attachment makes of the machine shown in Fig. 1, the combined wet and

dry grinder shown in Fig. 2. With this arrangement, the left-hand wheel is used for dry grinding, and the right-hand for either wet or dry. The attachment consists of a hood, splashing plate for the wheel, a water reservoir, and a settling chamber fitted with a centrifugal pump. The whole is bolted to the bottom of the pedestal, and is steadied at the top by a second bolted connection with the frame. The pump is so made that the bearings are above water, and it has no stuffing box. It is driven from a pulley on the end of the wheel spindle, as shown.

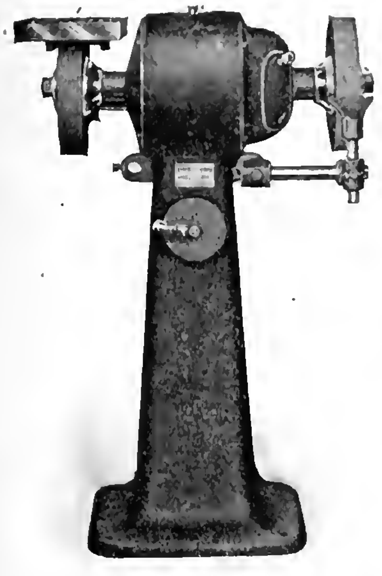


Fig. 1. Willey Electrically-driven Dry Grinder.

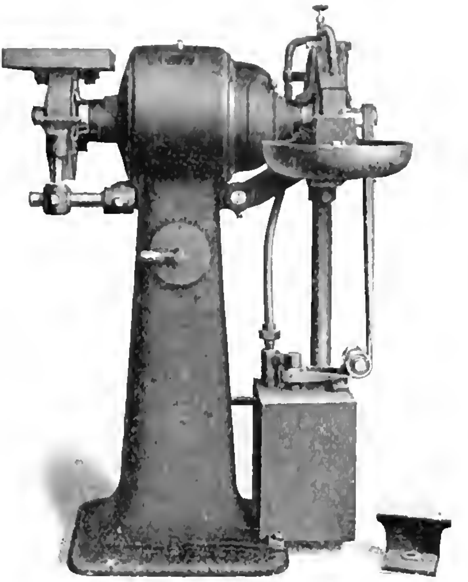

Fig. 2. The Grinder in Fig 1, with Pump and Reservoir Attachment.

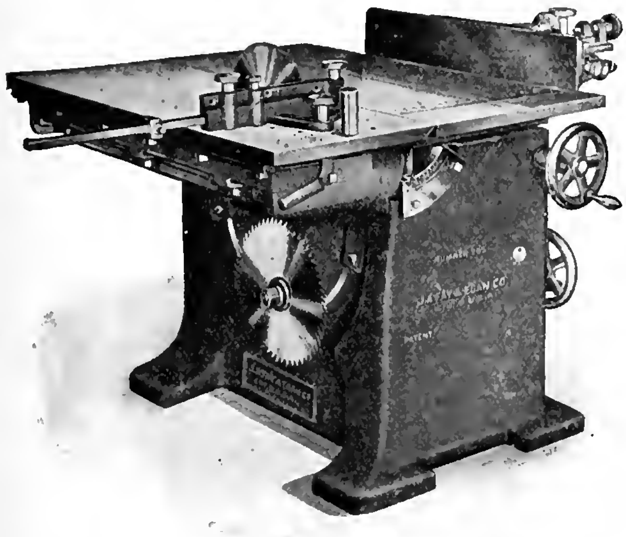
The height of this machine over all is 48 inches. The wheels used are 12 inches in diameter by 2 inches face, and they usually run at about 1,600 revolutions per minute. The net weight of the machine in Fig. 1 is 475 pounds. With the water attachment, as in Fig. 2, it is 670 pounds.

FAY & EGAN DOUBLE CIRCULAR PATTERN-SHOP SAW.

The J. A. Fay & Egan Co., West Front St., Cincinnati, Ohio, is building the improved saw table shown herewith. It is of the type in which cross cut and rip saws are both permanently mounted in the machine, and either may be brought into use as required. In addition to this, the machine is provided with such a variety of adjustments, attachments, gages, etc., as to make it specially adapted to the work of the pattern-shop.



A Combination Cross-cut and Rip Sawing Machine, especially adapted to Pattern Work.

The mechanism for changing the saws and adjusting them for height is distinctly different from other machines of the kind. Both saw arbors are carried in a revolving frame. This overhangs at the front of the machine so that it is a simple matter to take off or put on the saw without disarranging the table. Two saws up to 16 inches in diameter can be used at the same time; if only one saw is used, it may be as large as 20 inches in diameter.

The table is made in two sections; a moving section 44 x 16 inches mounted on anti-friction rollers, and a stationary section 44 x 20½ inches, provided with an extension so that material up to 20 inches in width can be rip-sawed. The moving section of the table has sufficient travel to edge or cut off stock up to 35 inches in length, and it will open to permit the use of a 2-inch grooving head. The whole table can be tilted by a hand-wheel to an angle of 45 degrees with the saw face. This angle is indicated by graduations.

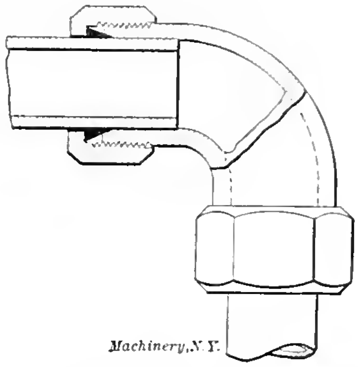
The ripping fence may be set to take stock up to 20 inches wide and be used on either the right or left section of the table. Micrometer adjustment is provided for setting it. The miter cutting-off fence is used on the sliding table, and covers a range from 45 degrees up to 60 degrees. On the front, as shown in the illustration, it is provided with a stop rod to be used for beveling stock to accurate lengths.

The builders will send full illustrations and descriptions of this machine and its mechanism on request.

UNION-CINCH PIPE FITTINGS.

The line engraving shown herewith illustrates the construction of a very ingenious line of fittings, made by the Sight Feed Oil Pump Co., Milwaukee, Wis. The particular feature of this line of fittings is the fact that by their use it is possible to do a complicated job of piping, with nothing more in the way of tools than a hack-saw, a file and a pair of monkey wrenches. The simplicity of this outfit is made possible by the fact that no threading has to be done, the joints being made tight against high pressure on the smooth ends of the pipes.

In the engraving it will be seen that first a gland nut is put on over the end of the pipe. This is followed by a tapered bushing of soft metal. The pipe is then inserted in the fitting, and the nut is screwed down tightly on it, thus compressing the bushing in the tapered space between the outside of the pipe and the flared opening of the fitting. This may be tightened down so firmly as to resist leakage of pressures up to 1,000 pounds per square inch.



An Example from the "Union Cinch" Line of Pipe Fittings, which require no Threading

The advantages of this method of piping are obvious. The connections are made without soldering, flaring, hacking, or using cement of any kind. The usual pipe vise and bench, with a full set of taps and dies and an assortment of pipe wrenches, is dispensed with. Every joint is a union, so that the pipe system may be taken apart at any point and reassembled. A neat looking job at a small expense may be made of steel or brass tubing conforming to the outside diameter of standard pipe sizes. This tubing, which will be furnished by the makers of the fittings, is inexpensive and is carefully annealed, so that it can be readily bent to any desired form.

Fittings are furnished for all required purposes. They are furnished in the form of L's, adaptors for changing from threaded to Union-Cinch pipe systems, T's, couplings, relief valves, etc. They are recommended by the makers for such work as piping up oil pumps, gravity oiling devices, gages,

and drop pipes especially on work of this character around ammonia handling machinery, where the steel tubing and steel fittings are well adapted to keeping the system perfectly free from leakage of the ammonia gas.

IMPROVED SPINDLE ADJUSTING DEVICE FOR MULTIPLE SPINDLE DRILLS.

The accompanying line engravings illustrate an improvement for the adjustment of the tools in metal working machines, recently patented by Mr. F. E. Bocorselski, superintendent of the Baush Machine Tool Co., Springfield, Mass. The illustrations show the device as specifically provided for a multiple spindle drill, and intended for rapid and independent adjustment of the various drill spindles both as regards their location relatively to one another in the horizontal plane as in the vertical direction.

In order to illustrate more plainly the application of the device, the head of a multiple spindle drill press is shown in Fig. 1 and the adjusting device itself is shown in detail in Fig. 2. In Figs. 1 and 2, *A* is the frame of the head of the drill press, *D* is a block attached to the frame by means of the projecting stud *B*, and *E* is a bracket containing a bushing *C* which guides the drill spindle. The object of the design is to provide a simple means by which the spindle guiding bracket *E* may be moved for considerable distance in relation to the head *A* without resorting to a slow screw adjustment. When the head has been placed approximately in the correct position, the minute adjustment may be accomplished by a screw engaging with a half-nut. The device also provides for independent adjustment of the various spindles in a vertical direction, so that any one of a number of drill spindles can be so adjusted that the working end of its drill will be in a horizontal plane with the working ends of the drills in the other spindles, irrespective of the length of the drills. The object desired is accomplished in the following manner.

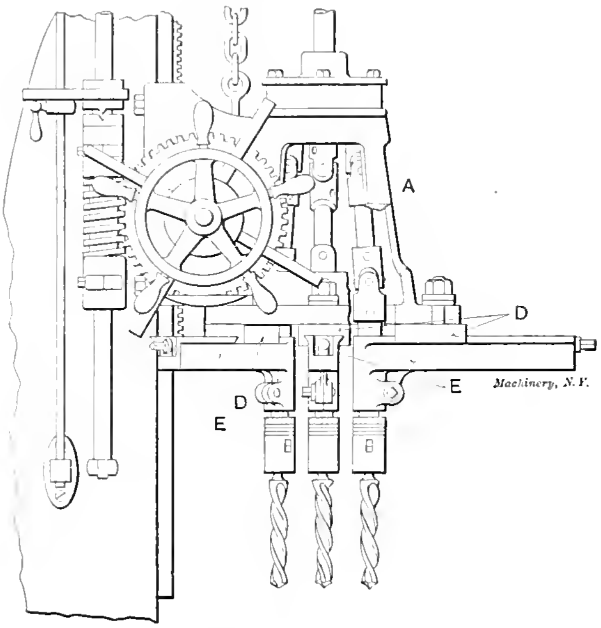


Fig. 1. Multiple-spindle Drill provided with Improved Facilities for Adjusting the Drill Spindles.

The block *D* having a swivel action in relation to the frame *A* permits the spindle *F* to be located in any position radially about the stud *B*. In the lower face of the block *D* a dove-tail slide is cut, into which a slide of the bracket *E* fits. The bracket is provided with a feed-screw *G* which is capable of a swiveling motion downward about the ball point at its further end, and which can by this means be thrown out of engagement with the half nut *H* attached to the block *D*. It is evident that when the feed-screw is out of engagement with the half-nut, bracket *E* can be pushed along by hand until the spindle *F* is approximately in the desired position. The feed screw is then again brought into engagement with the half-nut, and the final adjustment made by the screw. The arrangement of the screw and the half-nut is shown more clearly in the enlarged sectional view in Fig. 3. It will be seen here that the half-nut *H* is connected by studs to a block *K* which is cut out at its upper side to fit the outside of the screw, but which is not threaded. On the lower side of block *K*, the holes for the studs which connect the block with the half-nut are recessed, and springs interposed between the heads of the screws and the bottom of the recesses of the block. The springs keep the screw *G* ordinarily in engagement with the half-nut, but when pressure is applied downward on the end of the screw, the springs will permit it to be brought out of engagement with the nut.

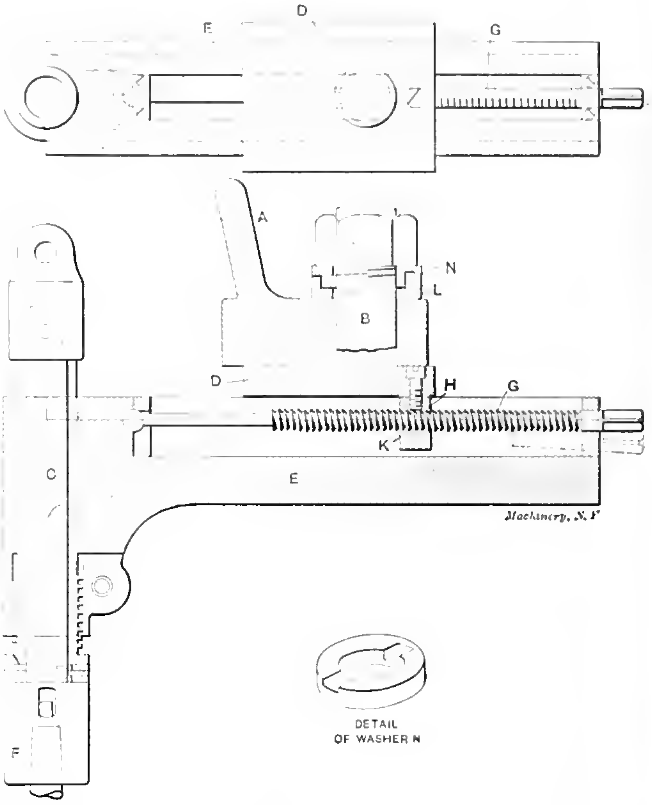

Fig. 2. Details of Bocorselski's Device for Rapid Adjustment of Multiple Drill Spindles.

Another interesting feature is introduced in the washer between the nut on stud *B* and the head *A*. In order to prevent the block *D* and bracket *E* from falling when the nut on the stud is unscrewed, a key is put through a slot in the stud; the ends of this key rest on the washer *L* as shown. On top of the key another washer, provided with a groove to accommodate the key, is placed. The key is tapered and at the large end the slot in the upper washer is not carried completely through, in order to prevent the key from slipping out of its seat accidentally.

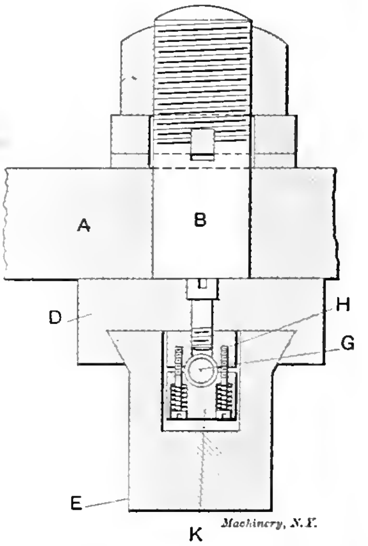

Fig. 3. Section through Half-nut, Screw and Spindle Guiding Bracket.

The vertical adjustment of the spindles is accomplished by means of threading the outside of the sleeve *C* and having it engage with a thread in the vertical hole for the bushing in block *E*. The drill spindle *F* is held firmly by shoulders to the bushing *C* in the longitudinal direction, but, of course, is free to rotate in the sleeve. When the sleeve is adjusted in the bracket, the spindle consequently follows, and thus an independent vertical adjustment is obtained.

While reference has been made especially to the application of this device to a multiple spindle drill press, it is evi-

dent that this is only one example of the utilization of the device, and that it is not limited to the type of machine here shown.

THE "RADICAL" ANGULAR DRILL.

The Radical Angular Drill Co. of 114-118 Liberty St., New York City, is introducing in America a tool for drilling square, triangular and other polygonal holes. It has been used for some time in Germany and other European countries. While this tool resembles all the others of its class, in its general construction, it has some special features which the inventor claims are original and have never before been employed. The most important of these features is the provision made for cutting holes with absolutely flat sides and sharp corners. The device is at least theoretically capable of doing this, and the only theoretical considerations in the way are the matter of accuracy of workmanship, and sharpness and correct form of cutting tools.

Fig. 1. A Device for Machining Square Holes, with Sharp or Round Corners.

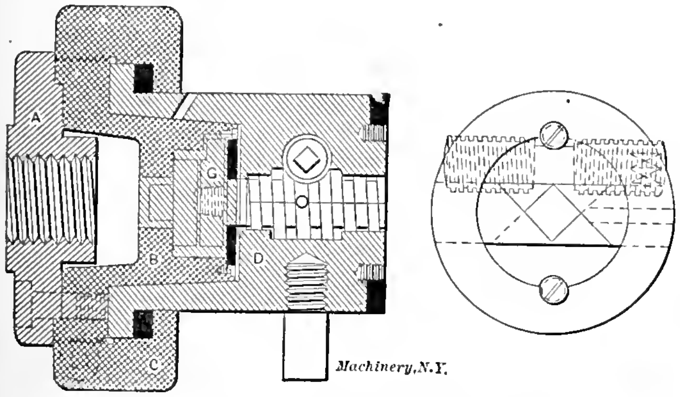

Fig. 2. Construction of the Angular Drilling Attachment.

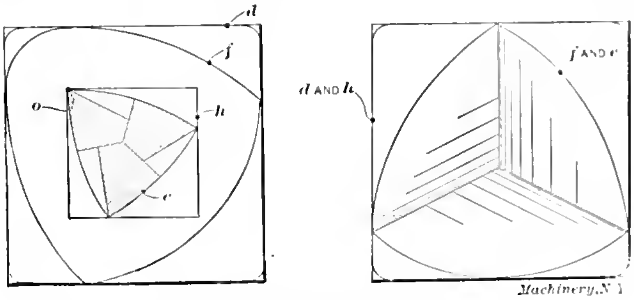
Fig. 1 shows the device with one of the cutting tools in place, and others lying beside it. An axial section through the attachment is shown in Fig. 2. Flange or face plate *A* is screwed onto the nose of the machine in which the work is to be done. This may be either a lathe, drill press, milling machine (see Fig. 6) or any other tool having the necessary rotary spindle and means for holding the work. To flange *A* is screwed the driving member *B*. Over this is fitted the chuck *D* which is held in place on *B* by nut *C*. This chuck is similar to the common design used for drilling chucks, and is provided with jaws operated by right and left-hand screws which give a square opening, as shown in the end view. This member is stationary, being fastened in some way to keep it from revolving. The size of the square opening, in connection with the tool used, determines the size of the square hole to be drilled. If a triangular hole is to be drilled, special jaws which give a triangular opening are provided. The tool itself, seen better in Fig. 3, is composed of the three-lipped cutting blade and a holder. The latter is screwed into the dog *G* which is driven from *B* in such a way that the tool is positively rotated, but allowed to float as required by the peculiar contour of the holder, in connection with the square opening in the jaws of the chuck. These jaws are tightened down so as to just fit the holder or shank, and still allow it to rotate.

The action in cutting a square hole will be understood from Fig. 4. The line marked *d* represents the square opening in the chuck jaws. The line marked *f* is the outline of the shank of the cutting tool. The hole being cut is shown at *h*, and *c* is the cutting blade. It will be seen that the action of *f* in *d* is identical with that of a familiar form of cam sometimes called a "3-cornered box cam." The particular construction which makes it possible to cut geometrically square corners lies in placing the center of the rounded one of the three corners of *f*, at *o*, which is exactly in line with one of the cutting edges of the tool *c*. This means that this one of the three cutting edges of the tool finishes the periphery of the square hole. It is led in straight lines, parallel with the sides of *d*, and at each corner is pivoted about itself, leading out at right angles to its entering direction.

Fig. 3. The Cutting Tool and Shank used for Sharp Corners or Round Holes



Figs. 4 and 5. Sketches showing the Principles of Drilling Square Holes with Sharp and Round Corners.

A construction previously used for cutting a square hole (see Fig. 5) involves the use of a shank *f* working in opening *d*, and guiding a cutting tool of exactly the same size and outline as *f*. In this case, while the sides of the hole produced (which is the same as *d*) are thus straight, the cutting edge of the tool does not cut clear in to the sharp corner, and slight fillets are left as shown. When it is desired with this attachment to cut square holes with small fillets, the

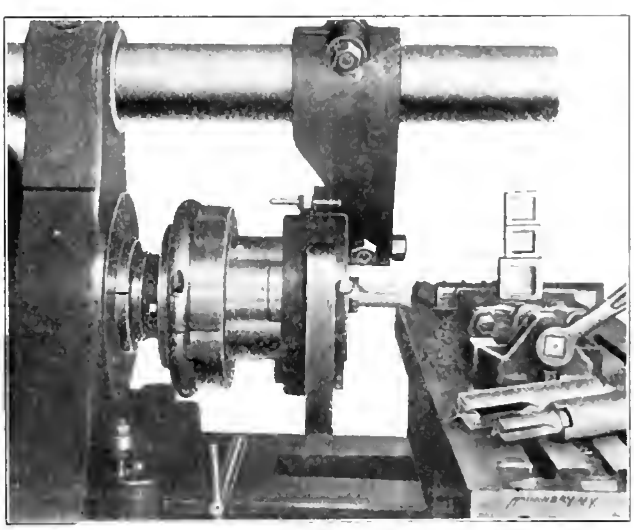


Fig. 6. The Attachment in use on the Milling Machine.

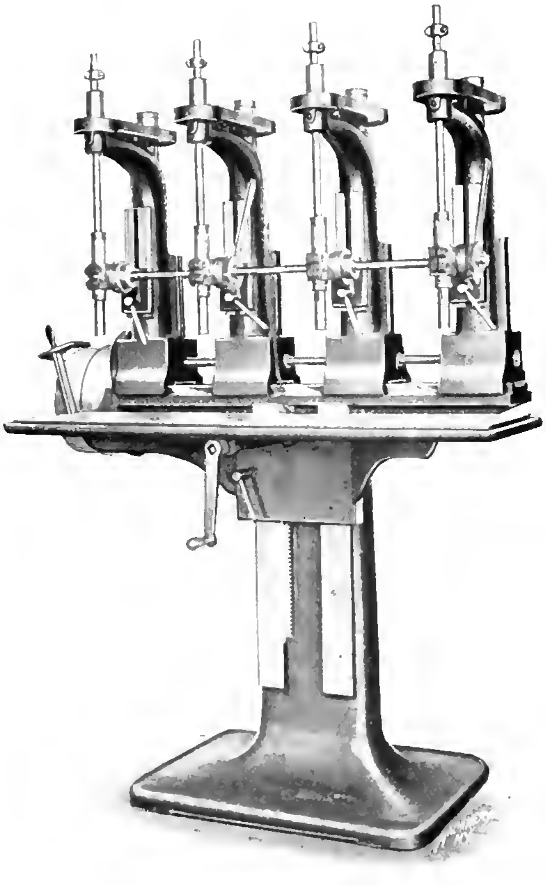
shank and tool are made of the same size and the shank is given the form shown at *f* in Fig. 5. The cutting of three-cornered and six-sided holes is effected by tool shanks and cutting tools of suitable outline working in special chucks. These have slight fillets, though it is almost impossible to discern them in the case of the hexagonal hole.

The grinding of the tools may be effectively done by means of a simple attachment provided by the makers. This attachment locates the tool by the corners of the shank in a V-block, which is set at such an angle as to present the cutting edge properly to the grinding wheel in a surface grinder, cutter and reamer grinder, or other similar machine.

In using this device in a machine spindle, a stop bar may be screwed into the chuck *D*, and rested against some stationary point, such as the frame of the machine. The angular position of the stop bar about the axis of rotation, of course, determines the angular location of the outline of the hole. Fig. 6 shows the tool in use in a milling machine. Here, the chuck is kept from revolving by a clamp ring which encircles it, and is attached to the overhanging arm. Samples of the work done by the tool, and samples of the tools themselves, both for sharp-cornered and round-cornered square holes, are shown on the machine table.

IMPROVEMENT IN SENSITIVE MULTIPLE SPINDLE DRILL PRESS.

The accompanying half-tone illustrates an improvement added to the regular line of sensitive multiple spindle drill presses manufactured by the Taylor & Fenn Co., Hartford, Conn. The feature of the improvement is that all the spindles can be fed simultaneously to the work by operating a single handle, the feed pinions having been connected with one another by means of a splined shaft running through to all the spindles. Of course, a feed lever may be applied at every spindle, and any feed lever may be operated for feeding all the spindles towards the work. This arrangement does not interfere with the adjustable feature of the various spindles. By simply releasing the keys in the hubs of the feed pinions, the connecting shaft may be disconnected at any time so that the spindles may be used independently.

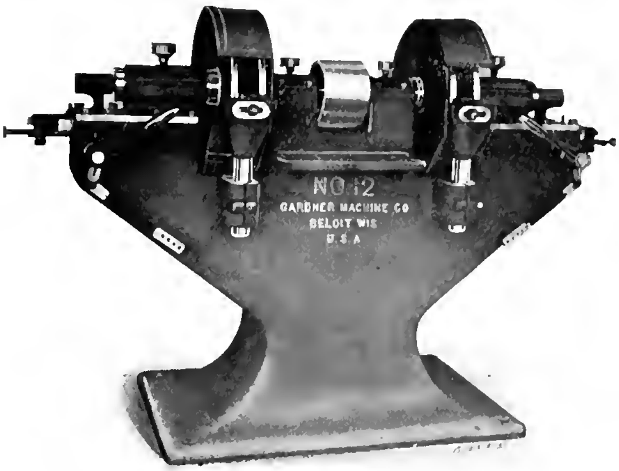


Taylor & Fenn Sensitive Drill Press arranged to Feed all the Spindles by Operating One Feed Handle.

This type of machine is built with any number of spindles up to six. As shown in the photograph the top columns are placed at equal distances apart, but they can be adjusted to any distance from one another, whether evenly or irregularly spaced. It is evident that for drilling a large number of duplicate parts, the arrangement permitting the feeding of all the spindles by one handle, is of great advantage, and that the rapidity with which the work can be performed is much greater than in the ordinary form of this machine, where each spindle must be fed to the work independently of the others. In all other respects, the machine is of the same design as those regularly manufactured by the Taylor & Fenn Co.

NO. 12 GARDNER IMPROVED DUPLEX DISK GRINDER.

In the July, 1908, issue of MACHINERY, a double disk grinder manufactured by the Gardner Machine Co., Beloit, Wis., was illustrated and described. The accompanying half-tone shows what is practically the same machine, but built in a double pattern, so that there are, in fact, two machines mounted on the same frame. It may either be used by two men simultaneously or by one operator rough grinding with the one pair of wheels and finishing with the other set. The same principle of driving by a single pulley as described in the July issue, is employed in the present machine. The outer disk wheels are mounted on hollow spindles supported on sliding heads; and driving shafts, coupled to the main spindle, drive the hollow spindles, the former being splined to engage with keys fastened in the latter. The lubricating arrangement is particularly well adapted to the purpose of the machine, and dust caps and other provisions for excluding dust from all wearing surfaces are provided. Disk wheels from 15 to 18 inches diameter may be used. The maximum distance between the wheels is 4½ inches, and the weight of the machine as illustrated is 1,900 pounds. With all accessories, including setting up press for the wheels, countershaft, splines, etc., and crated for domestic shipment the weight is 2,500 pounds.



No. 12 Gardner Improved Duplex Disk Grinder.

HOEFER CONE PULLEY POLISHING MACHINE.

The machine shown herewith is one of a number of special machines which were originally developed by the builders in the manufacture of drill presses and metal power saws. The particular purpose of this machine is the polishing of cone and driving pulleys. It is intended to take the place of the more tedious and costly hand methods of polishing these parts. As shown, the machine consists essentially of a power-driven head-stock and a tail-stock, mounted in a way somewhat resembling the speed lathe. At the back of the lathe is mounted a round horizontal bar on which loosely revolve two pulleys, the smaller of which is connected with the counter-shaft, while the larger one is belted to an emery wheel. This wheel is carried on a swinging arm, also pivoted about the rod at the back of the machine. The arm has a sliding

motion on the rod, which is controlled by the lever at the right. The emery wheel is beveled, and swivels about an axis at right angles to the sliding bar, so that it may be set to agree with any taper for the crowning of the pulley.

In order to dispense with the time lost in putting pulleys on an arbor, a very satisfactory substitute for this method of holding them was designed. A conical plug is used, supported in the end of the spindle, instead of the regular center. It is made of such size that it will take care of two or three different diameters of holes. This centers the pulley properly. To drive the pulley, a dog is placed on the face-plate, engaging one of the spokes in the work. In the tail-stock an auxiliary conical bushing, revolving on the regular center, gives proper bearing for the rear end of the hub. This tool has greatly reduced the time of polishing pulleys over the old methods, in the shops of the builders, the Hoefer Mfg. Co., Freeport, Ill.

A Machine for Finish Grinding Cone and other Pulleys.

FOOTE-BURT NO. 24 HIGH-DUTY DRILL.

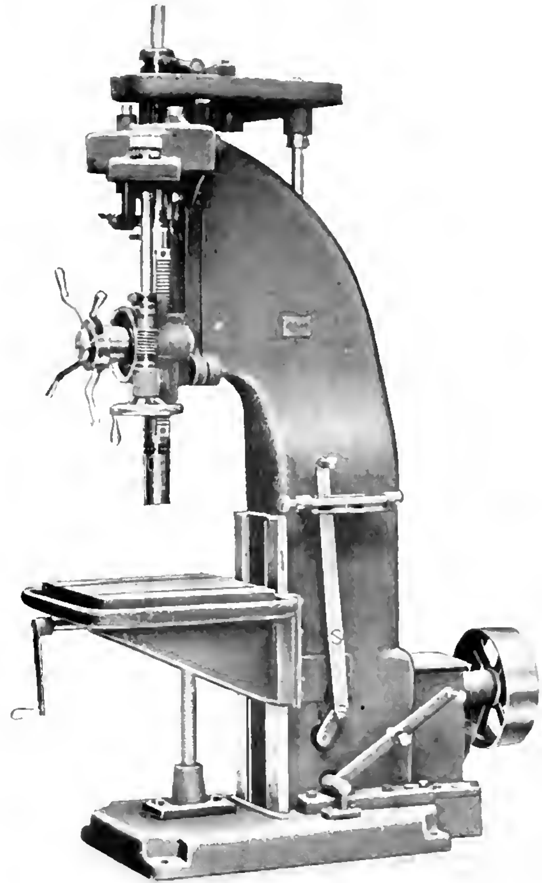
The accompanying illustration shows a drill of the heavy, box column, high-duty type, built by the Foote-Burt Co., St. Clair Ave. and 41st St., N. E., Cleveland, Ohio. This size of machine was designed to use a 1¾-inch high-speed drill to the full limit of its capacity in the hardest materials. An improvement over the usual construction of this type of machine relates to the provision of a single speed pulley drive, all the speed changes being obtained by the manipulation of the handles shown at the side of the column, which are within easy reach of the operator at all times. Spur gears are used throughout, except for one pair of slow running 2 to 1 bevel gears at the driving end, and one worm and worm-wheel for the feed.

The spindle is of forged high-carbon steel, fitted with ball thrust bearings made by the builders of the machine, and guaranteed not to crush under severe duty. Three changes of geared feed are provided for this spindle, any one of which is instantly available by the simple shifting of a lever at the front of the machine. This feed change can be made without stopping the spindle. An adjustable automatic stop and a hand throwout is provided. The hand feed is through the worm gearing shown; the quick traverse in either direction is accomplished through the spider hand-wheel at the front of the machine, which engages or disengages the feed connection by an in or out movement of any of the handles. The table is of the knee type, with a large square locked bearing surface on the vertical ways of the column, to which it is securely gibbed. It is adjustable vertically by a square thread screw, located just back of the center of the table, to permit boring a hole through the latter for passing boring bars or other tools, if desired. The work is clamped to it by means of the two T-slots provided, and it is surrounded with a liberal oil groove.

The driving and speed change gearing is mounted at the base of the column. The nine spindle speeds are obtained through a double train of spur gearing, which is always in mesh and runs in a bath of oil. There are two sets of three gears, any one of which in each of the two trains may be thrown into action by a sliding lock bolt or key. The three speeds obtained in each of these trains give nine speeds in all, any one of which are instantly available. The power is transmitted from the horizontal shaft of this speed mechanism, through bevel gears inside the column, to a vertical driving shaft, which is connected with the spindle by an idler spur gear, thus avoiding the necessity of more than one pair of bevels in the entire machine.

A tapping attachment will be furnished, operated by a positive steel clutch located on the idler gear at the top of the machine, thus obviating the necessity for driving the spindle through the keyed member of a clutch. This attachment reverses in the ratio of 2 to 1.

This machine has the following dimensions: The distance from the center of the spindle to the face of the column is 12 inches. The maximum distance from the nose of the spindle to the top of the table is 28 inches; the length of power feed is 16 inches; the spindle has a diameter of 3 inches at the nose, and is provided with a No. 4 Morse taper. The spindle driving gear is 8⅞ inches in diameter with a 1½-inch face. The table has a vertical adjustment of 20 inches. The nine spindle speeds range between 71 and 306 revolutions per minute. The three feeds are 0.007, 0.016, and 0.033 inch respectively. The net weight of the machine is 2,450 pounds.



High-duty Drilling Machine with Single Speed Pulley Drive.

As an extra attachment, a compound table will be furnished, with a knee specially built for supporting it. This compound table has a longitudinal adjustment of 14 inches, and a cross adjustment of 8 inches. The working surface is 16½ x 30 inches. When the compound table is furnished, the maximum distance from the nose of the spindle to the top of the table is decreased by 3¾ inches.

LODGE & SHIPLEY HEAVY AXLE LATHE.

The axle lathe illustrated herewith is built by the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio. The machine is of the standard construction, so far as its general plan is concerned. That is, the axle is driven by equalizing dogs from a hollow revolving driving gear at the center of the bed, the work being supported on two dead centers. Both journals may thus be turned simultaneously. Power is transmitted to the driving gear by a shaft lying in the center of the bed.

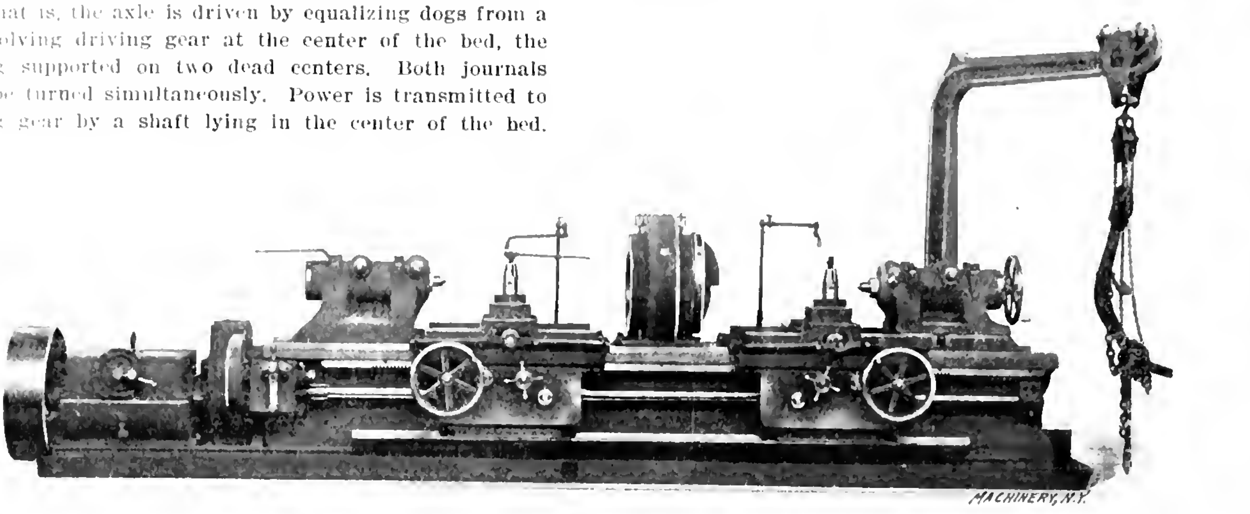


Fig. 1. Lodge & Shipley Single Pulley Drive Axle Lathe.

In the details of its design, this lathe is original throughout and is intended to mark a new step in the development of special machinery for this class of work. Essentially this tool is another evidence of the growing tendency to provide the heaviest machinery with all possible facilities for rapid manipulation. This tendency has, of course, been brought about by the remarkable shortening in cutting time made possible by modern high-speed steels.

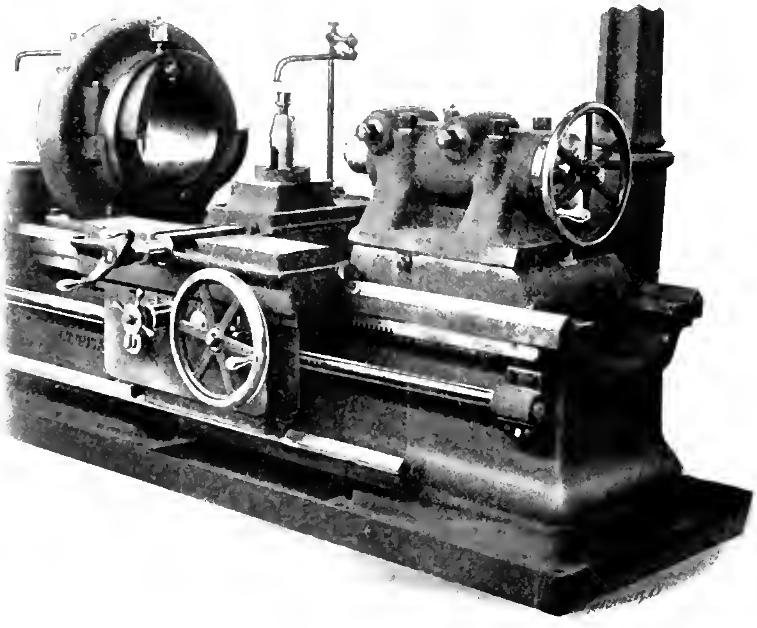

Fig. 2 Driving Head, Carriage and Tail-stock.

The bed is deep and heavy, as may be seen. It is provided with frequent cross braces of box section, and has, as well, a longitudinal stiffening member, also of box section, cast in the center of the bed for its full length. The ends of the bed are cut away so as to facilitate the removal of the tail-stocks, or to permit them to over-hang for a reasonable amount, on work of unusual length.

An especially important feature of this machine is the drive. This is best seen in Fig. 3, which shows the gearing in the speed box exposed, with the cover removed. Power is applied to the constant speed pulley of large diameter and wide face, running at high velocity. The three speeds are obtained by sliding gears, running in a bath of oil; this number is sufficient to cover the range required for the work of turning axles. All the shafts are carried in bushed, ring oiling bearings, and all the gearing is of steel. The driving shaft is of large diameter and is amply supported by journal blocks in the bed. There is no over-hanging on the pinion which engages with the main driving gear, as the shaft is supported at each end in long bearings; the driving gear is also provided with a double bearing. The compensating driver, secured to the gear in the head, is provided with steel faced driving dogs.

All the feed gearing is of steel. The rate of feed is changed by the gear box shown, attached to the left-hand end of the bed; this gives three rates, which may be changed while the lathe is in operation. The two carriages are of unusually interesting construction, as is shown in Fig. 4. It will be seen that they are of the double walled type, this construction being more completely carried out than in any lathe apron that has ever come to our notice. The apron itself is of box form, entirely enclosing the mechanism, front and back, except for the necessary openings. This gives great power and durability to the feed mechanism, and should enable it to withstand the rough service to which lathes of this type are inevitably subjected.

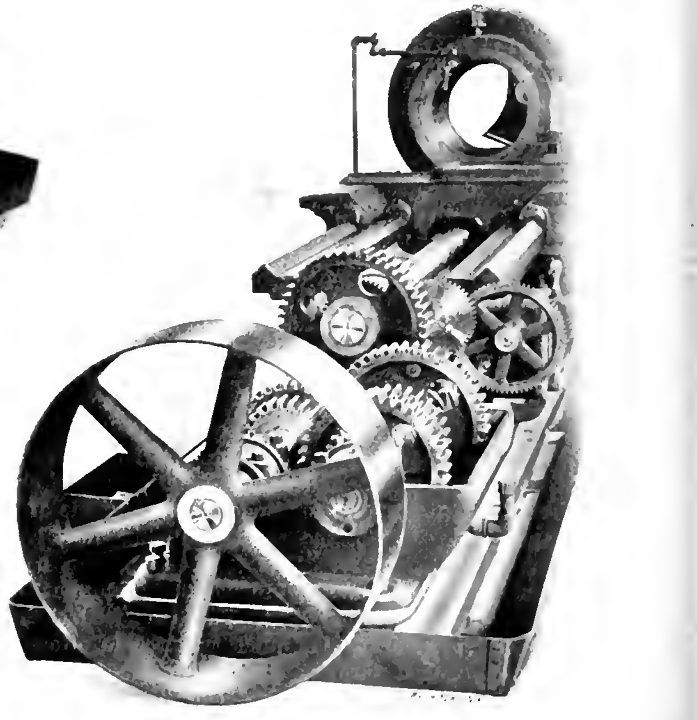

Fig. 3. Driving Gearing with Cover Removed.

The particular point of interest in the design of the carriage relates to its support by a third V, cast in the bed directly under the apron. This is best shown in Fig. 2. A tapered gib is provided for this bearing, which may be set so that the carriage is supported evenly on all three V's. The purpose of this construction is to support the apron at the bottom for both vertical and transverse stresses. The spring of the apron due to the thrust from the rack and pinion is thus effectively overcome. The carriage itself has a bearing on the flat way at the front side of the bed, on which the tail-stock slides, as well as on the V's at the front and rear. This bearing is carried over the 45-degree surface on the inner edge (seen at the end of the bed in Fig. 2). This, with the V's, furnishes sufficient provision against the heavy thrust that results not only from the cutting, but from the operation of burnishing as well.

Water troughs are provided around the tool slide and the wings of the carriage. The tool-posts are arranged with hardened toothed plates interlocking with the tool, and effectually preventing the possibility of its swinging or slipping under the heaviest cuts. The tool slide itself is of steel.

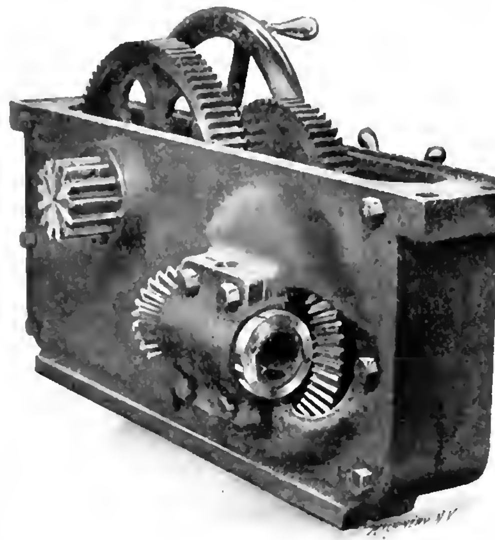

Fig. 4. An Apron that is really "Double Walled."

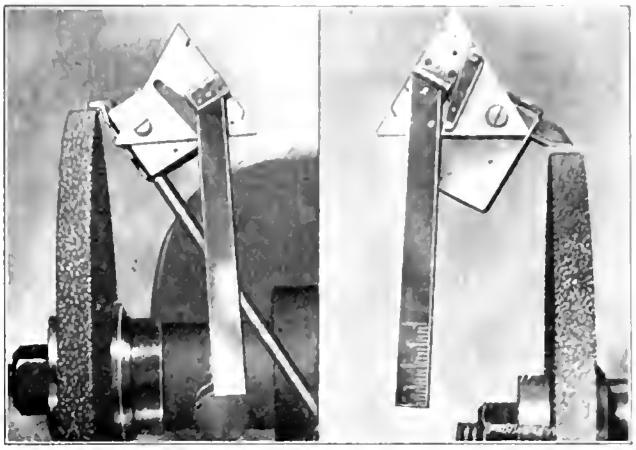
The tail-stocks are of heavy construction, clamped to the bed by four bolts as shown. These are brought to the top of the spindle barrel, where they can be easily operated from the working position at the front of the machine. The common arrangement, found on heavy lathes, of a pawl for the tail-stock engaging a rack cast in the bed is provided in this case. This arrangement tends to relieve the strain on the clamping bolts, and makes the locking of the tail-stocks positive against the strain of the heaviest cut. The tail-stock at the driving end has no cross adjustment. That at the right-hand end may be adjusted for aligning the centers to parallelism, or for turning tapers. The spindles of each tail-stock are clamped by two plug clamps of improved design. They are placed on top of the spindle barrel where they can be easily manipulated.

Altogether this lathe gives the impression of being a very creditable piece of design.

KRIEGER GRINDING GAGE FOR THREAD TOOLS.

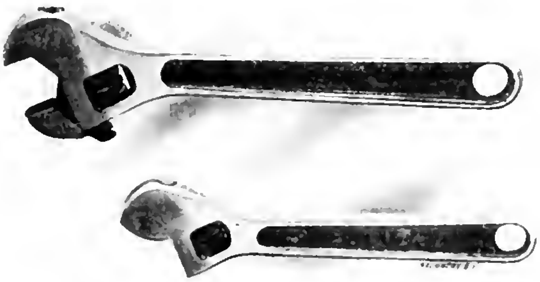
The accompanying half-tone illustrations show the use of a 60-degree inside and outside thread tool gage brought out by the Krieger Tool & Mfg. Co., 83-91 Randolph St., Chicago, Ill. This gage is intended to guide the operator in sharpening threading tools made from flat stock or in grinding the point of forged inside thread tools. It is well known that it is difficult to grind a 60-degree thread tool with any degree of accuracy when one is simply guided by the eye for judging the angles of the tool itself. By the use of this grinding gage it is possible with little experience to get a 60-degree angle so nearly perfect at the first grinding that no regrinding to a more correct angle will be necessary. This lengthens the life of the tool and saves time. The gage is also provided with a center gage so that the angle of the thread tool may be tested directly in the gage. The lever or arm extending from the gage and by means of which the operator gages the angle at which he holds the gage, is graduated with ordinary rule graduations, and the tool consequently makes a handy combination tool. Spring clamps are provided by means of which any tool is easily attached to the gage. In the illustrations, Fig. 1 shows the grinding of an internal thread tool, and Fig. 2 the grinding of a 60-degree external thread tool from flat stock. These illustrations indicate the manner in which the operator is guided by the arm of the device so as to see that he holds the tool in approximately the correct position when grinding, the arm then being parallel with the wheel.



Figs. 1 and 2. Grinding Internal and External Thread Tools, using Krieger Grinding Gage to obtain Correct Angles

CRESCENT ADJUSTABLE WRENCH.

The accompanying half-tone engraving illustrates the Crescent adjustable wrench made by the Crescent Tool Co., Jamestown, N. Y. In the designing of this wrench the outlines of the ordinary 22½-degree engineer's wrench, which is acknowledged to be the most serviceable of all solid wrenches for practical use, has been followed. The design is such that the wrench can be used in practically every opening where a solid wrench can enter, but one size of this adjustable wrench takes the place of a great number of solid wrenches; thus, the 10-inch wrench, which is the larger of the two shown in the engraving, replaces nine sizes of solid wrenches. The wrench consists of five pieces: the handle with one of the jaws forged solid with it, the adjustable jaw, the thumb screw by which this jaw is adjusted, a pin or stud, and a spring. The movable or adjustable jaw is provided with ample bearing surface in the handle and when in use locks itself against the handle, thereby relieving the thumb screw of the working stress. A small spring washer is placed between the thumb screw and the handle at the upper end of the former. This acts as a friction and prevents the thumb screw from moving too easily and changing the adjustment of the jaws, if the wrench should be laid carelessly on the bench or floor. It will be noted that the opening between the jaws is easily adjusted to fit the nut, with the thumb of the same hand that holds the

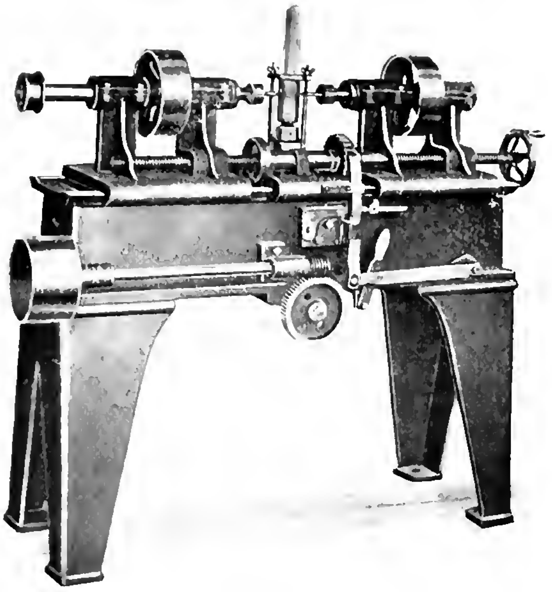


Two Sizes of Crescent Adjustable Wrenches, the Closed and Opened Wrenches are 8 and 10 inches, respectively.

wrench. The handle is made from drop forged carbon steel and the movable jaw from special alloy steel. At the upper end of the handle a hole is provided by which the wrench may be hung on a nail.

HOEFER SPLINING MACHINE FOR CROSS SLOTS IN SPINDLES.

Like the Hoefer cone pulley polishing machine described in this issue, this machine for milling cross slots in the ends of spindles, is the result of the needs of the Hoefer Mfg. Co., of Freeport, Ill., in its work of building vertical drill presses and power metal saws. This tool is entirely automatic in its action, and is extremely rapid, it being unnecessary to pay any attention to it except to change spindles when the work is completed.



Machine for Automatically Cutting Drift Pin Slots, etc.

The machine consists of a bed on whose upper surface are mounted heads carrying the cutter spindles, between which is vertically reciprocated a work spindle on which the part to be machined is mounted. The heads are strongly made, and are rigidly gibbed to the ways on the top of the bed, and are connected by right- and left-hand feed screws journalled in the work spindle head at the center of the machine. The rotation of this screw simultaneously feeds the cutters in toward or away from the work. The connection between the two ends of the lead-screw is by friction couplings, which allow the two heads to be adjusted independently for depth.

The cutter spindle at the left carries a pulley, belted to another on the shaft at the front of the bed, by means of which the feeding and operating movements of the machine are controlled. This shaft, through worm gearing, drives an adjustable crank, which reciprocates the plunger spindle on which the work is mounted. By means of the adjustment of the crank-pin, drift holes of various lengths can be obtained. The spindle to be milled is held firmly and solidly by means of the clamps shown, on a taper plug fast in the plunger. This provides the means for holding the work and reciprocating it vertically to agree with the length of slot to be milled.

The feeding of the heads inward at the end of each stroke of the work, is effected by means of cams on the inner face of the worm-wheel. These operate on the lever shown, which is in turn connected with the vertical pawl, engaging a ratchet wheel on the right- and left-hand feed-screw. This ratchet feed is automatically thrown out when the proper depth has been reached, by the striking of a pin on the left-hand head against an adjustable release dog controlling the movements of the pawl. It may also be thrown out by hand, by operating the short lever seen at the bottom of the bed, which raises the mechanism beyond the reach of the operating cams. A very thin shell is left between the cutters at the conclusion of the action. To remove this shell the two ends of the feed-screw can be separated as described, and one head alone used in cutting it out.

The accuracy of the work is insured by the alignment of the heads on the bed, and by the firm support given the fish tail cutters. The bed carries an oil tank and an oil pump, which furnish a steady stream of oil to the cutter.

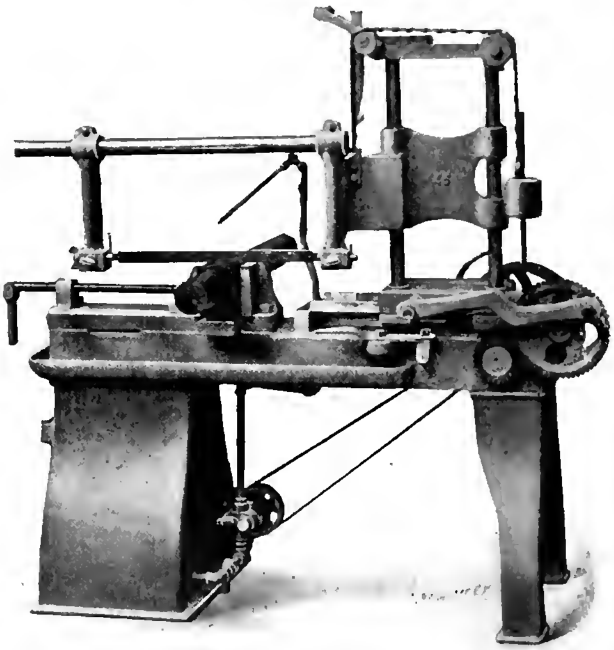
HIGH-SPEED "STERLING" HACK-SAW MACHINE.

The Diamond Saw & Stamping Works of Buffalo, N. Y., has recently placed on the market two new power hack-saw machines, known as No. 3 and No. 4 high-speed "Sterling" power hack-saws. The No. 3 machine is illustrated in the accompanying engraving. These machines take blades from 17 to 21 inches in length and can be run at a speed of from 80 to 100 strokes per minute.

The main driving shaft on which the pinion driving the gear for the saw frame motion is fastened, is 1 7/16 inch in diameter, and the large gear shaft is 1 3/16 inch. The bearings are thus large in diameter, and have also been given sufficient length so as to eliminate rapid wear. The area of the working surfaces of the main bearings, in fact, is 8 square inches. All bearings are provided with means for taking up lost motion with the exception of the main driving shaft bearings, where this has not been considered necessary. The drive is by means of tight and loose pulleys, and a pump for lubrication is provided so that oil or other lubricant can be used on the saw when running at high speed. The front leg of the machine is made with a cabinet frame and a tank for the lubricant is provided inside of the leg.

The construction of the saw frame and the means for counter-balancing are plainly shown in the engraving. The vise for holding the work is provided with a swivel base so that work can be cut off at any angle up to 45 degrees. The limiting capacity of the machine is 8 x 12 inches.

The No. 4 machine is identical with the No. 3 machine excepting that instead of the solid vise provided in the machine just described, the No. 4 machine is made with a centralizing vise and provided with adjustable stroke which enables the operator to use every part of the blade. When much small work is cut off, a certain portion of the blade only is utilized if the stroke is not adjustable, and therefore in shops where there is a large amount of cutting off to be done and the machine is almost continuously in operation, the saving in cost of blades due to the use of an adjustable stroke will soon amount to a considerable figure. It is estimated that from one-third to one-half of the amount of saw blades used can be saved when small work is being cut off by an



High-speed Hack-saw Machine made by the Diamond Saw and Stamping Works.

arrangement which permits using every part of the blade, and the value of this improvement is therefore apparent.

PRENTICE BROS. 16-INCH SHAFT TURNING LATHE.

Prentice Bros. Co., Worcester, Mass., is placing on the market a lathe of the type adapted to the turning of shafting, and especially for work having several diameters and shoulders. For this work, it is arranged with a carriage carrying a number of tool-holders, each of which is provided with a follower rest; and the construction of the tail-stock is such that these can be run back beyond it, so that various diameters can be turned at one single passage of the carriage, without adjusting or shifting any of the tools.

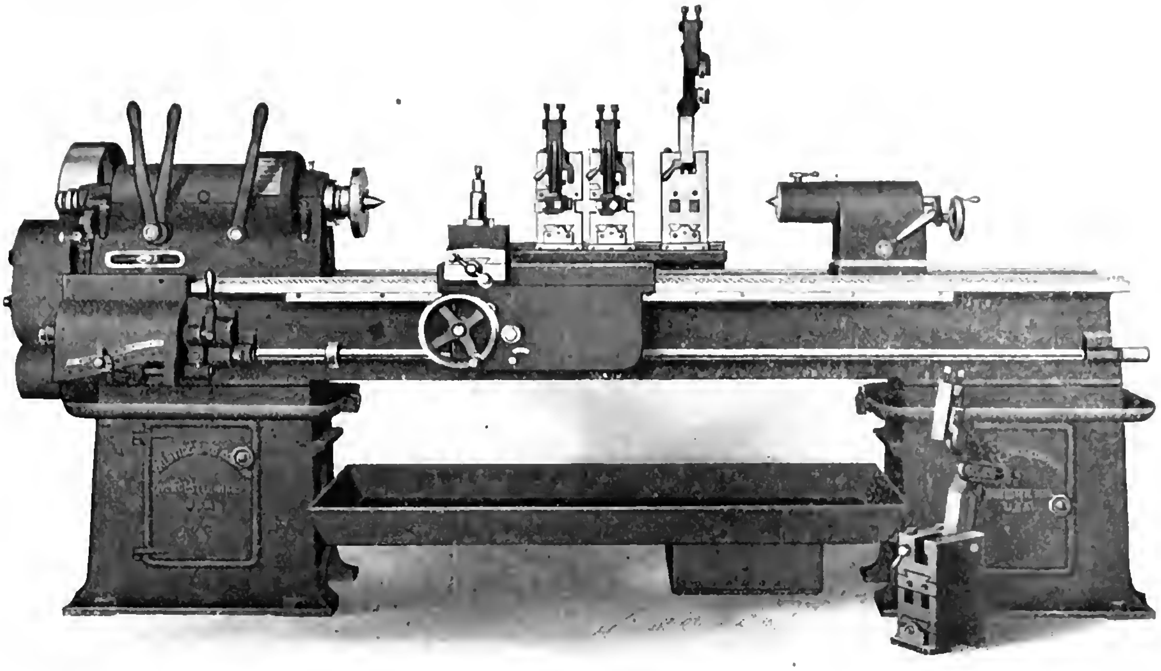


Fig. 1. New Design of Prentice Lathe, especially adapted to turning Studs, Shafts, etc.

The head-stock of this lathe (see Fig. 1) is the same as is used on the builders' regular high-speed geared-head lathes. The three levers at the front of the head-stock give eight changes of speed. These changes are obtained simply and conveniently, and with no possibility of error or mis-manipulation on the part of even the most careless workman. The use of a head-stock of this type gives the operator no excuse for not running the spindle at the proper speed for the diameter of work he is turning. The quick change gear mechanism is also the same as used on the makers' standard lathe, where it has proved itself to be entirely satisfactory. It is simple in construction and operation. As in the case of the head-stock it is impossible to lock any conflicting ratios of gears. The index plates accompanying the lathe clearly explain the operation of the levers.

The main point of interest is the carriage, which is shown in Fig. 2 with two tool blocks in place. It differs radically from the usual construction, in having, for one thing, the bridge at the left-hand end, with the bearing extending toward the right. This construction allows the tool blocks to pass back beyond the tail-stock. Another conspicuous departure from the usual construction will be noted in the fact that the tool blocks are at the rear of the lathe, so that (as the tools themselves, as shown in Fig. 2, are right side up) it is evident that the spindle runs backwards. The tool carriers or blocks are securely bound to the dove-tail on the rear bearing of the carriage, by means of three backing screws, which are reached from the front, and which hold it firmly in position. The cutting tools are held in slots in these blocks, by means of hardened steel taper wedges, which are brought into action by square end adjusting screws projecting from the block in front over each slot. For adjusting these tools for diameter, the same wrench as for tightening them is used on the cross adjustment screws, which shift the tool blocks on their dove-tail bases.

Each tool block is provided with a roller follower rest, whose use is largely responsible for the success of the machine. In Fig. 2, the left-hand tool block has the follower rest lifted up out of the way. To bring it into working position it is lowered, as shown for the other block, and is then pressed toward the right and forced under a ledge, which securely binds it in position. The fitting of these parts is so close that particles of dirt or chips will prevent the entrance of the rest under the ledge. The roll carriers may be fastened on either side of the follow rest, so that the rolls may be brought to bear on the work directly following the tool cut. The right-hand block in Fig. 2 shows clearly that this construction virtually makes a box tool of each tool-holder. Each of these tool-holders is provided with a separate supply of oil, from piping at the back of the carriage.

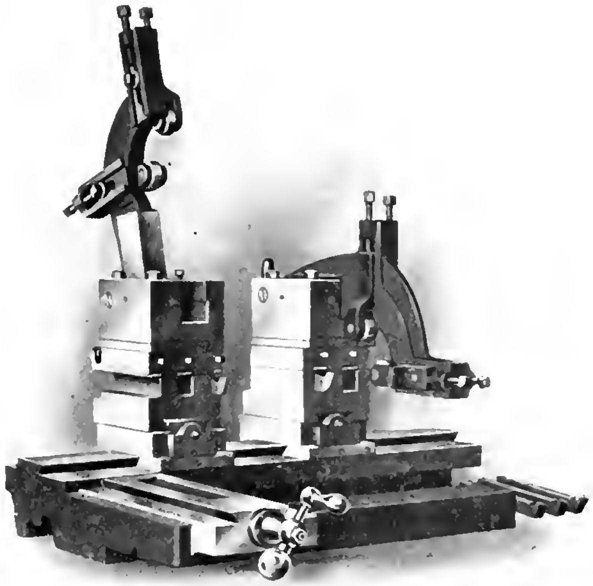

Fig. 2. The Carriage and Tool-blocks, with Follow Rests.

The tail-stock is shown plainly in Fig. 3. It is reversed from the usual construction, since the tool rests are required to pass it at the back instead of at the front. The clearance provided for the tools is unusually close, it being possible to set the latter for cutting down to 13/16 in diameter, and still pass them back of the tail-stock spindle for their

entire length. As may be seen, the spindle itself is of small diameter, and is grooved to permit the passage of the tool. When work is to be placed between the centers preparatory to turning, the tool carriage is run back toward the tail-end of the bed, so that the first tool will start in to cut at the end of the shaft. It is at this position that the tools must clear the tail-stock especially when turning small diameters.

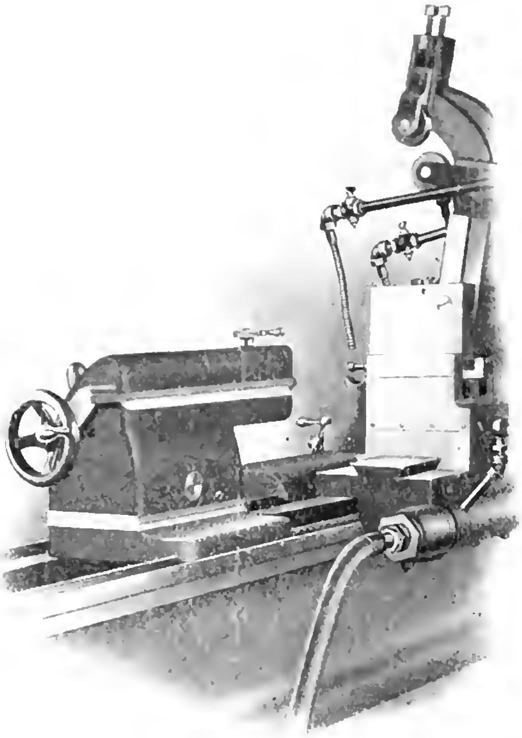

Fig. 3. Tail-stock cut away to clear the Tools.

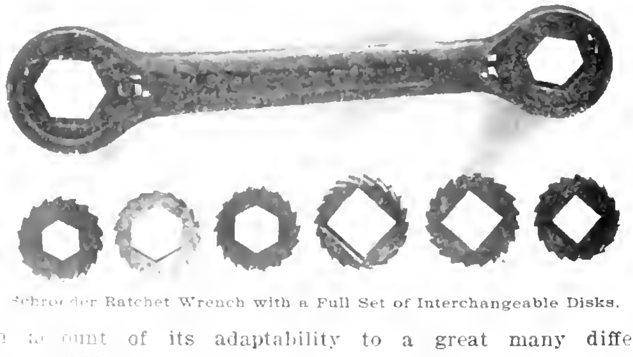
The work for which this lathe is especially adapted is the turning of shafts and studs of all kinds, in the sizes found in the ordinary run of work in the average machine shop. Its field is thus seen to be a broad one. It is not intended ordinarily to be used for screw cutting, but at a small extra expense a lead-screw will be furnished; in this case the work of the ordinary engine lathe can be done on the machine, using the regular tool-post shown at the left-hand side of the carriage in Fig. 1. This tool-post is intended ordinarily to be used for squaring down shoulders, if the work requires this.

The lathe swings 17½ inches over the ways and takes 62 inches between the centers on a 9-foot bed. The largest diameter the follow rests will take is 5 inches. The net weight of the machine, with a 9-foot bed, is 3,300 pounds.

SCHROEDER RATCHET WRENCH.

The Bullard Automatic Wrench Co., Providence, R. I., has brought out a ratchet wrench provided with interchangeable disks to take square and hexagon standard size nuts, which

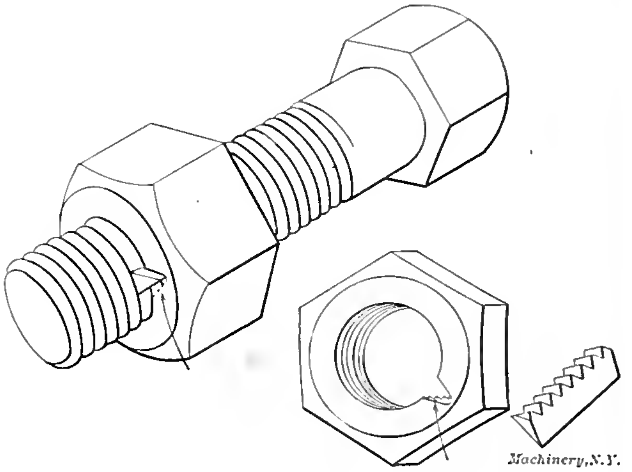


Schroeder Ratchet Wrench with a Full Set of Interchangeable Disks.

on account of its adaptability to a great many different conditions will undoubtedly be of interest to the trade. The main advantage is that one wrench handle will serve for seven or eight different sizes, and the change of disks, permitting this wide range, can be made in less than one-half minute. The accompanying engraving shows the general design of the wrench and also a series of disks which can be placed in the wrench in place of those shown in position. The construction of the wrench is very simple. A pawl is provided with a spring behind its plunger so that it will be constantly in contact with the disks when in use. In the center of this pawl a thin key is provided which enters into a groove in the disks, thus holding them in place when once inserted. When it is required to change the disks, all that is necessary is to pull the pawl back as far as it will go and the disk will fall out. When in use, the pawl is forced over against the step on the side of the slot provided for it, and the wrench acts practically as a solid tool. The frame or handle is made double ended, as shown, of high quality steel, drop forged and case-hardened. The interchangeable disks are made of soft steel and all the holes are made to fit standard hexagon nuts, or a set of disks may be provided for five hexagon sizes and three square nut sizes. Besides these disks there is an extension piece provided with the sets, one end of which fits the half-inch disk of the wrench, and the other end taking any of the disks in the set. With this combination the wrench may be used in many otherwise inaccessible places.

VIBRATION LOCK-NUT.

A self-locking nut has recently been brought out by the L. S. Brach Supply Co., 143 Liberty St., New York. It is the invention of Mr. W. L. Clark, vice-president of the Niles-Bement-Pond Co. In view of its simplicity it will undoubtedly be of interest to practical men and appreciated in mechanical work. The principle of the nut, which is termed by its makers the vibration lock-nut, is shown in the accompanying line engraving. The nut is made like an ordinary hexagon nut, and has a V-shaped slot cut longitudinally on the inside of the hole, with a threaded wedge or key fitting into the slot, so as to form a part of the nut. This wedge is so shaped that it does not interfere with the running of the nut onto the bolt; but when the nut is reversed for removal, the key is carried over against the opposite side of the slot, its teeth being forced against the bolt so as to firmly grip it. This prevents accidental loosening of the nut. When it is required to remove the nut, however, this can easily be done by inserting a pointed wire, or any pointed object, in the larger opening on the side of the key before starting to turn backwards. This will prevent the key from getting into position to act as a binding wedge, and the nut is removed as easily as an ordinary nut.



Self-locking Nut brought out by the L. S. Brach Supply Co.

It is clear from a study of the construction that the nut will lock itself securely at any point on the bolt without distorting or damaging the thread. It should be valuable wherever lost motion of the parts held is likely to occur, as it will hold firmly and indefinitely the parts it is required to secure. In fact, it is not only self-locking, but where the parts vibrate it is also self-tightening, inasmuch as the vibrations will move the nut onto the bolt, but the key or wedge

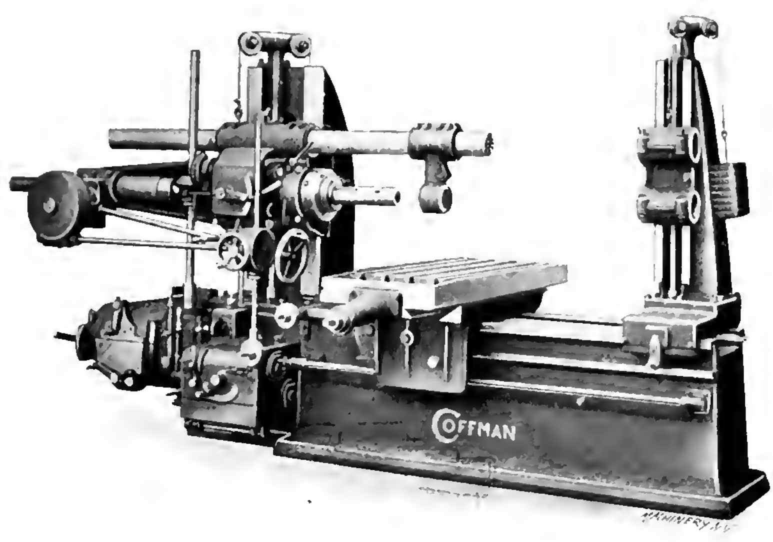
prevents the vibrations from moving it back to its original position. It is especially applicable for railway service on car trucks, fish plates, etc., dispensing with a large amount of inspection now necessary, and insuring safety at all times.

COFFMAN UNIVERSAL BORING, DRILLING AND MILLING MACHINE.

The horizontal boring, drilling and milling machine shown herewith is built by J. P. Coffman, Franklin, Pa. This tool is unusually complete in the adjustments and movements furnished, and would appear to warrant the use of the word "universal," which is applied to it by the builders. An inspection of the two engravings will indicate some of the improvements incorporated in the machine. Note, for instance, the provision of an overhanging arm, and the bringing of both the fine feed and the quick traverse hand-wheels for the boring bar, close to the operator's position. Other features will be noted in the course of the following description.

General Construction.

The main bed is of the box type of design, and is heavily ribbed and cross-braced. The stiff form of the column will be appreciated from an examination of Figs. 1 and 2. The spindle head or saddle is counterbalanced, as is also the outboard support for the boring bar. The saddle and support are adjusted vertically by accurately cut screws, geared together, so that they always move in unison.



Coffman Universal Boring, Drilling and Milling Machine.

Mention has been made of the overhanging arm, furnished for supporting the boring bar. This is not only useful in an obvious way in milling, but in boring it makes it possible to use bars in work where a number of holes are to be bored in line; supporting the bar in the center overcomes the danger of chattering, which is likely to occur in such work. It will thus oftentimes avoid the necessity for a special fixture. It should be noted that the outboard support for the boring bar is also provided with a support for the overhanging arm. The outboard bearings are especially wide. This permits the use of double bushings for supporting the boring bars, thus materially stiffening them.

Main and supplementary work-tables are provided, the former having automatic power cross feed, and the latter having cross slide ways which permit the work to be clamped to it, and still follow the movements of the main table. The main table is provided with oil channels for carrying off oil and cutting compounds. A reservoir for these is provided in the base.

The Spindle and Driving Mechanism.

The machine is built on the unit plan of construction, with the speed box, feed box, spindle drive gearing and feed drive gearing as the principal members. The machine shown has a speed box for constant drive. This, however, may be replaced. If desired by the customer, however, a cone drive or variable speed motor will be furnished instead. If a constant speed motor drive is to be used, the speed box is retained, and the driving shaft is directly connected by gearing or chain and sprocket with the constant speed motor. The speed change mechanism gives 12 rates of speed, there being four changes by a cone gear device, which is, in turn, multiplied by three positive change clutches. A reverse is also provided for in this box. In Fig. 2, handles *A* and *B* operate the cone gear change, while handle *C* operates the clutches. The reverse is effected by handle *D*, which controls a bevel gear and clutch directly on the vertical drive shaft of the spindle.

The lever *E* on the front of the spindle-head gives two rates of speed, and in the central position disconnects the spindle from the driving mechanism. The two rates of speed here obtained are in the proper ratio for the operations of boring and facing, and make it unnecessary to change the regular speed mechanism in performing these operations on a given-sized hole.

The nose of the spindle itself is provided with an internal split taper sleeve which, by means of a screw and socket wrench, may be forced in to clamp the boring bar for facing operations and similar work. When the bar is being fed through the spindle, it is tightened up just enough to give a firm bearing, thus obviating the looseness often resulting from wear at this point after long use. This clamping device also comes into play when holding milling cutters in the spindle. The spindle has a threaded steel nose-plate with a slotted face, adapted for holding the design of face mill that is screwed on with a spanner wrench and driven with a key. This permits running mills or facing heads positively in either direction.

The boring bar is of hammered crucible steel, ground and lapped true. The spindle is of semi-steel, provided with a long key or feather for driving the bar. The front sleeve bearing is taper and the rear one straight. Both are ground true and lapped, and run in bearings of "genuine babbitt" in which is set a spiral groove filled with rolled blocks of compressed graphite. Lubrication for these parts is effected from a reservoir in the bottom of the head.

The Feed Mechanism.

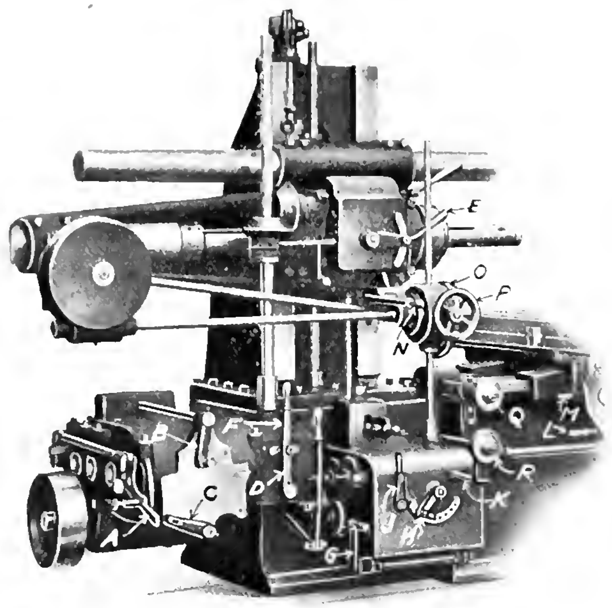
While not specifically so stated in the description furnished us, it seems safe to assume from the drawings and photographs furnished, that in this machine the feed is taken directly from the spindle, instead of from the driving mechanism. This gives the machine the same sort of feeding motion that is provided for the lathe and drill press—that is, one which varies directly with the spindle speed, and is stated as feed per revolution, instead of as feed in inches per minute. For all boring and drilling operations, this is a logical arrangement, though for milling the tendency more recently has been, of course, to provide a feed in inches per minute, such as would be given by regular millers provided with a constant speed drive. As drilling and boring operations will, under ordinary circumstances, constitute by far the greater work of a machine like this, the construction is a rational one. So far as our memory serves us, it has not been applied to any other boring machine of this type.

The feed, by means of one of the vertical shafts shown, is led down to the feed box at the front of the machine, where 21 changes are provided. This mechanism is similar in construction to that for the speed change. It is possible to operate either of them while the machine is in action. Levers *G* and *H* operate the gear cone mechanism, and lever *J* gives the reverse. The feed of the table and the boring bar, and the vertical feeds of the heads on the uprights, are all taken from this mechanism.

The bar feed is taken from a vertical shaft extending upward from the feed box as shown in Fig. 2. This feed is connected and disconnected by lever *K*. The motion is taken to the worm gear at the rear bearing for the boring bar. The hand-wheel *O* operates this movement, sensitively, by hand. By throwing lever *M*, the worm gear is disconnected from the

bar feed pinion shaft allowing a rapid movement to be effected by hand-wheel *O*. The cylinder rack sleeve form of feed is used for the bar. The rack is cut from the solid, and is of wide face and coarse pitch. The design permits the pinion to be brought near the center of pressure in the feeding, giving a decided advantage in drilling, or in spotting bosses with flat cutters.

The longitudinal adjustment of the table along the bed is effected by the square crank or index dial shown at *Q*. The power feed for the cross movement of the table is controlled by levers *L* and *M*. An automatic stop for milling is provided for this apparatus, the dog being adjustable in a slot on the front side of the table, as is usual for milling machines. The power elevating mechanism, controlling both the spindle head and the outboard hearing, is connected to the constant speed shaft so that it is not affected by the speed changes of the spindle. For sensitive adjustment by hand, the squared crankshaft shown at *R* is used.



Enlarged View of End of Machine showing Operating Levers.

Dimensions.

The boring bar is 3¾ inches in diameter. It will feed 30 inches at one setting or 60 inches at a double setting. The front end of the bar is bored to a No. 6 Morse taper. The height from the center of the bar to the top of the table may be varied between 1 inch and 33 inches. The greatest distance available from the base of the spindle to the outer bearing is 78 inches. The working surface of the table is 24 × 48 inches. It has a cross feed with automatic stop of 48 inches. The vertical feed of the saddle is 33 inches. The revolutions per minute of the bar may be varied in geometrical progression, in 24 changes, between 10 and 212 revolutions per minute. The geared positive feeds vary with 21 changes in geometrical progression between 0.004 and 0.500 inch to a revolution of the spindle. The net weight of the machine is about 11,000 pounds.

The design of this machine has been made, so the builders state, as nearly foolproof as possible, great care having been taken to insure it against breakage, and to insure the safety of the operator as well, by enclosing all parts. All the mechanism is accessible for inspection and repair. Dust-proof oilers are provided for all oil holes. Collar and shear pins are provided on all feed shafts, thus preventing injury to the driving mechanism in the case of running against a solid object with the vertical or cross feed. Particular attention should be called to the usefulness of the device as a milling machine. The provision of the overhanging arm, the wide range of feeds and speeds, the strong drive for the spindle, and the facilities provided for holding the cutter, as well as the cross feeds and automatic stop for the work-table, make this tool practicable and serviceable as a milling machine. It will be furnished by the builders, if desired, in the form of a plain milling machine, as a plain boring or drilling machine, or (as in the case here shown) as a universal boring, drilling and milling machine—all from practically the same patterns.

QUICK ADJUSTMENT PIPE WRENCH; Webb & Hildreth Mfg. Co., Gloversville, N. Y. This wrench is intended for general use on piping, lugs, screws, etc.

550-TON FLANGING PRESS; Wm. H. Wood, Media, Pa. This press is intended for the heaviest flanging work. It is provided with one main ram, capable of exerting a pressure of 550 tons. An internal clamping ram for holding the work gives a pressure of 100 tons. Besides this there are four auxiliary cams, and another in the head.

LIGHT PORTABLE DERRICK; Parker Hoist & Derrick Co., 725 Old Colony Bldg., Chicago, Ill. This derrick is intended for general use in contracting and manufacturing plants. It is easily portable, and may be used either as a guy or stiff-legged derrick for steam or hand power. It is made in two sizes, having a capacity of 1,500 pounds and 4,000 pounds respectively.

DRILL GAGE FOR GRINDING CORRECT LIP ANGLES; Remington Tool & Machine Co., 50 Congress St., Boston, Mass. The drill to be measured lies in a V-groove with its point matching the angle gage, which is adjusted to the height of the drill point. By this means the drill may be ground to cut evenly on both lips.

32-INCH PLANER; Rockford Machine Tool Co., Rockford, Ill. This firm has just completed the first of a lot of new 32-inch planers. These are similar in design to the 24-inch size of machine described in the February, 1908, issue of MACHINERY. It is of much heavier construction, however, and will have two heads on the cross-rail and two side heads.

No. 0 BACK-GEARED PLAIN MILLING MACHINE; Owen Machine Tool Co., Dept. M., Springfield, O. The No. 0 milling machine built by this firm has recently been supplied with a back-geared drive, for taking feeds heavier than is usually possible with machines of this size. In other respects, the new design is the same as the plain machine.

DIRECT-DRIVEN LEVER SHEAR; Thomas Carlin's Sons Co., Pittsburg, Pa. This tool is driven directly from a crank on the driving shaft, without the use of intermediate gears, thus giving a high number of cuts per minute. The shear is especially adapted for cutting scrap, etc., of soft steel up to 1½ inch square. The knives are 8 inches long, and the approximate weight of the machine is 6,400 pounds.

THREAD MICROMETER; Ernest R. Seaward, 76 Campfield Ave., Hartford, Conn. This thread micrometer has an adjustable anvil which is set to agree with the required offset for the pitch to be measured. The line of adjustment is parallel with the side of the tool of a 60-degree thread. Formulas and readings for standard threads are stamped on the frame of the micrometer.

MOTOR-DRIVEN PORTABLE DRILLING, GRINDING AND BUFFING OUTFIT; Coates Clipper Mfg. Co., Worcester, Mass. This outfit is somewhat similar, though on a larger scale and for different uses, to the drafting-room outfit built by the same firm and described in this issue. The equipment includes a breast drill, old man, emery wheels, polishers, speed change device and so forth.

METAL NUMBERING MACHINE; American Numbering Machine Co., 291 Essex St., Brooklyn, N. Y. This firm's new Model P metal numbering machine is designed for stamping consecutive numbers on metal pieces, in the power or hand press. Indexing of the figures is done automatically. The speed of the device is limited only by the capacity of the operator. Any size or style of figures can be furnished.

Duplex Grinding Machine: F. H. Otis, 191 Mill St., Rochester, N. Y. This grinding frame carries two others, one of which is provided with a water reservoir and splash pan for wet tool grinding, while the other has the usual rest for miscellaneous dry grinding, and is provided as well with a work-table beneath the wheel, accurately adjustable for height, and useful for surface grinding of dies and other such work.

Tapping Machine for Light Work: John J. Grant, Cleveland, O. This tool is driven by a single belt, running over a three step cone pulley. The reverse belt for backing the tap out has been done away with, this movement being effected instead by gearing contained in the cone pulley. The machine is intended for light tapping, and is of the type in which the reverse is effected by endwise movement of the spindle.

Air Compressor for Shop and Foundry Service: George H. Comstock, Mechanicsburg, Pa. This air compressor is of the enclosed two-cylinder, center-crank, single-action, belt-driven type. The main frame is a single casting, embracing both cylinders (which are water jacketed), the crank shaft bearings and the crank case. The cylinders are 4-inch diameter by 4-inch stroke, and will operate a 2½-inch chipping hammer or two smaller tools when running at 180 revolutions per minute.

Heavy Quadruple Crank Press: E. W. Bliss Co., No. 5 Adams St., Brooklyn, N. Y. This machine is in reality composed of two double crank presses side by side, giving a press with a bed 154 inches long by 10 inches wide, and a correspondingly long slide. The adjustment of the length of the pitman is effected for all four cranks simultaneously, by means of bevel geared shafts operated by sprockets and chains from a driving shaft in the rear, which is in turn operated by power from tight and loose pulleys controlled by a belt shifter. The total weight of the press is over 36 tons.

Hydraulic Variable Speed Drive: Manly Drive Co., 17 State St., New York City. This form of variable speed drive employs a multi-cylinder pump as a driving member, with a similarly constructed engine as the transmitting member. The speed control is effected by varying the stroke of the pump plungers, thus furnishing a greater or less supply of fluid in gallons per minute to the motors. While especially designed for automobile or motor truck service, it should also be useful for other places where the variable speed device is required.

22-Inch Planer: Cincinnati Planer Co., Cincinnati, O. This is the smallest planer ever built by this firm. Aside from being a new size, it incorporates some improvements in design, relating particularly to details. The shifting device is of new construction, designed with special reference to high speed and short stroke work. It is provided with a safety locking device, and is connected with a handle on the opposite side of the bed, so that the machine may be operated from either position. The crank adjusting handles are fixed in position, and are provided with revolving grips, so that the operator can retain a tight hold while turning the screw or rod rapidly.

Hydraulic Valve: Caskey Valve Co., 422 Arcade Building, Philadelphia, Pa. This firm is selling a valve intended particularly for hydraulic service, though it may be used as well for steam or air. It is a plug valve, but is unusual in its construction, in that the plug is straight, instead of being tapered as usual. It is so constructed that the higher the pressure, the more tightly the valve is packed. This is done by introducing the pressure behind leather washers, which are thus spread to fill the holes and prevent leakage of the fluid. This form of valve is built for the large area and low pressure service of the locomotive blowout type, as well as for hydraulic press service.

Precision Lathe: Frederick Pearce, 18 Rose St., New York City. This precision lathe was developed by the builders originally for their own use. It is intended to have the fine workmanship required by makers of delicate instruments, and at the same time to be capable of taking a reasonably heavy chip, considering the size of the lathe. The construction of the bed and slide rest departs from the usual lines, in that the carriage is mounted on ways at the front of the bed instead of on the top, while the tool rest is carried on a vertically adjustable slide on the carriage. This arrangement, besides furnishing an adjustment for the height of the tool, should also make of the machine a convenient precision miller for many varieties of work. Owing to the arrangement of the carriage ways, the carriage may be fed clear past the headstock to the head end of the bed.

Clutch for Imparting Variable Speed to Machines: Variable Speed Clutch Co., Milwaukee, Wis. This clutch is intended not only for starting and stopping machines, but for varying the speed as well. In one form of the device the clutch members are thrown into contact by an air cylinder in which the pressure is maintained at a constant point by a reducing valve. The clutch levers are thrown out of engagement by the centrifugal action of revolving weights. When the speed of the driven member is so high that the weights fly outward against the air pressure, the clutch is relieved, thus setting the limiting speed of the drive. By varying the reducing valve adjustment this speed may be adjusted to any desired amount, giving more or less slip in the clutch. Another valve provides for throwing the air pressure on or off, thus starting and stopping the driven member. The clutch would seem to be the mechanical counterpart of the often conceived hydraulic by-pass arrangement for transmitting power at variable speed, and would apparently be subject to the same limitations.

* * *

In the description of the Collis high-speed drill (made by the High Speed Drill Co., of Dubuque, Iowa) published in the new tools department of the December issue of Machinery, we inadvertently stated that with these drills, special holding chucks are *necessary*. This is, of course, a typographical error. It should have stated that special holding chucks are *unnecessary*.

* * *

RAPID WORK WITH POWER HACK-SAWS.

An interesting test was recently undertaken at the E. C. Atkins & Co.'s plant, Indianapolis, to ascertain the cutting qualities of what is termed the A.A.A. hack-saw blades manufactured by the company, when used on the company's "Kwik Kut" power hack-saw. A piece of circular machine steel, 6 inches in diameter, was placed in the hack-saw machine and a cut was taken through the work in less than two hours, the machine being speeded up to fifty strokes per minute. The cut was true and straight so that no machining or planing was necessary. The machine was then slowed down to forty strokes per minute, and a second cut was completed in one hour and thirty minutes. A third cut was then made at the same speed, but with a five-pound weight added on the saw frame. This time the 6-inch diameter machine steel bar was cut through in one hour and fifteen minutes. In another test of the same hack-saw blades, in order to ascertain their durability, they were kept at work for thirty-two hours cutting annealed tool steel, and it was found that they stood up well for the work and were not entirely worn out. The accompanying half-tone shows the cuts made during the experiment, and illustrates the truth of the surfaces and straightness of the cuts taken.

Rapid Cutting with "Kwik Kut "Hack-saws.

We are interested in all changes of positions of foremen, superintendents, shop managers and contributors, and request notices of such changes, and of deaths, for publication.

THE CLEVELAND AUTOMATIC MACHINE CO.'S CHICAGO DEMONSTRATING ROOM.

The demonstration of the capabilities of automatic machine tools, perhaps, is more important than that of any other class of machine tools sold. The prospective customer first wishes to be assured that the machine will produce the parts desired true to size and shape, and with the required finish. He also wishes to be convinced that the machine can produce the work in the time specified, and to see with his own eyes the character of the tool equipment. Recognizing the desirability of accommodating "the man from Missouri," the Cleveland Automatic Machine Co., Cleveland, Ohio, last fall opened a demonstrating room at 67 West Washington Street, Chicago, in which are installed four working Cleveland automatic machines. These are the plain, three-holed, standard and new model designs, respectively.

The accompanying illustration shows the demonstrating room and the general arrangement of the machines. The machines, it will be noticed, are arranged *en echelon* on the plan generally followed in screw machine installation, that is, so the bar stock of one machine overlaps and parallels the next machine, and so on. This saving of floor space as compared with that required for the straight alignment generally followed with engine lathes is of much importance. The demonstrating room thus is made a model for automatic machine arrangement in installations for manufacturing.

The Cleveland Automatic Machine Co.'s Chicago Demonstrating Room.

All four machines are performing operations that are commonly regarded as extremely difficult. Customers can be shown the machines under difficult working without imposing on the hospitality of some good-natured manufacturer in whose plant similar machines are at work. Demonstrating rooms are not strictly a novelty in this country, but there are so few of them in which the machines are shown under full working conditions that the opening of this store is likely to attract considerable interest among the trade.

FIRST ALCOHOL MOTOR CAB IN NEW YORK.

The first alcohol motor cab has made its appearance in New York. It is the product of the factory of the H. H. Franklin Mfg. Co., Syracuse, N. Y., where the engineers have long been experimenting to provide an alcohol motor that would give results equal to those of the gasoline motor. The engine was tested over hundreds of miles of road before being sent out from the factory, and has demonstrated a capability of covering as great a distance for each gallon of alcohol as other motors of like size do for each gallon of gasoline. The new vehicle is of eighteen horse-power, and is identical with the gasoline motor cabs of the 1909 Franklin model except for the provision made for the use of alcohol in place of the gasoline. At first experiments were made with a regular gasoline engine, but after a study of its action an engine was made specially designed for alcohol, and it is this with which the new cab is propelled. Alteration is made as to compression and carburetion. The alcohol is found to produce no bad effect upon the motor. The problem of making a workable alcohol motor has been the subject of much attention on the part of the governments of France, Germany and the United States. The Franklin cab will now demonstrate its every-day practicability in competition with over 500 gasoline motor cabs of the landaulet type in New York City.

* * *

LAST WIRE OF THE MANHATTAN BRIDGE CABLES STRUNG.

The last wire of the four cables of the new Manhattan Bridge across the East River, New York, was strung December 10 in the presence of Mayor McClellan, and other notable guests. The improved method of stringing the cables, illustrated and described in the October issue of MACHINERY, has made the work proceed rapidly, 24,000 miles of wire having been strung in just four months. The span is 1,470 feet, or 130 feet less than the Williamsburg Bridge. The cables are 21¼ inches in diameter and each contains 37 strands of 256 wires each, making a total of 9,472 wires per cable. The wire is 0.192 inch diameter, No. 6 Roebling gage. Following the stringing of the wires begins the work of binding the cables together to shape them into cylindrical form to protect them from the elements. Miles of wire will be wrapped around them and hydraulic presses will be employed for pressing the strands together into the cylindrical shape of the completed cables.

* * *

A clever device for making deadly revolver shooting at night possible by inexperienced shooters, has been patented that is worth attention because of the interesting principle involved. An electric flash lamp is mounted on the revolver barrel parallel with its axis, having a push-button located on the back end convenient for the shooter's thumb. Pressure on the button lights the electric lamp and projects a disk of bright light at a considerable distance, illuminating the object to be aimed at. In the center of the circle of illumination is a dark spot, this being the shadow of a tiny bead in the focus of the flash-light. This shadow marks the exact spot where the bullet will hit, and if the shooter can hold the shadow steadily on his victim he is assured of deadly aim. The attachment really makes it easier for a poor shot to hit an object at night than for a good shot to do accurate shooting by day-light.

OBITUARY.

Geo. W. Corbin.

George W. Corbin, a prominent manufacturer and capitalist of New Britain, Conn., died at his home in that place November 30 in the fiftieth year of his age. Mr. Corbin had been in ill-health for a year or more, but up to a short time before his death appeared to be recovering, and then the end came suddenly. At the time of his death he was president of the Union Mfg. Co., the Corbin Brass Co., the Dean Steel Die Co., the Corbin-Church Co., the People's Savings Bank—all of New Britain, and for several years had been president of the Corbin Cabinet Lock Co. of the same place, resigning last May when ill-health made it impossible for him to attend further the duties of the position. His business career began in the employ of P. & F. Corbin, of New Britain, with which company he remained timekeeper until 1880. Mr. Corbin was a man of much personal popularity, and was made mayor of New Britain in 1894. He was prominent in the fraternal and patriotic societies, having acquired the thirty-third degree in the Masonic order and various honors in other societies. He is survived by a widow and four daughters.

Edwin H. Jones, president of the Vulcan Iron Works, Wilkesbarre, Pa., died at his home in that city December 2, aged sixty-four years.

Warren E. Hill, president of the Continental Iron Works, Greenpoint, Brooklyn, died December 8 of heart disease, aged seventy-four years. Mr. Hill was a member of the Society of Naval Architects and Marine Engineers, and the American Society of Mechanical Engineers.

* * *

PERSONAL.

Henry Kerr has resigned his position with the Boston Gear Works, and has become connected with the New England Gear Works, Boston, Mass.

L. H. Mesker, who has been connected with the Motch & Merryweather Machinery Co. of Cincinnati is now connected with the Cleveland office of Manning, Maxwell & Moore.

Meldon H. Merrill recently resigned his position as salesman for the Westinghouse Electric & Mfg. Co., and has accepted a similar position in the Boston office of the Allis-Chalmers Co.

John L. Walker, formerly auditor for the Buda Foundry & Mfg. Co., has resigned his position, and has been made manager of the "Use-Em-Up" socket department of the American Specialty Co., Chicago, Ill.

Arthur Letherby, who for ten years has been superintendent of the Hamilton Machine Tool Co., has bought the interest of Mr. Philip Fosdick in the Kern Machine Tool Co., Cincinnati, Ohio, and becomes vice-president and superintendent. Mr. Letherby assumes his new duties January 1.

G. M. Basford, assistant to the president of the American Locomotive Co., 30 Church St., New York, has been made acting-secretary of the Railway Business Association. This association has been organized for the purpose of promoting confidence in railways and transportation interests generally.

Joseph A. MacLennan has resigned his position at the Philadelphia works of the Link-Belt Co. to become president of the Wilmot Machinery Co. of New Orleans. Mr. MacLennan was associated with the Link-Belt Co. for over twelve years, and lately was superintendent of the Philadelphia works. His early training was obtained in the erection department of the Wm. Cramp & Sons Ship & Engine Building Co., Philadelphia, Pa.

William P. Sargent, the author of the series: "The Design and Construction of Meal-Working Shops," now running in the engineering edition of this journal, goes with the Curtis Publishing Co., Philadelphia, on or about January 1, in the capacity of mechanical expert to investigate and suggest ways and means for solving the engineering problems that develop with a great publishing business. The company is building a new plant which will be completed in about two years, and it will be designed throughout for the economical production of its publications on a large scale. The circulation of its two journals now is over 6,000,000 copies per month, and plans will be made for the handling of a much larger circulation. The position is peculiar, the parallel of which probably does not exist anywhere else.

JESSE M. SMITH.

Jesse M. Smith, the newly-elected president of the American Society of Mechanical Engineers, was born at Newark, Ohio, 1848. In 1862 he moved to Detroit, Mich., with his father's family, and in 1865 entered Rensselaer Polytechnic Institute, Troy, N. Y., remaining there three years. He traveled in Europe one year and then attended Ecole Centrale des Arts et Manufactures, Paris, three years and received the degree of mechanical engineer, therefrom, in 1872. During vacation periods he visited manufacturing plants in France, Germany and Belgium, and listened to lectures in the Polytechnic Institute of Berlin.

Jesse M. Smith.

Mr. Smith began the practice of engineering in 1873, designing and superintending the erection of blast furnaces for melting iron and native ores with the raw bituminous, in the Hocking Valley, Ohio. He also made surveys of coal mines, opened mines and built coal handling machinery for them and surveyed and constructed railroads from mines to furnaces. He represented the U. S. Electric Lighting Co. in Ohio and Michigan in 1884 to 1886, during which time he erected a number of early incandescent electric light plants, including one of 1,000 lights in the Stillman Hotel, Cleveland, Ohio, which was the first hotel lighted exclusively and continuously by electricity. Mr. Smith returned to Detroit

MILLING MACHINES FOR HEAVY SERVICE

Brown & Sharpe Mfg. Co.

PROVIDENCE, R. I., U. S. A.

Experts in Milling Construction and Practice

Careful study of the requirements of milling machines for *Heavy Service* has produced the B. & S. Constant Speed Drive Milling Machine, an example of

POWER AND RIGIDITY

Attention is called

to the massive frame, its great width and depth and the large heavy base supporting it—The extreme vertical depth and large working surface of the table—The length and vertical depth of saddle—The rigid design of the knee which is strongly webbed on the inside and has exceptionally long bearings on the column—The stiff support of the overhanging arm—The driving pulley which is 20" diameter, takes a belt 7" wide and runs at the high speed of 320 R.P.M. developing *ample* and *constant* power for the heaviest cuts within the capacity of the machine—The massive spindle having a recess in the end instead of a slot across and supported by unusually long boxes of large diameter—The large diameter, wide face, and coarse pitch of all the gears—Both the speed and feed changing gears which are hardened, a feature, the value of which no authority will dispute—The lever type of tumbler gear lock which locks that gear rigidly and automatically as soon as the lever is released—The long and wide bearing surfaces accurately scraped and the rigid mounting of all shafts which are hardened and bushed with bronze.

Do these features not show a design of machine capable of developing power without undue stress in any of its parts?

when his father died in 1889 and opened an office as consulting engineer. He designed and erected several power plants and several plants for electric lighting and electric railways, and also apparatus for steam heating with exhaust steam in large manufacturing plants.

In 1883 Mr. Smith was called into service as an expert witness in patent litigation in the U. S. courts. This practice gradually increased, displacing his work as consulting engineer, until in 1898 he moved to New York City to continue the practice of expert in patent causes, exclusively. Among the notable cases of patent litigation in which he acted as an expert witness were: Steam injectors under the Hancock inspirator patents; cylinder lubricators for locomotives; quick-action air brakes under the Westinghouse patents; induction electric motors under the Tesla patents; incandescent electric lamps; cyclone dust collectors, roller mills and middlings purifiers for flour manufacture; pressure filters; steam heating apparatus; typewriters; calculagraph; armored concrete construction, etc.

Mr. Smith became a member of the American Society of Mechanical Engineers in 1883 and was a member of the council as manager 1891-94. He acted as vice-president 1894-96 and again, 1899-01. He is a member of the American Institute of Electrical Engineers, Societe des Ingenieurs Civils de France, Association des Anciens Eleves de l'Ecole Centrale des Arts et Manufactures, Detroit Engineering Society, Society for the Advancement of Science, American Geographical Society, Engineers' Club, and Ohio Society of New York.

* * *

COMING EVENTS.

December 31-January 7.—Ninth annual show of the American Motor Car Manufacturers' Association at Grand Central Palace, New York City.

January 5.—First session of the fourth annual meeting of the Society of Automobile Engineers in New York City held in connection with the Automobile show at the Grand Central Palace.

January 12.—The next monthly meeting of the American Society of Mechanical Engineers will be held in the Engineering Societies' Building on Tuesday evening, January 12. The paper will be by Mr. Carl G. Barth of Philadelphia: "The Transmission of Power by Leather Belting," illustrated by lantern slides. It will be a comprehensive summing up of the theory and practice of belting in which conclusions are drawn from the work of Lewis, Bancroft, Bird and others, who have made experiments upon the transmission of power by belting. Valuable charts have been prepared by the author for the solution of belting problems. Mr. Barth's long experience in the scientific running of machine tools, in connection with the introduction of improved shop methods, has shown the need of definite data for the application of belting to machinery and led to the development of the results contained in his paper. His data have been applied to belting in different plants for many years, giving an unusual opportunity to study the problem in great detail.

January 16-23.—Ninth annual show of the Association of Licensed Automobile manufacturers at Madison Square Garden, New York City.

January 22.—Final sessions of the fourth annual meeting of the Society of Automobile Engineers held in connection with the annual show at the Madison Square Garden, New York City.

June 16-18.—Annual convention of the American Railway Master Mechanics Association at Atlantic City, N. J.

June 21-23.—Annual convention of the Master Car Builders' Association at Atlantic City, N. J.

NEW BOOKS AND PAMPHLETS.

Report of the Commissioner of Education, 1907. 522 pages, 6 x 9 inches. Published by the United States Bureau of Education, Washington, D. C.

Railway Capital and Wages. By W. H. Williams. Pamphlet of 22 pages, 8 x 10 inches, publishing the author's remarks before the Traffic Club of New York.

Mechanical World, Pocket Diary and Year Book for 1909. 395 pages, 4 x 6 inches. Published by Emmott & Co., Ltd., 65 King St., Manchester, England. Price, 6d.

The twenty-second annual issue of the work contains a varied collection of notes, rules, tables and miscellaneous data for mechanics and engineers. The sections on steam turbines and friction clutches have been re-written and extended and a section on chain drives introduced. A number of blank pages in the back part of the book provide for a diary and memoranda.

Producer Gas, Gas Firing and the Advantages of Gas Firing Over the Direct Use of Coal. By Ernest Schmatolla. 16 pages, 5½ x 8½ inches. Published by the author, 317 High Holborn, London, W. C., England. Price, 1 shilling.

This pamphlet states the advantages to be derived from the use of producer gas in preference to that of fuel fed directly into the furnace; also information concerning the methods of utilizing fuels of inferior quality in specially constructed producers, so as to give results superior to high-class coal fired in the ordinary way.

Mine Sampling and Chemical Analyses of Coals Tested at the United States Fuel Testing Plant, Norfolk, Va., in 1907. Bulletin 362. By John Shober Burrows. Published by the Department of Interior, U. S. Geological Survey, Washington, D. C.

Pamphlet giving location of coal beds and detailed sections of the seams at the points where the mine samples were taken, showing the amount of clean coal, and the partings of shale, bone coal, etc., together with chemical analyses of these samples and of the car-load lots as they were received at the testing plant after exposure to the weather for various periods.

Annual Report of the Chief of the Bureau of Steam Engineering to the Secretary of the Navy for the Fiscal Year 1908. Published by the Navy Department, Bureau of Steam Engineering, Washington, D. C.

The report contains financial statement of expenditures for the year in the maintenance of navy yards, naval vessels, etc., purchase of material and other incidental expenses, together with an account of the general operations of the Bureau, including a summary of the work done at the various navy yards of the United States, and a register of ships giving machinery data of all ships carried on the active list and those authorized by Congress and now under design or construction.

Morrison's Spring Tables. By Egbert R. Morrison. 84 pages, 6 x 9 inches. Published by Morrison and Martin, Sharon, Pa.

This book contains data on helical and elliptical springs, both heavy and light. The author has considered a helical spring whose bar is less than 1/16 of an inch in diameter, and an elliptical spring whose plate is less than 1/16 of an inch in thickness, to be a light spring. The tables give the length per inch of solid height; the weight per inch of solid height; free height per inch of solid height; and capacity. There are in addition formulas for calculating the properties of helical springs of round and rectangular section and elliptical springs. Mathematical tables are included to facilitate the use of the formulas.

Forging. By John Lord Bacon. 112 pages, 6½ x 9¼ inches. 178 illustrations. Published by the American School of Correspondence, Chicago, Ill. Price, $1.00.

A manual of practical instruction in the hammering, working, forming and tempering of wrought iron, machine steel, and tool steel, including details of the modern processes of electric welding. The work contains throughout numerous illustrations which supplement and make clear the reference in the text. The chapter headings are as follows: Equipment; Welding; Calculation of Stock for Bent Shapes; Forging Operations; Simple Forging; Calculation of Stock for Forged Work; Tool Steel Work; Tool Forging and Tempering; Heavy Forging; Miscellaneous Processes; and Electric Welding Development.

The Apprenticeship System in its Relation to Industrial Education. By Carroll D. Wright. 116 pages, 6 x 9 inches. Published by the United States Bureau of Education, Washington, D. C.

This is a work of valuable information concerning the industrial school problem. The need for a combination of the apprenticeship and academic education, and ways in which the combination may be effected, as shown by recent experiences in a few of our leading industries, are pointed out. The extent of the apprenticeship system in the United States and other countries is given, together with a description of various new apprenticeship systems which are the educational features of a few typical concerns in this country. Appended to the work is a digest of the apprentice laws of the various states.

Algebra Self-Taught. By W. P. Higgs. 104 pages, 5 x 7 inches. Published by Spon & Chamberlain, 123-125 Liberty Street, New York.

Tenth edition of a volume for the use of mechanics, young engineers and home students. The contents of the book by chapters is as follows: Symbols and the Signs of Operation; the Equation and the Unknown Quantity; Positive and Negative Quantities; Multiplication, Involution, Exponents; Negative Exponents, Roots, and the Use of Exponents as Logarithms; Logarithms; Tables of Logarithms and Proportional Parts; Transformation of Systems of Logarithms; Common Uses of Common Logarithms; Compound Multiplication and the Binomial Theorem; Division, Fractions and Ratio; Geometrical Means; Limit of Series; Square and Cube Roots; and Equations.

Mechanical Drawing and Elementary Machine Design. By John S. Reid and David Reid. 439 pages 6 x 9 inches. 301 illustrations. Published by John Wiley & Sons, New York. Price, $3.00, cloth.

This volume (second edition) is designed to apply the principles of mechanical drawing to the solution of practical problems in machine construction, and to familiarize the student with the arrangement and proportions of the most important machines and their details, and also the best practice in design and construction. The various chapters are as follows: Introductory Instructions; Screws, Nuts and Bolts; Keys, Cotters and Gibbs; Rivets and Riveted Joints; Shafting and Shaft-Couplings; Pipes and Pipe Couplings; Bearings; Sole-plates and Wall Box-frames; Belt Gearing; Toothed Gearing; Valves, Cocks and Oil-cups; Engine Details; Elementary Machine Drawing; Present practice in Drafting-room Conventions and Methods in Making Practical Working Drawings.

CATALOGUES AND CIRCULARS.

Fort Wayne Electric Works, Fort Wayne, Ind. Practical guide for transformer testing.

Allis-Chalmers Co., Milwaukee, Wis. Bulletin 1513 on portable and stationary air compressors.

Western Electric Co., 463 West St., New York. Bulletin No. 5370 on steam turbines built under the Rateau patents.

Western Electric Co., 463 West St., New York. Booklets on design E and design L generators and motors.

American Boiler Economy Co., North American Building, Philadelphia, Pa. Catalogue of the Copes boiler feed regulator.

Western Electric Co., 463 West St., New York. Booklet No. 1078 on magneto telephone wall sets, illustrating the construction.

Westinghouse Electric and Mfg. Co., Pittsburg, Pa. Circular No. 1157, descriptive of Westinghouse type "S" transformers.

General Electric Co., Schenectady, N. Y. Catalogue of motor generator sets, varying in capacity from 0.2 K.W. to 1,500 K.W.

Independent Pneumatic Tool Co., Chicago, Ill. Circular L of "Thor" pneumatic tools and appliances for metal working and wood working.

Artisans' Guild, Benton Harbor, Mich. Catalogue of automatic oiler loose pulleys and automatic oiler sleeves for wood and large iron pulleys.

General Electric Co., Schenectady, N. Y. Catalogue of fan motors and small power motors, embracing both alternating and direct current types.

Cleveland Twist Drill Co., Cleveland, Ohio. Catalogue "Peerless" high-speed reamers in which the blades of high-speed steel are joined to the body by the "Brazo-Hardening" process.

Carpenter Steel Co., Reading, Pa. Pamphlet issued in commemoration of the Vanderbilt Cup Race, on the importance of alloy steels in modern automobile construction.

Hyatt Roller Bearing Co., Newark, N. J. Leaflet entitled "Push Your Business with Less Friction," being an advertisement of the Hyatt anti-friction bearings.

Follansbee Bros. Co., Pittsburg, Pa. Catalogue entitled "Tin Truth" illustrating the manufacture of tin plate in the company's open hearth works and mills at Follansbee, Brooke County, W. Va.

G. M. Yost Mfg. Co., Meadville, Pa. Leaflets listing solid jaw and swivel bottom machinists' vises, universal woodworkers' vises, "Uwanta" special railroad monkey-wrenches, blacksmith's leg vises, etc.

Fosdick Machine Tool Co., Cincinnati, Ohio. Circular illustrating and describing the Fosdick universal radial drills which are built half and full universal in 4-, 5- and 6-foot sizes.

National-Acme Mfg. Co., Cleveland, Ohio. Leaflet of new Acme automatic machine No. 515, which has a chuck capacity of 9/16 inch and a feed of 3 inches.

Norman W. Henley & Son, 132 Nassau St., New York. Catalogue of books for machinists, engineers, mechanics, mechanical engineers, inventors, foundrymen, electricians, draftsmen, etc.

W. H. Nicholson & Co., Wilkesbarre, Pa. Catalogue of Nicholson's inserted blade gas pipe taps, illustrated and described in this number. These taps are made in sizes from 1 to 12 inches inclusive.

MACHINERY

February, 1909.

AXLE TURNING—METHODS AND PRODUCTION.

WILLIAM P. SARGENT *

THERE has always been an unsatisfied feeling in the mind of the writer because of the fact that the power, strength and rigidity of machine tools are so seldom taxed to the extent that the designer provides for, and because the actual output from machines falls so far below an estimated output, based on the cuts and feeds that the machines were capable of carrying.

Any knowledge or understanding of the forces tending to restrict production should be of value to the designer and to the owners of machine tools, and articles treating of the operation of machine tools under actual shop conditions and not with the bright side always showing, should make towards progress in the world of designing. It is this belief that prompts the writer to offer the following observations:

During a recent period of the writer's experience, it involved upon him to make a study of axle turning in a number of shops in the Middle West from which came reports showing an increased production from the machines. After sifting the many notes made during these visits, the methods in vogue in three of the shops were taken as a basis for the forming of a routine of operations that would conserve the time and efforts of the operator and work the machines up to their power and strength. Naturally, some changes in design resulted from this study of machines in operation—not under rosy conditions, but in the cold, hard realm of actual practice where conditions of lighting, heating, power and conveniences for the men were more adverse than favorable.

The following conditions tend towards a large output from axle lathes, especially from the double axle lathe with center drive:

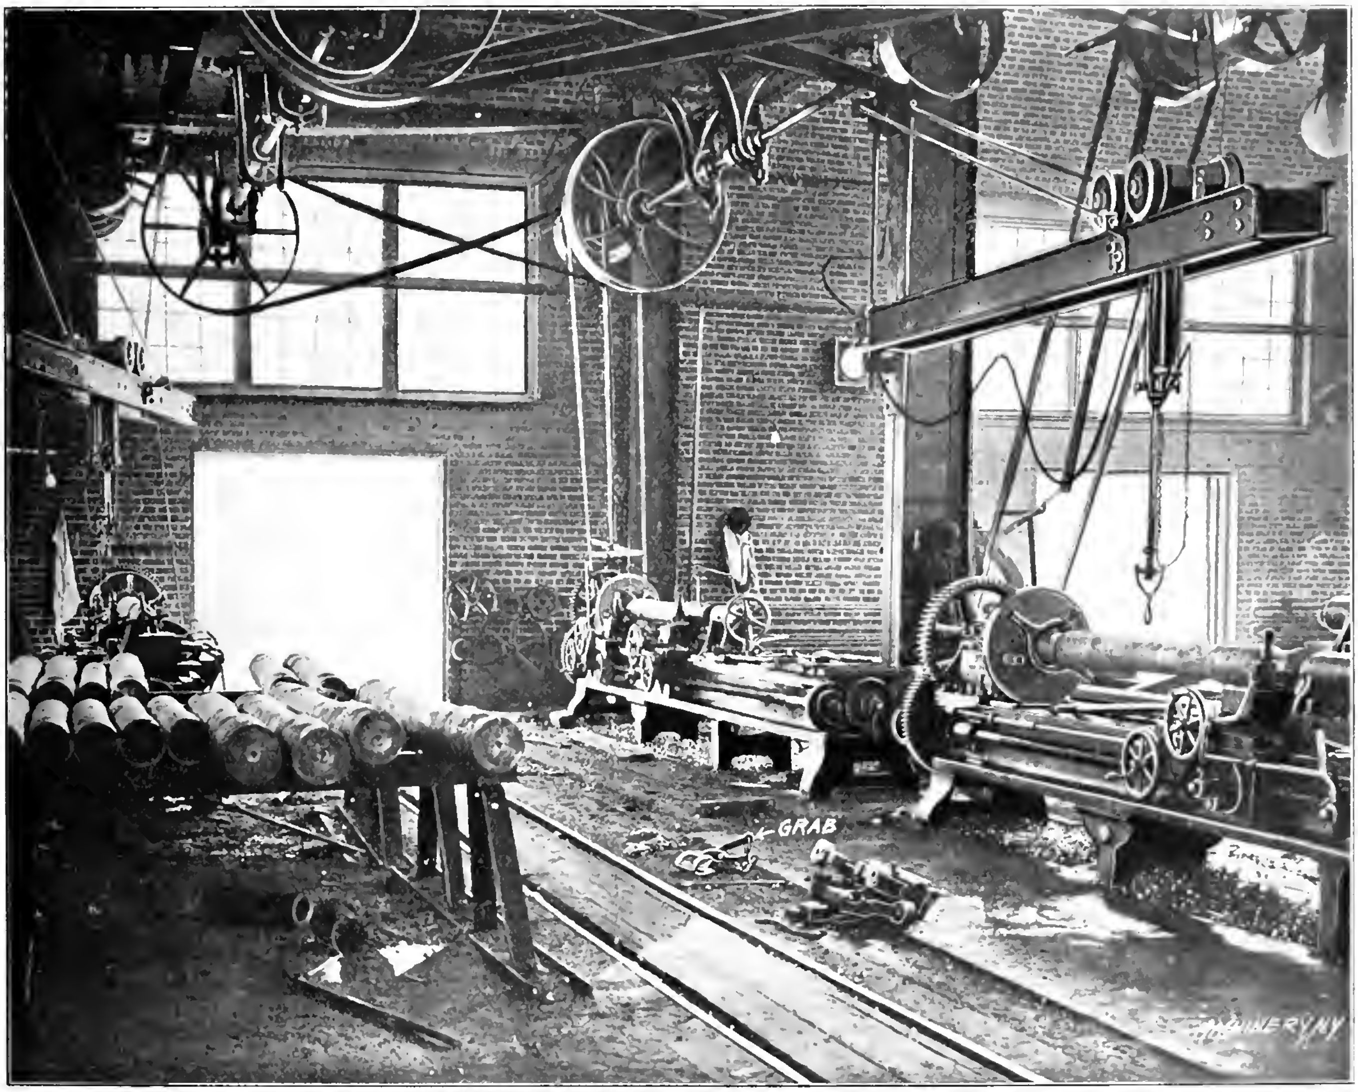

Fig. 1. Axle Turning Department, Shop No. 1.

Machine.—A minimum of obstacles to getting the work in and out; quick-setting driving dogs; quick and easy means of changing speeds and feeds; positive feed stops; a surplus of power.

Machine Auxiliaries—Tools and Gages.—Quick-acting hoists with fairly sensitive control; an abundance of cooling fluid for the tools; tools of efficient cutting angles; duplicate sets of tools for each machine; tools ground in tool-room to approved shapes; tools tempered properly; fixed points on machine for setting tools; limit gages for diameters; length and shoulder gages.

Shop Conditions.—Good light and good ventilation; plenty of work ahead of the machines; axles taken to the wheel press immediately.

Workmen.—A stable piece-work rate, or preferably some form of premium plan.

In order that the reader may make his own deductions and

---

* Address: 1528 Arch Street, Philadelphia, Pa.

perhaps work out a routine better than will be given later, the notes will be presented in much the same order in which they were gathered.

The axle turning in shop No. 1, of which the axle department is shown in Fig. 1, seldom went farther than the roughing operation, the axles being forged at this plant, roughed to within 1/8 inch of the finished size and sold to car shops and railroad shops. This phase of the commercial production of axles is presented in connection with the methods of a car-building plant and a railroad shop in order to cover the subject fully. Many of the axles were of the P. R. R. 100,000-pound car type of steel. (See Fig. 2.) These differ from the M. C. B. standards in having the tapering center portion rough turned. This is the explanation of the use of the single axle lathe, which permits of the use of a taper attachment. The rest of the axles were of the M. C. B. 60,000-, 80,000-, or 100,000-pound type, or locomotive driver axles of 7-, 8-, 11-, 12-, or 14-inch diameters. On a single axle lathe, the carriages both feed in one direction and because of this, car axles have to be reversed when being turned. Axle lathes built by the Niles Tool Works of the Niles-Bement-Pond Co. are used exclusively in the shops where the notes were compiled, and are considered to fulfill the demands of the varied conditions successfully.

Methods in Shop No. 1.

The axles are picked up, from the horse at the left in Fig. 1 by means of the grab shown on the floor in the center of the space near the track, and swung around onto the lathe centers, white lead being used as a lubricant for the centers.

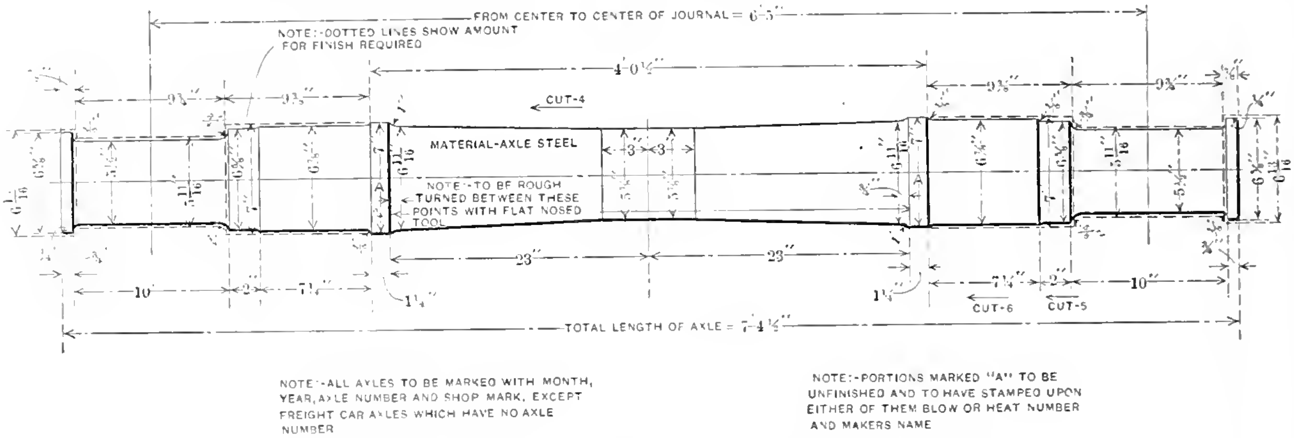

Fig. 2. Pennsylvania Railroad Co.'s 100,000-pound Car Axle, Journal 5 1-2 x 10 inches.

Tools.—The tools used were of high-duty steel, of course, 1 x 2-inch stock, ground as per Fig. 3. the radius *a* being the same as the large fillet of the journal bearing next the "leather bearing" (Fig. 5), and the radius *b* being the same as the small fillet next the collar.

The feed used was generally 1/16 inch per revolution and the average speed of cutting was 45 feet per minute; the tools stood up to this duty for five and six axles.

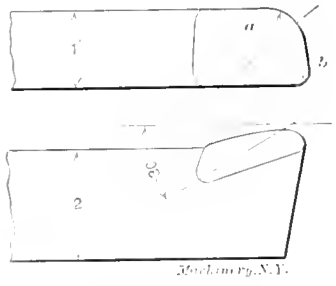

Fig. 3. Lathe Tool used in No. 1 Shop.

The consecutive tool movements are designated as "cut No. 1," etc. (See Figs. 4 and 5.) The tool setting for cut No. 1 was obtained from the machined collar diameter of the previous axle before removing the same from the lathe. The operator stands by the tool for the twelve or more revolutions necessary for this cut, and then feeds the tool in with the cross-slide (calipering for the journal diameter) on cut No. 2, then throws in the power feed for cut No. 3. His next move is to start cut No. 4 with the left-hand tool (an over-run on this cut can do no harm) and he has ample time to return to the right-hand end, throw out the power feed, and feed by hand to finish the journal length to gage. The tool is then set to turn the collar, after which the carriage is run as far towards the tailstock as possible, preparatory to turning the axle end-for-end in the machine. Cut No. 4 is finished by this time, and the axle is then reversed.

Cut No. 5, Fig. 5, is then started and then No. 6. Cut No. 5 is completed by the time No. 6 is started, so No. 7 and No. 8 follow, duplicating No. 2 and No. 3 on the other end. The operator now has two long cuts going at the same time and gets a breathing spell. When cut No. 6 is finished, cut No. 9 is started; then cut No. 10 follows No. 8, the operator staying with No. 10 until the correct length of the leather seat (sometimes called "leather bearing" or "dust-guard bearing") is obtained, allowing the tool on cut No. 9 to over-run and "cut wind." After throwing out the feed on cut No. 9, the right-hand tool is set to the collar diameter ready for the next axle.

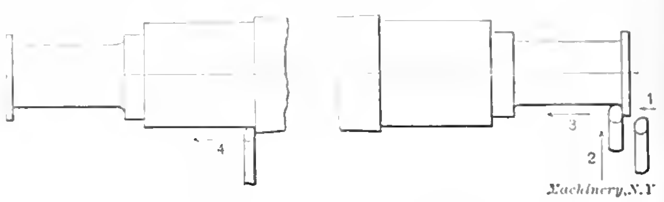

Fig. 4. Cuts taken with First Position of Axle.

Turning Pennsylvania Railroad 100,000-pound Car Axles.

The routine for turning the axles shown in Fig. 2 is simpler than for the M. C. B. type, as the lathes are designed with this particular work in view. Cuts Nos. 1, 2 and 3 are started in succession, and when cut No. 3 is well under way, cut No. 4 is started, using the forming slide (similar to the familiar taper attachment slide on engine lathes). Cuts Nos. 5 and 6 are taken consecutively and the axle is reversed when these cuts are completed.

Production in Shop No. 1.

The output from axle lathes in most shops is governed by the maximum average daily wage that the workmen believe will be permitted without bringing about reductions in the piece-work prices. This proposition holds true in this instance, as may be seen in the following figures; the number of axles per day times the piece price approximates $2.50 per day (the prevailing rate in shops in the immediate vicinity). The time taken to rough finish a 60,000-pound car axle, to within 1/8 inch of the finished size, was 20 to 22 minutes.

Kind and Size.	Number per Day.	Price Paid.
P. R. R. 100,000-lb., turned all over	9 to 10	25 cents.
M. C. B. 100,000-lb.	18 to 20	14 cents.
M. C. B. 80,000-lb.	22 to 24	
M. C. B. 60,000-lb.	25 to 28	10 cents.
Driver Axles.		
14-inch	5	50 cents.
11–12-inch	6 to 7	40 cents.
7–8-inch	9 to 10	25 cents.

NOTE.—The M. C. B. 100,000-pound axles were of very hard and tough steel, and would sometimes require two cuts although they were forged closer than the smaller axles.

Turning 60,000- and 80,000-pound Car Axles at Shop No. 2.

Axles at the car shop No. 2 were turned on a smaller Niles lathe designed for street-car axles, but still the output and quality compared favorably with the work done on the heavy machines at the railroad shop No. 3. The methods in vogue at shop No. 2 were very interesting, particularly because the operator handled his work unassisted, while the workmen in shop No. 3 would often get help from the laborers when putting the axles into the lathe. At shop No. 2 the axles were brought into the shop on high two-wheeled trucks, carrying two or three axles at a time, and rolled onto horses set at the height of the lathe centers. The arrangement of the machines and trestles is shown in the plan Fig. 6. Axles were picked up and swung into the lathe by means of the lever hoist (Fig. 7) arranged to traverse on the arm of a jib-crane of about 10-foot radius. It will be noticed that the work is put in the machine from the front side contrary to the usual practice where the crane is attached to the back of the lathe. When the axle was through the center head it was let down, or rather dropped unceremoniously onto the tool carriages.

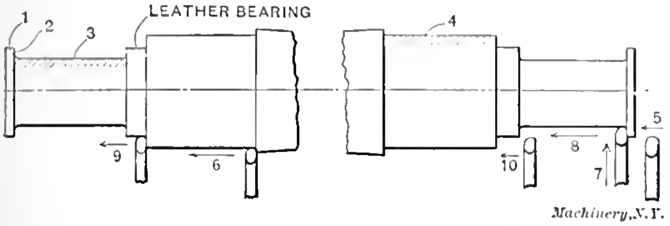

Fig. 5. Cuts taken with Axle Reversed in Lathe.

The left-hand end was raised to its center by means of a small lever, and the right-hand end to its center with the hoist.

Tools.—The tools used were similar to those in use in the railroad shop (see Fig. 11). The cutting angles were 27 degrees for roughing and 20 degrees for finishing. While the axles were on the horses, they were gaged for total length as sometimes the over-length would amount to ½ inch. This extra length was left on the collars, making the distance from shoulder to shoulder the same on all axles. This distance being uniform, the wheels were easily and quickly pressed on to the proper point in relation to the journals, these shoulders serving as reference points for gaging the wheel-pressing.

Feeds.—Feeds of 1/16 inch or 1/12 inch were used for roughing and 1/8 inch for finishing. Following is the order and character of the cuts:

Cut No. 1, *Fig.* 8.—The collar is roughed with right-hand tool. This tool feeds about 2 inches before the operator can return from starting the left-hand tool on the duplicate cut on the other collar. Note.—All right-hand cuts are duplicated on the left-hand end.

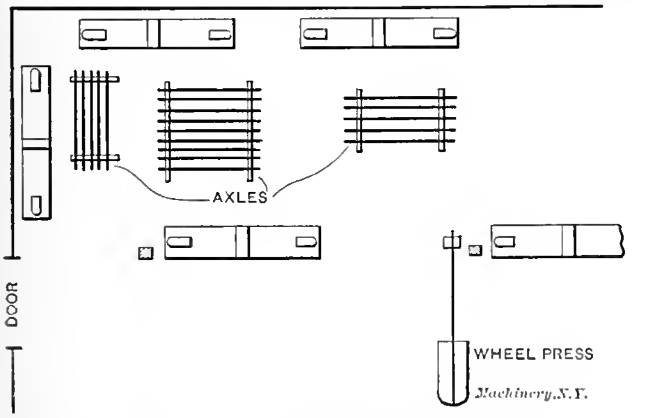

Fig. 6. Arrangement of Machines, Shop No. 2.

Cut No. 2, *Fig.* 8.—The tool is forced into the axle cutting down inside of collar, making allowance for over-length, deep enough to get under the scale where there is the least stock; then the power feed is thrown in.

Cut No. 3, *Fig.* 8.—The right-hand tool is fed by power until the journal length is obtained, using gage as shown.

Cut No. 4, *Fig.* 8.—The right-hand tool makes second cut on journal. The tool is fed in to within 1/32 inch of finished diameter and power feed thrown in.

Cut No. 5, *Fig.* 8.—Roughing cut on leather seat to gage.

Cut No. 6, *Fig.* 8.—Only cut on wheel fit, fine feed, to gage.

Cut No. 7, *Fig.* 8.—Outer edge of collar is chamfered.

Cut No. 8, *Fig.* 8.—Operator puts in finishing tool and finishes cut on collar.

Cut No. 9, *Fig.* 8.—Cutting down inside of collar, finishes the fillet.

Cut No. 10, *Fig.* 8.—Finishing cut on journal, using the other edge of the gage for the fillets.

Cut No. 11, *Fig.* 8.—Operator slightly tapers the wheel fit for about ½ inch to facilitate entrance into the hub of the wheel when pressing on.

Burnishing, Fig. 9.—The finishing tool is taken out and the burnishing roller is put in. This roller is of hardened steel, smoothly polished, and is forced against the axle sufficiently to roll down the high tool marks, leaving a smooth glazed surface. The feed is about ⅛ inch per revolution.

The rolling tools are then taken out and the left-hand roughing tool is set from the collar, ready for the next axle.

Limits.—The axles are turned to within 1/32 inch of the diameter on the journal and to within 0.01 inch of the diameter on the wheel fit. These limits may not seem very rigid for a turning operation, but the workmen consider them so. That they are close enough is self-evident from the number of wheels and axles in use and the uniformity in the reading of the pressure gage when the wheels are being pressed on.

Production.—The above routine of operations enables a 60,000-pound car axle to be put into the lathe, roughed, finished and burnished, and taken out in 45 minutes. This time was made on very tough, hard Carnegie steel. The time on 80,000-pound axles was 60 minutes.

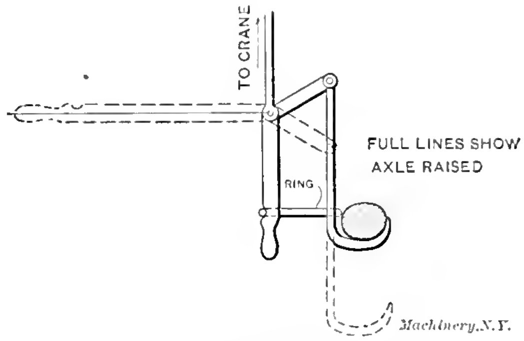

Fig. 7. Lever Hoist for Axle Lathe.

Notes from the Railroad Wheel Shop No. 3.

The first impression was that of the cramped quarters and the poor arrangement of the lathes, car-wheel borers and the wheel-press relative to one another. Then the power was at all times deficient and sometimes almost nil, as the line-shafts were driven by a vertical slide-valve engine whose source of steam supply was at a remote point and inadequate. This condition of the power affected the time per axle greatly, as the operators could seldom carry the amount of feed they wanted, because the amount of stock on the journals varied from ¼ inch to ¾ inch. The axles are centered from the wheel-fit.

The foreman of the wheel shop was a broad and considerate man and well liked by the workmen. This feeling of good will had a great deal to do with keeping the average output up to a mark well above the average in the majority of wheel shops of other roads.

The routine of operations will be taken up briefly, as it followed that of shop No. 2 excepting the order in which some of the cuts were taken and the type of gage used.

Tools.—The roughing and finishing tools were similar to those used in shop No. 2 as shown in Fig. 11. Fig. 10 shows the gage used, no attention being paid to the variation in the length of the axles.

Speeds.—The speeds of cutting averaged 45 feet on the wheel-fit and 35 feet on the journal bearing; the belt remaining on one step of the cone for all cuts. The Niles lathe since has been changed so that a speed correct for the various diameters can be obtained without loss of time. The power required for axle turning justifies a large motor to each tool,

and the ease of making speed changes would naturally bring about an increased output were the wages of the workmen increased by a fair premium plan.

Feeds.—A feed of 1/12 inch was generally used for roughing, and 1/8 inch for finishing. A coarser feed would have been used for finishing but for the difficulty of grinding a sufficient length of straight edge on the tool. This objection would not have held if the tools had been ground to shape in the tool-room.

Routine.—In the following description, the right-hand cuts only will be mentioned. The left-hand cuts follow each right-hand cut in turn. The first roughing cut is taken on the collar and as the leather seat is the same diameter, the operator then moves the tool over and starts this cut, avoiding the calipering necessary in the routine of shop No. 2. The third cut roughs the wheel-fit.

The fourth cut finishes the wheel-fit, the tool not being changed but simply knocked around to present a scraping edge to the work, and the feed changed to 1/8 inch. The journal is then roughed with a 1/12-inch feed. For the sixth or finishing cut on the journal the operator changes to the finishing tool and 1/8-inch feed. This cut removes about 1/64 inch on a side. The seventh and eighth cuts finish the collar and the leather seat. The collar edges are then chamfered. The rolling operation would naturally follow without removing the axle from the machine, but at the time of the writer's visit the journals were burnished in another lathe involving a second handling and taking about ten minutes time of another man's time, besides the time of handling. Since then, however, the burnishing has been done in the same lathe and less than five minutes is added to the time of roughing and finishing. The burnishing roller, shown in Fig. 9, is about 4 inches diameter and of 1¼ inch face. This roller must be very hard, yet not allowed to go out of round in hardening, and must be polished like a mirror, if true, round journals would be obtained.

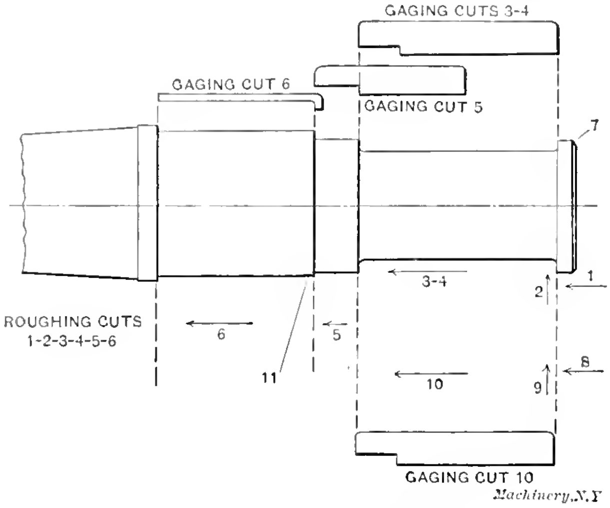

Fig. 8. Order of Axle Cuts in Shop No. 2.

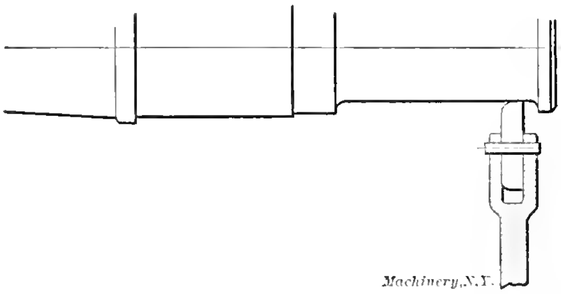

Fig. 9. Burnishing Tool.

Production in Shop No. 3.

To get a line on the production of the lathes was somewhat difficult, as steel, and wrought iron axles were turned in the same lots. Some iron axles were much more difficult to turn than those of steel on account of seams, though the output of iron axles was somewhat greater. Often iron axles would be three-fourths finished and counted as finished, when they were thrown out as defective; also the effective speed was greater on iron axles. The belt was on the same step of the cone for iron axles as for steel, but the resistance to cutting was less and the speed of the line shaft would not drop so much when all the lathes had heavy cuts going at the same time. The foreman of the shop gave the output that could be obtained by crowding, if the workmen felt sure that the piece-price would not be cut, as follows:

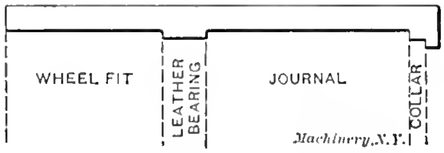

Fig. 10. Gage used in Shop No. 3.

Axle.	Daily Average.	Maximum per Day.	Piece-price.
60,000-lb.—			
Iron	20	24	20 cents.
Steel	16	20	25 cents.
80,000-lb.—			
Iron	16	20	25 cents.
Steel	14	18	35 cents.

These figures were for the roughing and finishing operations. The figures on record from one lathe for a month's run on 80,000-pound axles, more than half of which were of steel, were for 24 ten-hour days—a total of 315, or a daily average of 13. The maximum per day for steel, was 14 and for iron, 18. On one day (writer's observation) on 60,000-pound axles, the first lathe turned 17; the second, 18, and the third, 19, in a ten-hour run.

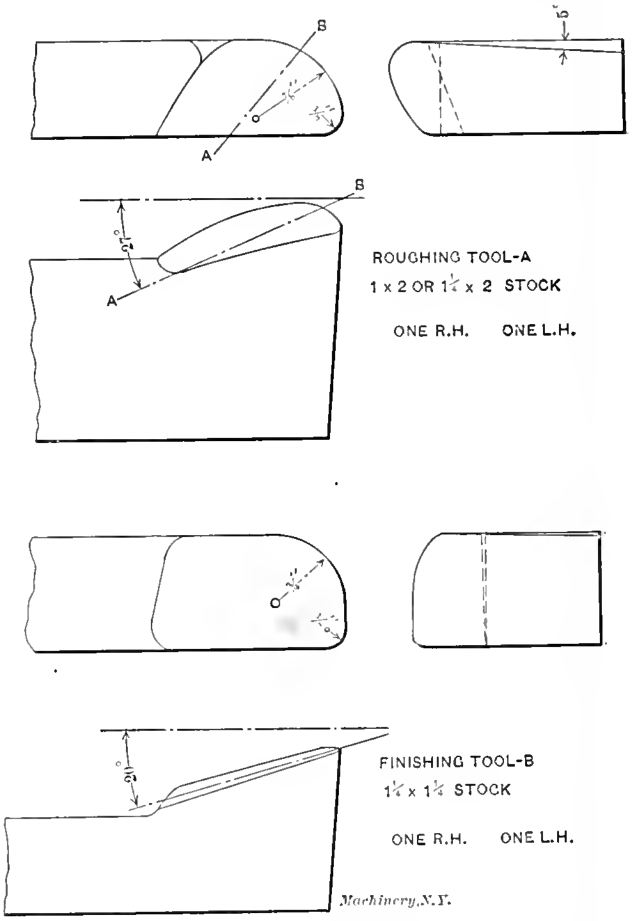

Fig. 11. Tool Shapes A and B.

The time per axle in shops No. 2 and No. 3 is shown comparatively by the following:

	Shop No. 2.	Shop No. 3.
Steel, 60,000-lb.	45 minutes.	32 minutes.
Steel, 80,000-lb.	60 minutes.	48 minutes.

The difference was in a measure due to the less rigid inspection in the railroad shop No. 3 and to a higher wage rate per day.

Recommended Routine.

From the study of the methods of the three shops the following routine was evolved, which has been proven out a number of times, to the writer's knowledge, by a demonstrator. The favoring conditions as presented at the beginning of this paper, should rule if the time is to be approached. This routine is for a double axle lathe and the right-hand cuts described should be duplicated at once with the left-hand tool unless otherwise noted.

Fig. 14 shows a standard M. C. B. axle with a 5 x 9-inch journal with the finished sizes and maximum amount of stock allowed on the different diameters.

Tools.—The tools must be of high duty steel and forged and treated to get a maximum of endurance. The shapes and angles shown in Fig. 11 are recommended as being durable and economical in the power consumption.

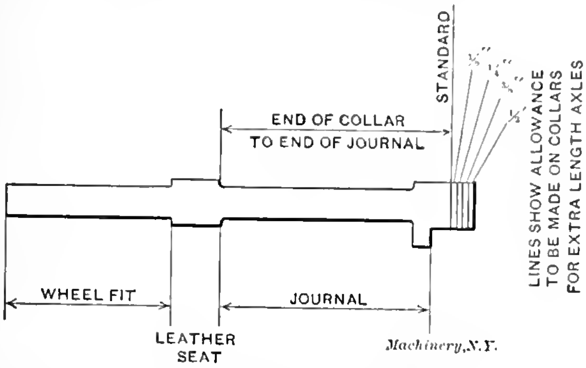

Fig. 12. Approved Form of Gage.

Speeds.—With the above tools and sufficient power, a cutting speed of 45 to 60 feet per minute can be maintained and the tools will not require grinding oftener than every fifth or sixth axle.

Feeds.—When there is less than ⅜-inch stock on a side, ¼-inch feed can be carried easily; when more than ⅜ inch of stock on a side, use 1/12-inch feed.

Gages.—An over-all length gage should be provided. This can be of ¼-inch square steel rod, one end formed with a hook and the other end marked with lines showing the standard length and the surplus lengths by ⅛ inch up to ½ inch.

A gage to be used on the lathe is shown in Fig. 12. This gage combines the features of the gages used in shops No. 2 and No. 3.

The axles should be brought into the shop and placed on horses at a height 3 or 4 inches lower than the lathe centers. The center holes should be lubricated with white lead or heavy grease. Axles should be gaged for length noting the over-length. The form of scissors grab used in shop No. 1 is recommended, as the axle cannot slip but nevertheless it can be released instantly. The driver-dog should be hanging on the nose of the right-hand tailstock ready to slip on the axle when in place. The axles should be gripped at about the same place every time so that they can be placed on centers easily. The hoist can then be swung back out of the way and be ready to take the axle out of the machine without searching for the point at which the axle balances.

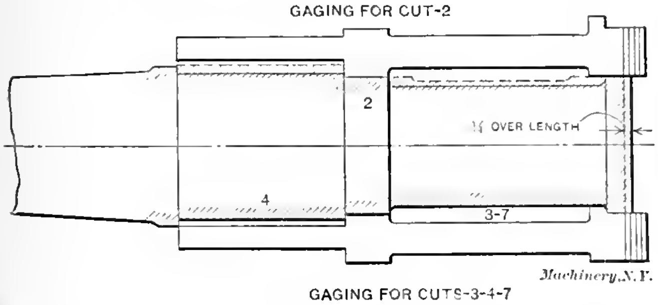

Fig. 13. Illustrating Use of Gage.

Cuts.—As this routine contemplates entering the axles from the rear, the setting for the roughing tool for the first cut on the collar can be obtained by placing a piece of cardboard between the tool and the finished collar before removing an axle from the lathe. For references, see Figs. 13 and 14.

Cut No. 1.—Right-hand collar; tool *A*, Fig. 11; throw in feed right-hand and left-hand; throw out feed right-hand.

Cut No. 2.—Tool *A* on leather seat, right-hand; run the tool over by hand and start the feed; throw out feed on left-hand cut No. 1. Start feed on second cut left-hand; use gage as shown on right-hand cut No. 2, Fig. 13, and throw out feed; same with left-hand tool.

Cut No. 3. Set tool *A* on the journal bearing; feed tool in to within 1/16 inch of finish size, gage as shown; throw in power feed; same with left-hand tool; gage journal length and throw out feed right-hand; same with left-hand.

Cut No. 4. Set tool *A* on the wheel-fit; start cut and caliper; same for left-hand; gage, and throw out feed; same for left-hand. If two cuts are necessary use ⅛-inch feed for both cuts.

Cut No. 5. Set finishing tool *B* on the collar; chamfer outer edge and throw in feed (¼ inch); same for left-hand; throw out feed right-hand.

Cut No. 6. Set tool *B* on the leather seat; change to ⅛ inch feed; run carriage over and start feed; throw out left-hand tool on cut No. 5; gage and throw out feed right-hand; start left-hand tool on cut No. 6; gage and throw out feed left-hand.

Cut No. 7. Set tool *B* on the journal; change feed to ¼ inch; cut down inside of collar; caliper and throw in feed; same with left-hand tool; gage and throw out feed right-hand; same left-hand; finish journal length feeding by hand; same left-hand.

Cut No. 8.—Taper the entering end of wheel-fit, feeding by hand; same left-hand.

Burnishing.—Change feed to ⅛ inch; put in roller right-hand; force roller against journal bearing until desired finish is obtained; throw in power feed; same with left-hand roller; throw out feed right-hand; throw out feed left-hand; roll large fillet right-hand; same left-hand, feeding by hand.

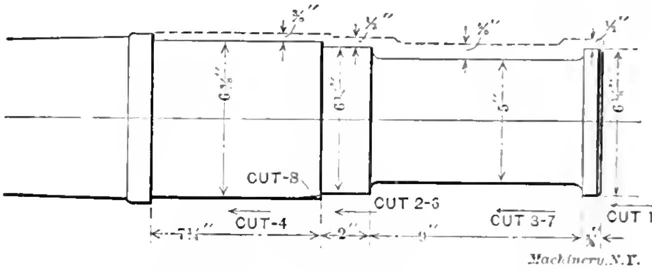

Fig. 14. Master Car Builders Axle, 5 x 9 inch Journal, showing amount of Stock to be Removed.

Change to roughing tools; set to the collar diameter with cardboard between tool and collar; hang the driving dog on the tailstock nose; put sling on axle; draw back the right-hand center; hoist axle clear; run the hoist back on crane arm; swing crane back; lower axle.

By the above routine an axle can be finished with some lost time in from 25 to 30 minutes, and a maximum for a day of ten hours would be from 18 to 20 axles.

It has been stated to the writer, by a reliable observer, that an operator on a Niles motor-driven double axle lathe in the Angus shops of the Canadian Pacific R.R., when "real mad" and on his mettle, had roughed, finished and burnished a 100,000-pound car axle of steel, in 25 minutes, counting from the time of picking up the axle to putting it back on the horse. This was much quicker than the least conservative estimate by the method described, and has been taken as evidence that the writer's estimate is within reason, given that the operator is sufficiently remunerated for the effort, agility and interest required.

* * *

In a recent issue of *Engineering* it is stated that an engine built in 1808, or over a hundred years ago, for a British firm, by Messrs. G. Rennie & Co., of Greenwich, England, has just failed by the breaking of the crank-shaft. The company which built the engine has been called upon to make repairs, and after an examination of the rest of the engine, it was found to be in excellent condition, so that it has been concluded to set it to work again as soon as the repairs have been completed.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—2.

FRAMING AND GENERAL DESIGN OF CRABS.

R. B. BROWN.

The great difference in appearance of electric crabs lies chiefly in the design of the framing. Some very different opinions seem to exist on the primary question of material, for while certain makers have standard crabs with steel frames for all sizes, others manufacture crabs with cast-iron frames up to a considerable weight. Both types are undoubtedly substantial enough, but there is a limit to their adoption. One of the principal objects in designing an electric crab should be to make the various component parts as accessible as possible for renewal and repair, and in this direction the steel frames, undoubtedly, have the advantage. Another point in favor of steel frames is their lightness, and the consequent saving of material in the girders. Perhaps, in the case of small crabs, say up to five tons, cast-iron sides may be cheapest, if large quantities are being made, but for larger sizes the steel frames are certainly more advantageous to manufacturer and purchaser alike.

Frames made up of double steel plates, or steel plates framed with angles, are much used, but although they make a substantial crab, nothing special can be said in their favor, and they present the same disadvantage as cast-iron sides, in having several closed bearings.

Fig. 4 shows the crab for a 20-ton, three-motor crane with a steel frame of modern design and similar to which large quantities have been made with satisfactory results. Fig. 5 illustrates the same crab, slightly altered to receive an auxiliary barrel for light loads, as sometimes found advantageous. The crab for a four-motor crane is usually of similar construction to the one just referred to, the auxiliary barrel being ar-

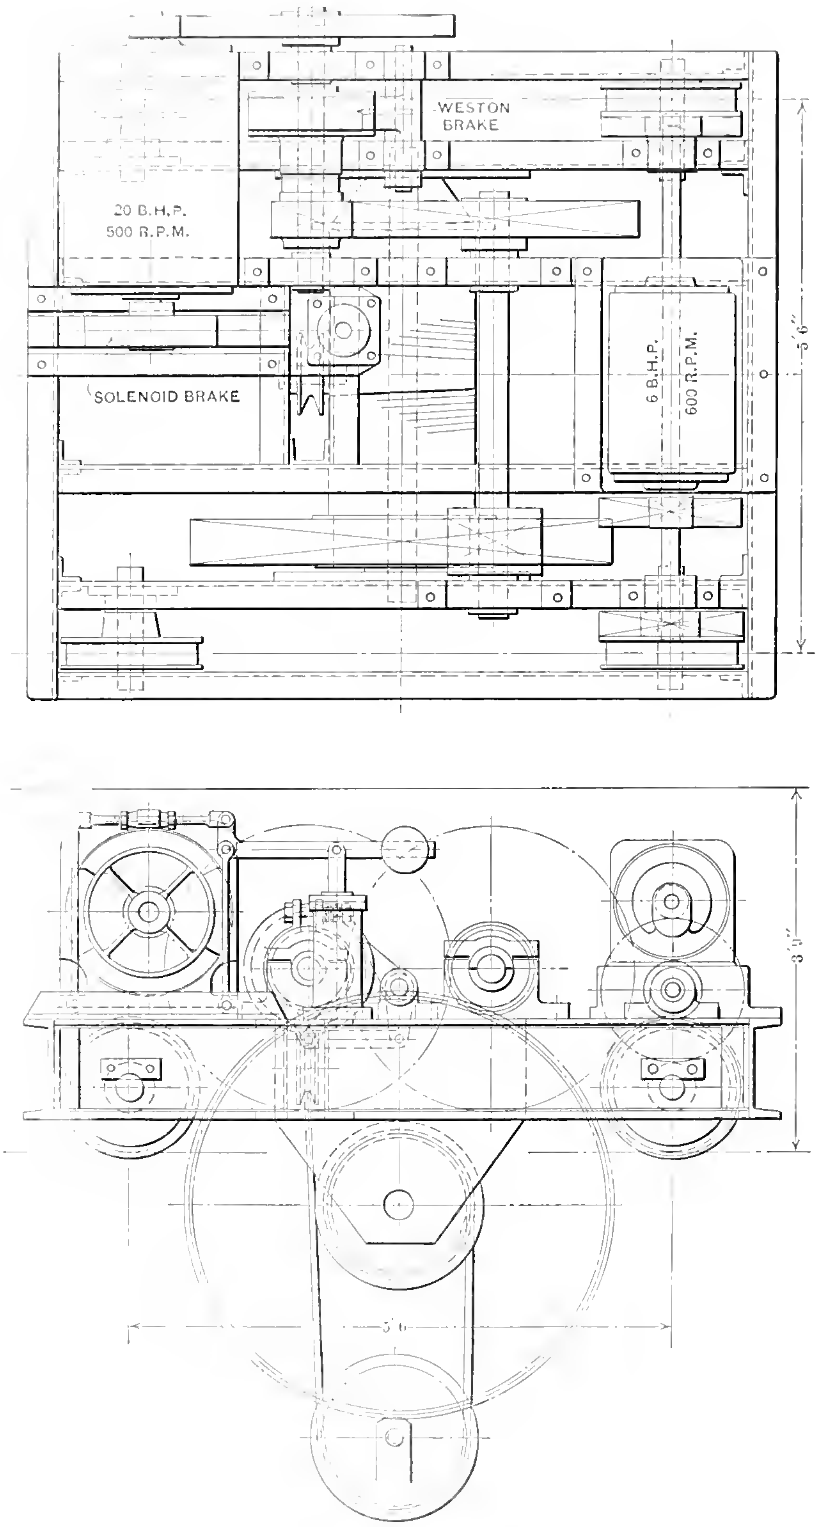

Fig. 4. Crab for 20-ton Three-motor Electric Overhead Crane with Steel Frame.

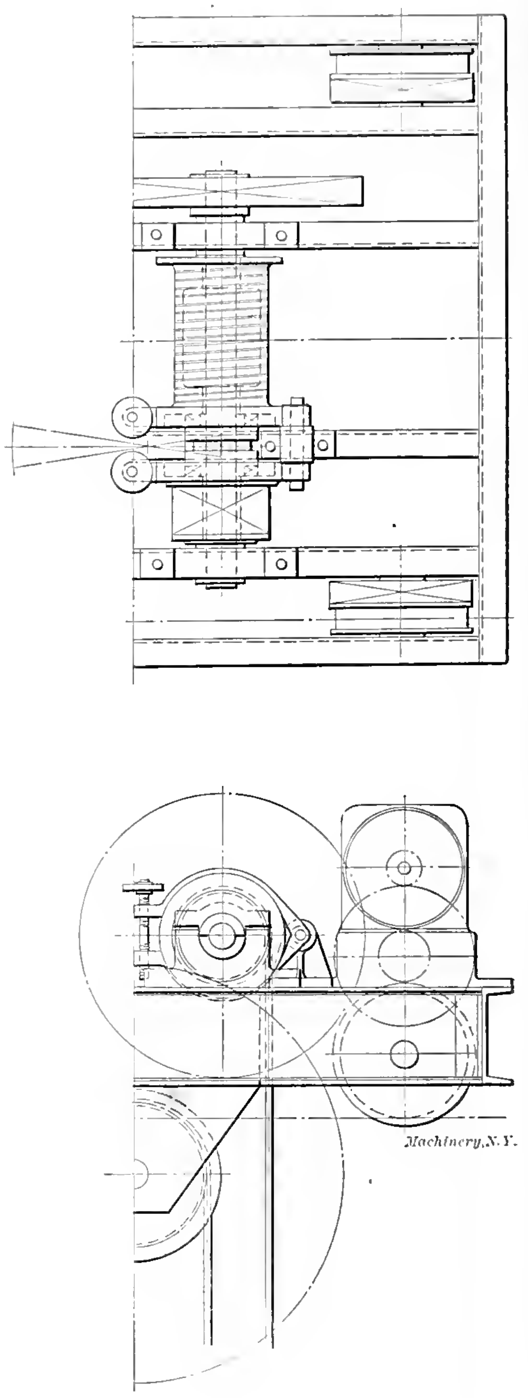

Fig. 5. Crab, Similar to the one shown in Fig. 4, slightly altered to accommodate Auxiliary Barrel for Light Loads.

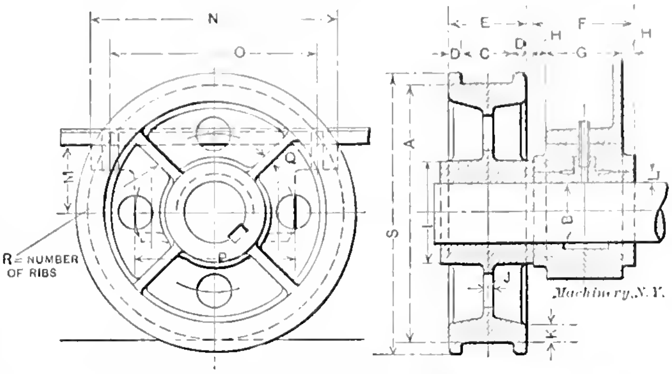
ranged to suit the framing of the crab. As will be seen from Figs. 4 and 5, all the bearings in crabs of this type are adjustable, except those for the barrels and perhaps the running wheels, which are bushed; since these latter have slow running shafts, and ample bearing surface can be provided, there is no necessity for adjustable bearings. In the designs shown, it will be seen that the main barrel shaft is so situated that by jacking up the crab it can be drawn out clear of the rails, and the barrel and wheel lowered direct to the ground for rebushing or other attention.

Owing to the variety of designs of crab frames in general use, it is practically impossible to give any definite calculations or details which would be of general value. In the case of small crabs, the smallest convenient sections which can be used are generally strong enough to resist all the strains with a large margin of safety, but with the larger sizes, the strength of the sections should be calculated and the stress limited to 4½ or 5 tons per square inch, in order to avoid possible deflection and subsequent binding of shafts and attendant disadvantages.

TABLE III DIMENSIONS OF RUNNERS, AXLES AND BEARINGS.



Size of Crane, tons.	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	Material
5- 7½	12	3¼	2¼	⅝	3¾	4½	3½	½	6	⅝	¾	5/16	3	14½	11¼	8½	⅝	4	13½	Cast iron
10-15	15	3¾	2¼	¾	4	4½	3½	½	6	⅝	¾	⅜	3½	15½	12½	9½	⅝	4	16½	Cast steel

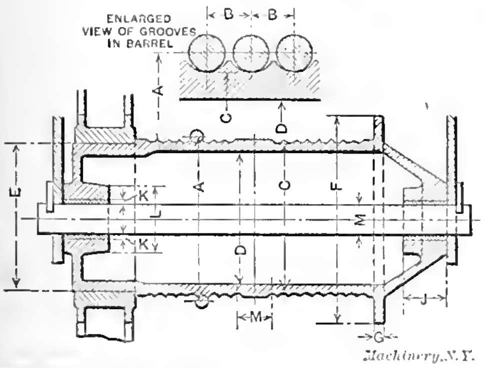
Running Wheels and Axles.

The first question to be considered concerning the crab running wheels is the material, and since they are subject to considerable wear, their durability ought to be considered. For the best class of work, cast-iron runners should not be used for cranes above 10 tons; otherwise the tread may wear quickly, due to the pressure. For crabs below this size, however, cast-iron has been found quite suitable. Crab running wheels should always be made as large in diameter as practicable, and similarly the axles as small as possible, in order to reduce the tractive resistance and consequent current consumption. Table III gives the principal dimensions of runners as usually made, and also the sizes of axles and bearings, which have been calculated as follows:

TABLE IV. DIMENSIONS OF LIFTING BARRELS.



Load, tons.	Number of Ropes.	Size, Circumference, inches.	A	B	C	D	E	F	G	H	J	K	L	M
3	2	1¾	12	⅝	11.45	10½	9¾	12½	⅝	2½	3½	5/16	5	2½
5	2	2¼	15	¾	14.30	13	12¼	15¼	¾	2¾	3½	5/16	5½	2½
7.5	4	2	12	11/16	11.37	10½	9¾	12¾	⅝	2¼	3½	5/16	[illegible]	2½
10	4	2¼	15	¾	14.30	12¾	12¾	15¾	¾	2¾	3½	5/16	5½	2½
15	4	2¾	16½	1	15.62	14½	13¾	18½	[illegible]	3¼	4	[illegible]	6¼	3
20	4	3¼	18	1⅛	17.00	15¼	15¼	19½	1	3¼	4	[illegible]	6½	3
25	4	3½	21	1¼	19.90	18	17½	22¼	1⅛	4	4½	7/16	8	4
30	4	4	24	1⅜	22.70	20½	20	25½	1¼	4¼	4½	7/16	8¾	4
40	4	4½	27	1½	25.50	23	22½	28	1½	5	5	7/16	9½	4½
40	4	5	30	1¾	28.40	30	29½	32	1½	5½	5½	7/16	10	4½

The axles are subject to combined bending and twisting, the former being due to the overhanging distance, which is generally taken from the center of the wheel to the center of the bearing, to ensure stiffness, and the latter from the resistance to traction at the tread of the wheel. For example, it will be seen from Table III that the runner for a 20-ton traveler is 15 inches in diameter; the wheel pressure will be about 6½ tons. Taking the maximum possible resistance to traction at 90 pounds per ton, we have the torsional moment

$$M_t = \frac{90 \times 6.5 \times 7.5}{2,240} = 1.95 \text{ inch-ton.}$$

The maximum effective overhang may be taken at 5 inches, and consequently the bending moment

$$M_b = 6.5 \times 5 = 32.5 \text{ inch-tons.}$$

The equivalent bending moment M_e may be found by the following common formulas:

$$M_e = \tfrac{1}{2} M_b + \tfrac{1}{2}\sqrt{M_b^2 + M_t^2} = 16.25 + \tfrac{1}{2}\sqrt{32.5^2 + 1.95^2} = 16.25 + 16.3 = 32.55 \text{ inch-tons.}$$

Assuming a stress on the material of 5 tons per square inch, the section modulus is

$$\frac{32.55}{5} = 6.51,$$

to which a diameter of 4 inches corresponds.

The working strain in the axles may be increased to 5.5 tons per square inch in the case of crabs of 25 tons and upwards, but it is advisable not to exceed this amount, because even a slight deflection will cause the shaft to bind in the bearings and consequently absorb more power.

After determining the diameter of the axles, sufficient length of journal should be allowed so that the pressure on the bearings is not more than 900 pounds per square inch of projected area. The bearings are usually of cast iron, with a brass lining on the pressure side and fitted with a light cast-iron cap beneath. It is of the greatest importance that these journals should be fitted with proper lubricators, since this provision will lead directly to a reduced current consumption. For crabs of 40 tons and upwards a self-lubricating bearing, as shown in Fig. 6, although more expensive, has been found advantageous. This bearing is designed on the same lines as these which are sometimes fitted to the main traveling wheels. Roller bearings are also occasionally used for these axles.

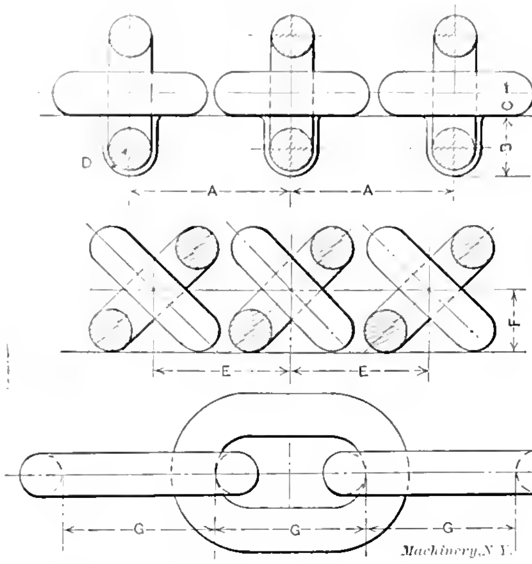
With crabs of 60 tons and upwards it is generally found more economical and convenient to employ short axles supported by a bearing on either side. By this means much smaller journals can be used, and at the same time the gearing can be more compactly arranged since there are no cross axles to clear. One wheel on each side has to be geared with this arrangement.

Barrels, Ropes, and Chains.

Lifting barrels are invariably made of cast iron, cast blank for rope, and the grooves turned out to suit. For chain falls

the grooves are generally cast in. Practically all modern travelers are now fitted with wire rope falls, the alternatives being ordinary chain and pitch link of Gallé chain, the latter being used mostly on the European continent, or for special cranes. Table IV gives particulars of steel ropes suitable for lifting purposes and drums or barrels for same. The factor of safety usually adopted for lifting rope is eight, which allows a good margin of strength even after a few strands have broken. The life and value of the rope depends to a great extent on the size of the barrel and pulleys around which it has to pass. Some rope makers recommend a barrel diameter of six and a half times the circumference of the rope. This is quite suitable and convenient for cranes using ropes under 3½ inches circumference, but above this size it has been found satisfactory to make the barrel and pulleys from five and a half to six times the circumference.

TABLE V. DIMENSIONS OF CRANE CHAINS.



Size, inches	Load, tons.	Weight per Foot, pounds.	A	B	C	D	E	F	G

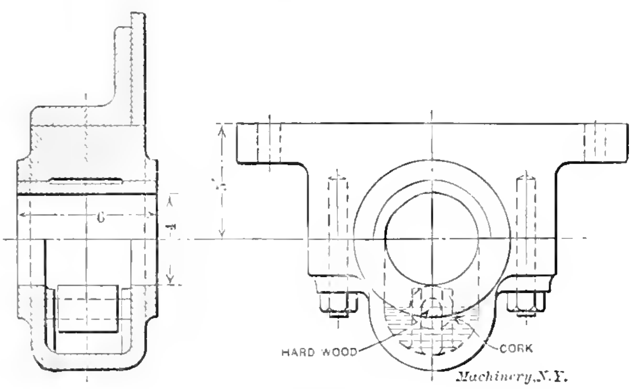

Fig. 6. Self-lubricating Bearing for Shafts in Crabs of 40 ton Capacity and larger.

Another point of importance is the spacing of the ropes or centers of the grooves. For all sizes up to 4 inches circumference, it is necessary to allow one-eighth inch between the ropes, but above that size three-sixteenths inch gap should be provided, if possible. This allowance is due to the fact that the ropes flatten out slightly under the load, and if there is not sufficient side clearance they grind against each other and are likely to break some of the strands.

When chain is used, it is of the type known as short link crane chain, having a breaking strain of about 23 tons per square inch, and is usually stressed from four and a half to five tons per square inch under the working load. Table V gives working loads and dimensions of standard crane chains, and shows the spacing and leading dimensions of suitable chain barrels. The length of the lifting barrel is a quantity which naturally depends on the height of lift, but when designing a standard traveler, it is advisable to allow for sufficient rope to give a vertical lift of thirty feet with two spare coils on either end, this being the maximum height required under ordinary conditions.

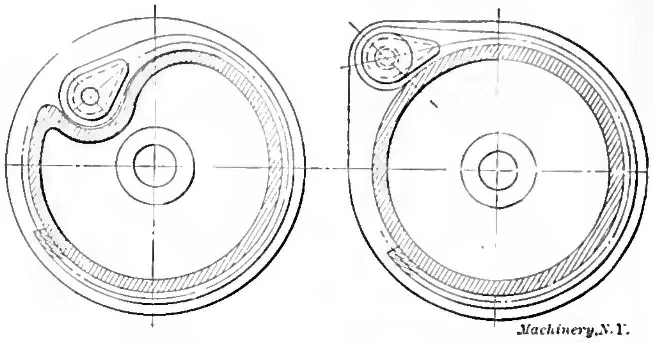

Fig. 7. Two Methods in use for Anchoring the Lifting Ropes.

Chain falls should be avoided for longer lifts than twenty feet, otherwise the barrels become inconveniently large. The principal reason for providing the spare coils referred to is to reduce the strain on the anchors, which, however, should always be strong enough to take the full load. Several methods of anchoring the rope are in use, of which probably the two methods shown in Fig. 7 are the best. In either case, a solid cast iron eye is woven into the end of the rope, and a hole drilled in the eye for a turned pin or stud. This makes a very substantial connection.

It has become universal practice to so arrange the lifting ropes or chains that the load will be lifted centrally and thereby distribute the load equally over each girder. This arrangement is necessary for all cranes above five or seven tons, from which size up to fifty tons the loads should be lifted on four parts of rope, two parts being coiled in right- and left-hand grooves on the barrel, the other end passing around a compensating pulley, as will be seen by referring to Fig. 4. This pulley need not be more in diameter than about twice the circumference of the rope, since it is not subjected to any motion. For cranes up to and including three tons the load should be lifted on a single fall, while for loads of five, six, and seven tons it is more convenient to employ two parts, one coiling on the barrel. There is practically no advantage in providing a central lift for these light cranes, since it is generally impracticable to make the girders light enough to give an ordinary working strain and the little extra weight that will be thrown on one girder will not destroy the economy of construction.

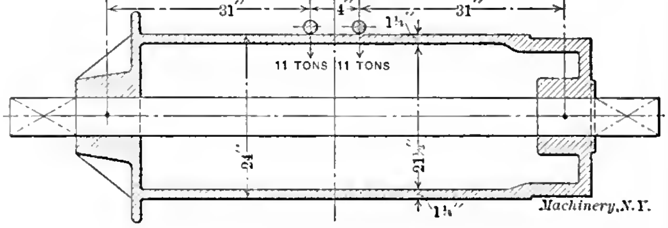

Fig. 8. Barrel for a 40-ton Overhead Electric Crane.

The barrels used for ordinary overhead travelers seldom exceed 30 inches in diameter, and up to this size the method shown in Table IV of fixing the barrel to the wheel has been found to be the cheapest and is almost universally adopted. The thickness of metal in the barrel should be sufficient to resist the maximum bending which occurs when the load is

in the highest position and the ropes are in the center. If the stress from bending is not greater than about 0.75 ton per square inch there will be an ample margin of strength left to safely provide for the compression from the ropes themselves. For example take a forty-ton crane barrel as shown in Fig. 8. The maximum span over which bending takes place is from center to center of the bearings, and the maximum bending moment $M_b = 11 \times 31 = 341$ inch-tons.

$$\text{Section modulus of annulus} = \frac{\pi}{4} \times \frac{R^4 - r^4}{R} = \frac{\pi(12^4 - 10.75^4)}{4 \times 12}$$
$= 483.$

$$\text{Stress} = \frac{341}{483} = 0.7 \text{ ton per square inch.}$$

The size of the barrel shaft should be made sufficient to take the bending from the center of the support to the center of the bearing at a stress of about 5 tons per square inch, and the length of the bearing should be such that the pressure on same is about 900 pounds per square inch.

* * *

FLOATING CHUCK FOR FACING GEAR BLANKS.

As we have before remarked, there is much more to the problem of obtaining accurate gears than is involved in careful attention to the cutting operation itself. For instance, having the finished teeth run true involves more than simply having a true running work arbor, especially if the blanks are mounted on the arbor in gangs and are cut several at a time. Under such conditions, it is very necessary to have the blanks accurately faced in parallel planes, exactly normal to the axis of the central hole. If this matter is disregarded, the blanks will spring the gang arbor very much out of true when tightened on it.

Various methods are followed to produce parallel faces. One of these, used in the shops of the Cincinnati Shaper Co., employs a special tool slide with roughing and finishing facing tools, arranged to operate on both sides of the blank, which is keyed to a drive arbor. This method was described in connection with the builders' key-seating attachment in the new tools department of the September, 1908 issue of MACHINERY. Other methods that the writer has seen tried, involve the grinding of the sides of the blanks, which are held on magnetic chucks in special face grinding machines. This operation is not done for the sake of any fineness of finish or accuracy in the thickness of the finished product, but simply for the purpose of obtaining accurate gear cutting in the case of blanks mounted in gangs.

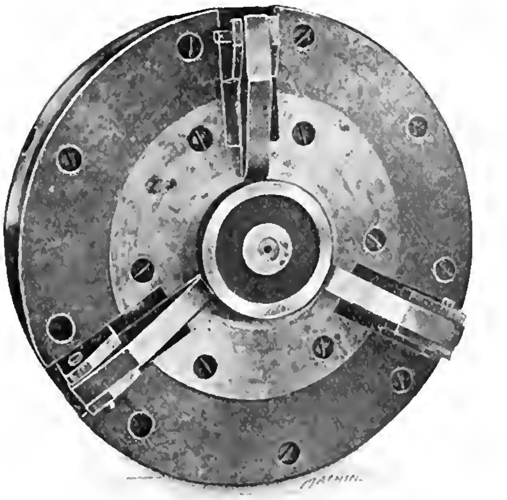

Fig. 1. A Chuck for Facing Gear Blanks, which holds them without Side Strain or Distortion.

One of the most ingenious and satisfactory solutions of this problem that has come to our notice is that followed in the shop of the Fellows Gear Shaper Co., of Springfield, Vt., where it is used particularly for finishing blanks such as those used for change gears, which are made in large quantities. The first operation on these blanks consists in facing one side and chucking the hole, in an ordinary turret lathe. The only point worth mention in this operation relates to the necessity for taking enough cuts across the face and through the bore to insure that these two surfaces shall be finished very accurately with relation to each other.

After this operation has been completed, the blanks are faced on the unfinished side in the chuck shown in the accompanying illustrations. This is the most interesting operation, as the chuck is decidedly novel in its action. As may be seen in Fig. 2, where it is shown dismantled, the device was made from an old scroll chuck of the usual construction, which had become so worn that its accuracy was more than questionable. What little accuracy it had left was, in fact, eliminated, by machining out the seat for the scroll to a greater width, so that it could float in the groove with ⅛ inch or so of movement. Special jaws of the kind shown in Fig. 2 were next made, fitting the scroll and the slides in the body of the chuck, and provided with pivoted holding-down dogs and "spuds," similar to those commonly used for holding thin work on the planer. Over the face of the chuck was screwed the plate shown, which was provided with a central hole in which was driven a stud closely fitting the bore of the gear blank.

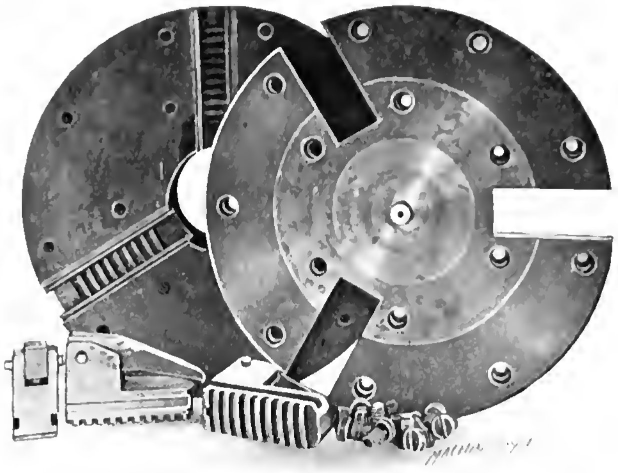

Fig. 2. The Chuck Dismantled, showing Clamp Jaws and Floating Scroll.

The use of this chuck will now be clearly understood. In Fig. 1 the blank is seen placed on the stud, with its finished face against the plate. Each time the chuck is placed on the machine, this plate is refaced, and a new plug is put in and turned down to fit the bore of the hole. If the lathe is in a reasonably good condition, assurance is then given that the locating surfaces for the work will run with the utmost accuracy. The work being placed on the stud and pressed with its finished face against the plate, the jaws are screwed down, with the edges of the dogs pressing against the periphery of the blank in such a way as to hold it firmly against the plate. It will be seen that the loose fit of the scroll in its seat equalizes the pressure on the three sides of the blank, so that it is simply pressed backward into position, without the possibility of being forced sidewise and out of true in any direction. When the facing is completed on a blank thus held, every assurance is given that the face will be true with the bore, parallel with the finished surface on the opposite side of the blank.

The final turning operation is done on a gang arbor, mounted in the spindle of the lathe. The utmost accuracy in turning the periphery of the blank is not necessary, although, if the gang arbor is true, the preceding operations will insure good work in this final turning. Finishing the work in gangs like this reduces the cost of this operation to a very low figure even though it requires three operations. It might perhaps be done somewhat more cheaply by a set of screw machine tools that would finish the blanks in one operation (using special chuck jaws, back facing attachment, etc.), but the greater truth obtained by this method makes the operation less costly in the long run if quiet running gears are desired.

RECENT DEVELOPMENTS IN GEAR-CUTTING MACHINERY.

RALPH E. FLANDERS.*

The past year has been one of great activity in machine design, as is plainly shown by the files of contemporary technical journals In no line has this activity been more marked than in that of gear-cutting machinery in its various forms.

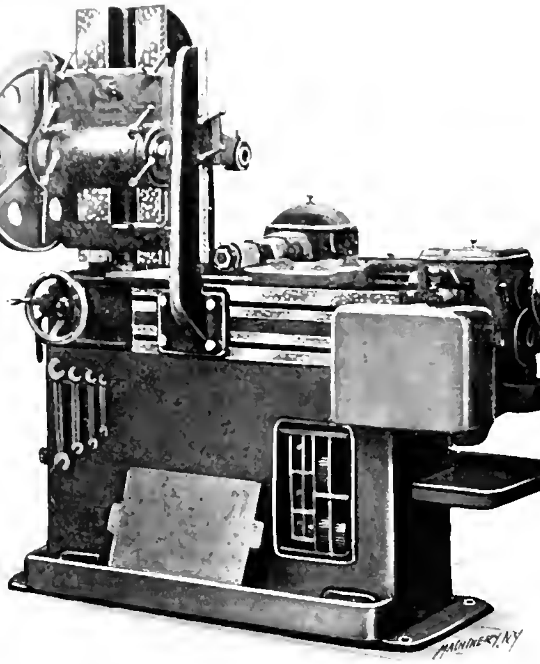

Fig. 1. A German Automatic Spur Gear Cutter which shows the Influence of American Design.

In the months covering the publication of the author's series of articles on this subject (see the issues of MACHINERY from January to September, 1908) the department of New Machinery and Tools illustrated a number of designs which were not included in the articles. Several new examples of foreign gear-cutting machinery have also come to light. This article will briefly describe such of these machines as have not previously been illustrated. The classification of the series of articles referred to will be followed.

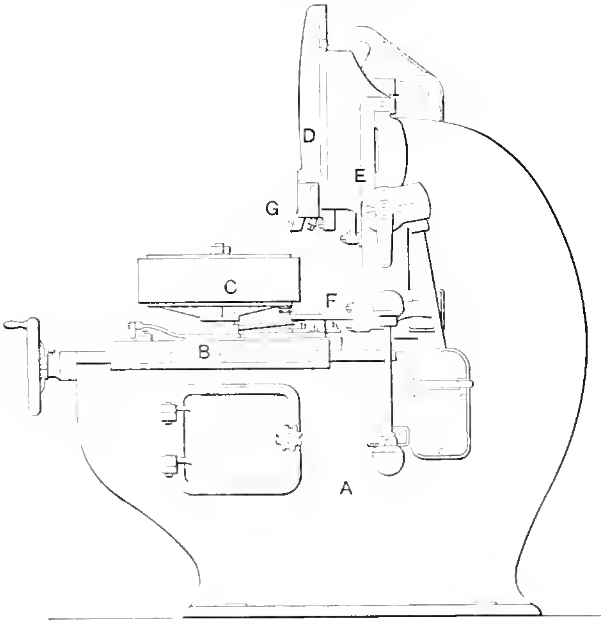

Fig. 2. Elevation of a French Spur Gear Generating Machine employing a Rack Tooth Form of Shaper Tool.

Machines for Cutting the Teeth of Spur Gears.

In Fig. 1 is shown a German machine of the orthodox type which shows American influence very strongly. The mechanism is carefully enclosed, fixed handles are provided for all the adjustments, and the usual form of rim rests, outboard supports, etc., are also provided. The speed and feed changes, as well as the indexing, are effected by change gears. This machine is built by Shubert & Salzer, Chemnitz, Germany.

Two new machines have been developed in Europe for cutting spur gears on the molding-generating principle by the shaping operation. A tool, which is given the shape of a rack tooth, is fed in the direction of the travel of an imaginary rack, past the gear blank, which is, at the same time, rotated in the proper ratio. The first of these machines, shown in Figs. 2 and 3, is built by the Société Francaise de Machines-Outils, St. Ouen, Paris. The resemblance of this machine to a slotter is at once evident. The work, which is shown mounted on the work arbor at *C*, is carried by table *B* which is adjusted in and out on the bed *A* of the machine to give the adjustment for diameter. The tools *G*, having the outline of the rack tooth, are mounted on a ram *D*, which is, in turn, guided in a cross slide *E*, which travels on a cross rail solid with the frame of the machine. In cutting a tooth, the tool starts in at one side of the blank, and the ram *D* on cross slide *E* is fed from right to left, in the face view of the machine. This lateral motion is transmitted by means of rack teeth on arm *F*, engaging suitable mechanism on the work table for rotating work *C* in unison with the lateral movement of the tool. When one tooth has thus been cut, and the slide *E* has been returned to the starting point, the work is indexed, and a second cut is taken in the same manner—and so on until all the teeth are cut. The capacity of this machine is for work up to 20 inches in diameter.

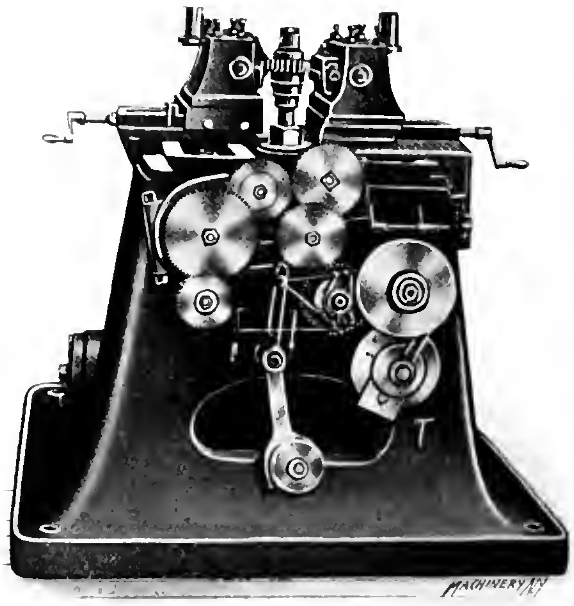

Fig. 4. An English Spur Gear Generating Machine employing Multiple Tools of Rack-shaped Outline.

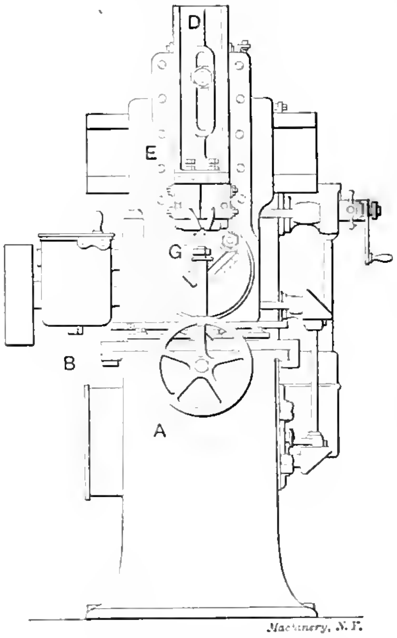

Fig. 3. The Face View of Spur Gear Generating Machine.

The second machine is built by Spencer & Spiers of Huddersfield, England. The construction and movements are entirely different from the previous example, though the principle is the same. There are two sets of tools *AA*, as shown in the plan view Fig. 5, disposed on opposite sides of the work *B*. Each of these tools is formed of several rack teeth.

---

* Associate Editor of MACHINERY.

As the work is reciprocated up and down between them by crank *G* and connecting-rod *F*, these tools are fed in the direction of their pitch line in opposite directions, and the work is revolved in unison at the proper ratio. To effect this, the tools are mounted on parallel slides *E*, which carry racks engaging gear *D*, within the base of the machine. *D* also has worm-wheel teeth cut on it, driven by a worm which is connected by change gearing with worm-wheel *C*, which rotates the work. Owing to the fact that the two tools have several teeth each, it is possible to finish pinions and small gears at one passage. For larger gears, provision is made for bringing the tools to the starting point again, and taking a second cut, with the work turned to present a new portion of the periphery to the action of the cutting edges.

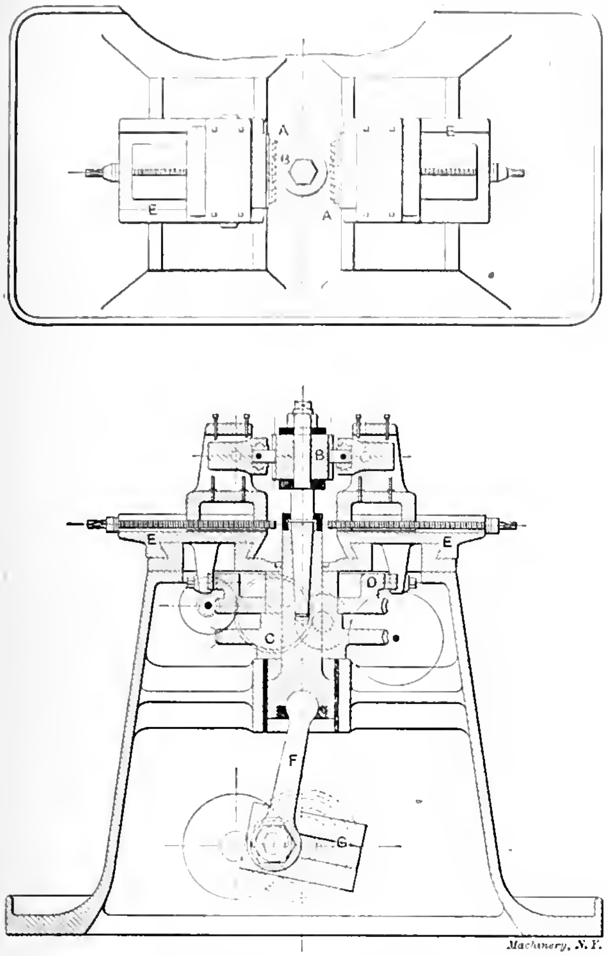

Fig. 5. Plan and Vertical Section through the Machine shown in Fig. 4, with Details of Controlling Mechanism.

The makers of this machine state that no outboard supporting bearing for the work arbor has been found necessary, owing to the fact that the cuts are perfectly balanced. This is effected by the use of the two tools, one on each side of the work. A larger machine has been built in which the tool slides reciprocate vertically instead of the work, the latter being mounted on a spindle which revolves as the cutters are fed past it. The design illustrated in Fig. 4 has been somewhat improved in later models.

The activity in the design of hobbing machines also continues unabated. Four new examples of this class of gear cutters are shown herewith. The first of these is built by the Ateliers de Constructions Mecaniques ci-devant Ducommun, Mulhouse, Alsace. As may be seen in Fig. 6, it has the appearance of being of unusually rigid construction. The work spindle head slides through an opening in the column, being firmly supported in all directions. A heavy outboard bearing of the usual form is provided. The work spindle head is counterbalanced. As nearly as may be judged from the engraving (definite information on this point is lacking) the machine is also arranged for the cutting of spur and spiral gears by the formed tool process. The dividing plate for hand indexing will be seen below the index wheel at the left of the engraving.

Another machine of the same type built by Gildemeister & Co., A. G., Bielefeld, Germany (see Fig. 7), is of the more usual form in which the cutter spindle is carried on the column while the work table is adjusted on the bed. Fig. 8 shows this machine cutting a spiral gear with a formed cutter. This operation requires very little change in the mechanism needed for straight spur gear hobbing, it being only necessary to connect the change gears for driving the work spindle with the feed-screw, instead of with the cutter spindle, and to provide means for hand indexing. The wide provision of this arrangement on European machines is doubtless due to the patent restrictions on the spiral gear hobbing process.

Another hobbing machine, built by Wilhelm Junghans Werkzeugmaschinenfabrik, Chemnitz, Germany, has the base and column in one solid casting (see Fig. 9). It is also provided with elaborate rim and work supporting arrangements, there being an outboard bearing for the spindle, and rim supports both front and back. This machine is designed for hobbing spur and worm gears. It is also provided, when so desired, with hand indexing mechanism for cutting spur gears with formed cutters.

Mention might be made here of a rather unusual extension of the hobbing process, and one which at first thought would seem to be impracticable. This is reported in a paper read before the British Institution of Mechanical Engineers in July, 1908, on "The Evolution and Methods of Manufacture of Spur Gearing" by Mr. Thomas Humpage, the maker of a hobbing machine previously illustrated. Mr. Humpage relates that he has experimentally built and used a corundum "hob" for finishing gears on which a few thousandths had been left for grinding. In using these hobs or worms, the tool is adjusted axially so that one side of the thread touches one side of the teeth of the work. The wheel is then fed down automatically, grinding one side of all the teeth and generating them to the finished form. The machine is next stopped, the wheel raised by hand, and a finishing cut taken. The other sides of the teeth are then ground and finished in the same way. The author proposes to make a machine using a hob of this kind in which a device like that on the fly-tool worm-hobbing machines will be used for traversing the corundum to distribute the wear across its length. It is found that the wear on the worm is very slight, being about a thousandth of an inch in the worn part for cutting a 70-tooth, 7-pitch, 1¼-inch face cast iron wheel, which was finished in eight minutes. In the complete machine, the author proposes to mount a corundum wheel for truing up

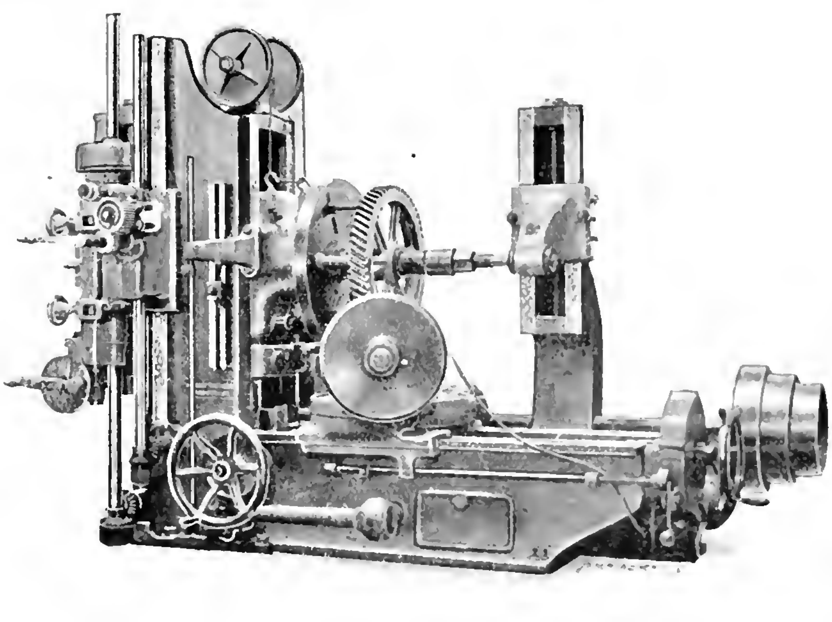

Fig. 6. Ducommun Gear-hobbing Machine cutting a Spiral Gear.

the worm. He suggests also that this finishing process should be applied to all gears, whether soft or hardened.

Machines for Cutting Internal Gearing.

The only new development in cutting internal gearing which has come to the writer's notice during the past year is that shown in Fig. 10, which illustrates the surprising operation of hobbing an internal gear. This operation bears the same relation to the hobbing machine in which it is done, that the use of an internal gear-cutting attachment bears to the orthdox spur gear cutting machine. The method of driving through a train of gearing connecting the cutter with the regular spindle, is identical. With this attachment, the hob has a pitch surface of a barrel-shaped form, with the radius of curvature corresponding with the pitch radius of the wheel to be cut. In producing these hobs, a master internal toothed wheel is hardened, so that the teeth act as cutters. The soft hob blank is then placed in the machine the same as when at work, as shown in Fig. 10, and a theoretically correct profile is generated on it by the hardened internal wheel. The hob itself is then relieved, hardened and ground ready for use. It is adapted only to cutting gears of the diameter and pitch for which it was made. David Brown & Sons, Huddersfield, England, are the originators of this device.

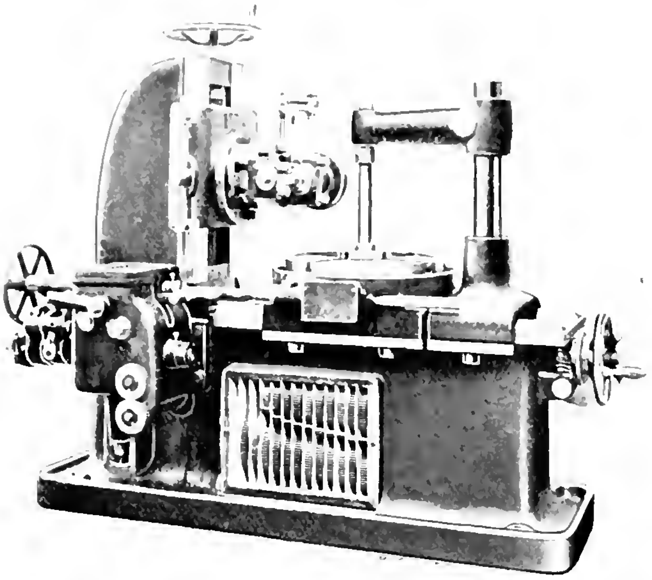

Fig. 7. The Gildemeister Gear Hobbing Machine.

Machines for Cutting the Teeth of Worm Gears.

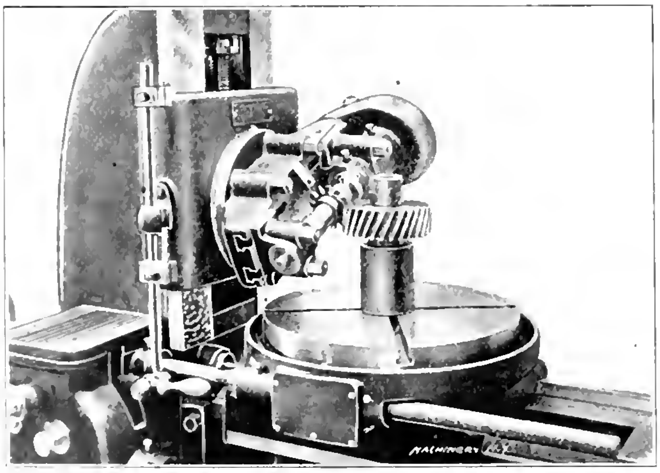

Fig. 8. The Gildemeister Machine cutting a Spiral Gear by the Formed Tool Process.

A machine similar to those illustrated in Figs. 119 to 128 of the previous series of articles, has recently been placed on the market by J. Holroyd & Co., Ltd., Perserverence Works, Milnrow near Rochdale, England. The machine is, of course, under the classification given it, adapted for using either a tapered hob or a fly tool for cutting the teeth of worm-wheels. The cutter bar is moved axially for the feed, and is so connected by differential gearing with the worm-wheel revolving the work spindle as to keep the tool and work constantly in register. This machine, as may be seen in Fig. 11, is similar in general design to that illustrated in Fig. 122, in that the work spindle is vertical and stationary as to location on the bed, while the cutter slide is carried by a column horizontally adjustable for the diameter of the work. The machine is of unusual size and capacity. It will hob wheels from 12 inches to 72 inches in diameter. The main bearing of the work spindle is 8 inches in diameter by 16 inches long. The approximate weight of the whole apparatus is ten tons. This same firm builds a machine of similar design for smaller work in which, however, the work spindle, instead of the cutter slide column, is horizontally adjustable.

Machines for Cutting the Teeth of Bevel Gears.

A firm in Budapest, Hungary, whose name translated into English reads "Small Arms and Machine Factory Co., Ltd.," has built for a number of years the templet bevel gear planer shown in Fig. 12. In this machine the work spindle is adjustable for the pitch cone angle, by moving it in a concave circular seat in the bed. This seat keeps the axis of the work spindle always in line with the horizontal axis of the swiveling adjustment. The outer end of the work arbor is supported in a yoke which swivels about this axis. The mechanism on the upper part of the machine is the tool head, which carries two crank-driven slides, each of which carries a tool. These slides are confined by guides which are pivoted about an axis passing through the apex of the pitch cone. The whole mechanism swivels about the horizontal axis passing through the same point. As the tools are swung down into the teeth about this horizontal axis, they are spread apart about the vertical axis by the action of fingers on each tool slide guide, which bear on opposite sides of a suitably formed templet, held in the templet holder at the upper right of the machine. The swinging downward of the tool slide mechanism is accomplished by a revolving nut on the swiveling screw which connects this mechanism with the bracket to which the templet is clamped. This latter is held in slides which are adjustable for both vertical and horizontal movement. In having the tools swivel about both axes while the work remains stationary, this machine resembles the Gleason machine shown in Fig. 151. It is not, however, automatic.

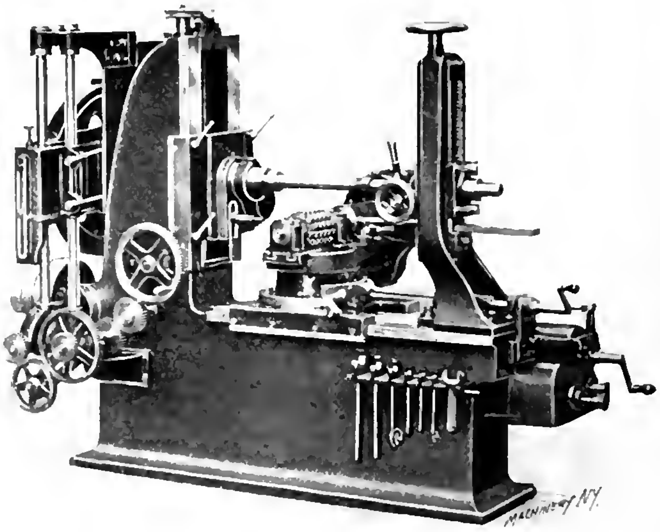

Fig. 9. Junghans Spur Gear Hobbing Machine.

In Figs. 13 and 14 is shown a recently developed templet machine for finishing the teeth of bevel gears, made by Earl H. Browning, of the Browning Engineering Works, Cleveland, Ohio. As in the previous case, two tools are used, each mounted in separate slides which are swiveled about a common horizontal axis passing through the apex of the pitch cone of the gear to give the desired outline to the tooth. This swiveling of the cutter slides under the action of the templet takes place simultaneously with the swinging of the work-carrying head about a vertical axis. That is to say, as the tooth of the gear is swung in between the points of the tools the latter are opened up with the proper movement to give the

desired tooth outline. As the points of both tools travel toward the apex of the pitch cone of the gear, the outline of the templet is reproduced on a decreasing scale from the large to the small end of the tooth. In the details of the design this machine is original. One of the points of novelty is the use of the quick change speed gear box seen on the work spindle head in Fig. 13, for the indexing mechanism. This gear box, in combination with a further change of four ratios, gives the entire range for cutting any ordinary number of teeth without the use of loose change gears. The changes of speed and feed are also effected by quick change gear boxes. Fig. 14 shows a face view of the cutter slides, with the tools in place in the toolholders. The line of movement of the cutting points of the tools is toward the apex of the pointed rod shown at the center of the swinging attachment of the slides. In this machine, the templet, which is not here shown, is in the form of a cylindrical cam, which is rotated in unison with the swinging of the work spindle head around the bed. This cam has two grooves, each of which controls a roller attached to the outer ends of the tool slide guides, which are thus controlled.

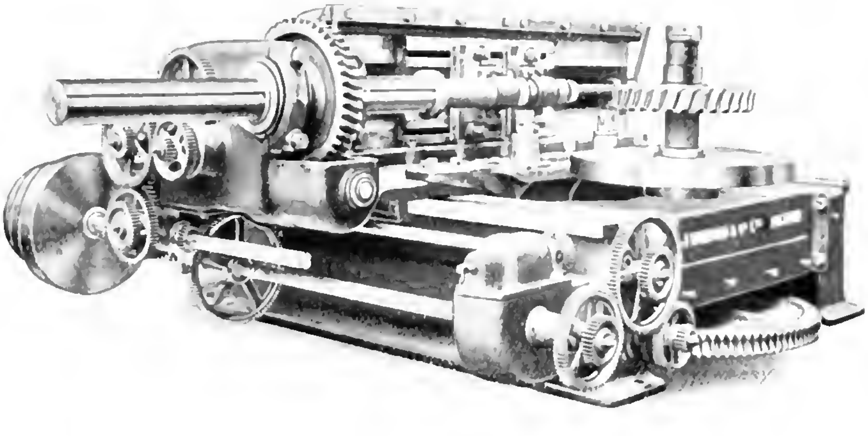

Fig. 11. The Holroyd Worm Gear Generating Machine using a Fly Tool or Taper Hob.

An English machine of the molding-generating type operating on the shaper principle is shown in Fig. 15. Here the axes of both the work and the imaginary crown gear are stationary, the blank and the tool swinging about these axes. The proper ratio of rolling movement of these two parts is obtained by change gears.' The machine has two distinctive features not found in other generating machines, so far as the writer is aware. One of them is the provision made in the mechanism for automatically gashing the wheel preparatory to the finishing generating cut. In this operation the blank is swung around into the reciprocating tool, the slide being locked in position, until the proper depth has been cut. It is then returned rapidly and the work is indexed for the next cut, which is taken in the same way. This swinging of the work into the cutter and back again is effected by the adjustable crank shown at the front of the machine, which has a slow ratchet feed for cutting to depth, and a quick movement for returning. This same crank mechanism is used without the slow ratchet feeding for bringing the cutter into depth for starting the generating cut, and swinging it back at its completion to clear for the automatic indexing in the finishing operation. The other distinguishing feature of this machine is the provision made for correcting the teeth for interference. In other generating machines, this correction is made by altering the addendum and dedendum of the gear and pinions in cases where it is necessary. In this case it is done by modifying the tops of the teeth the same as in the standard shapes for spur gears. To accomplish this the swiveling movement of the tool slide is retarded as the tool is leaving the point of the tooth. A slotted cam groove will be seen, cut in a sector which is fastened behind the outer end of the swinging tool slide. This cam groove controls the movement of a short slide, which, in turn, by means of the diagonal groove and block shown, gives a relative movement between the slide itself and the sector on which it is mounted. This movement is sufficient to trim the tops of the teeth as required. The builder of this machine is the Churchill Machine Tool Co., Ltd., Manchester, England.

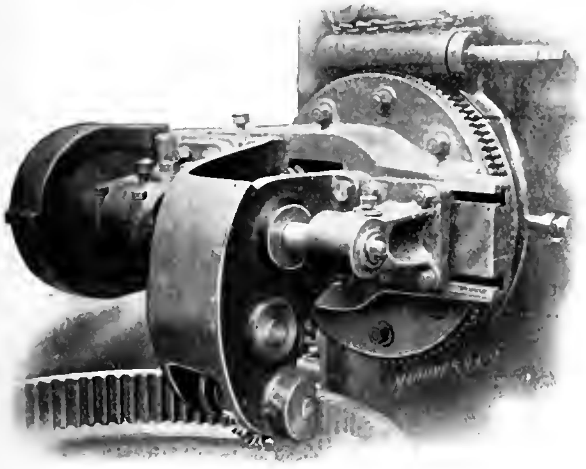

Fig 10. An Attachment for Hobbing Internal Gears.

* * *

The United States Geological Survey's annual report on the mineral resources in the United States for 1906 has just been issued. It appears that the value of the metallic products of the country in 1906 was $866,110,856 and of the nonmetallic $1,016,194,350. Coal is the most important of the mineral products and iron comes second, the value of the products of each in 1906 being slightly more than $500,000,000. Copper comes third with a value of $177,595,888. The clay products come in the fourth place, gold occupies the fifth place, and petroleum the sixth. It is noteworthy that the lead output of the country exceeds that of the silver output. The greatest increase in the year is shown in the production of coal, copper, and cement. Pennsylvania produces nearly one-third of the mineral output of the country, Ohio one-tenth, and Illinois, New York and West Virginia occupy, respectively, the third, fourth and fifth places as mineral producing states.

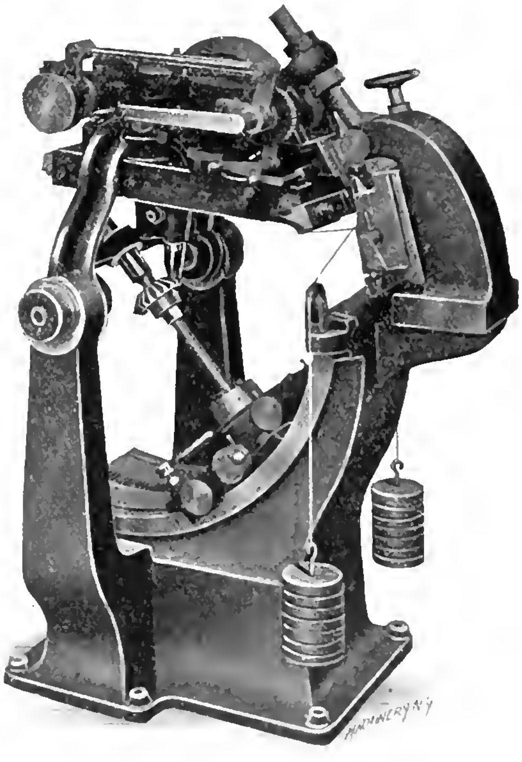

Fig. 12. A Hungarian Templet Bevel Gear Planer.

CENTRIFUGAL PUMPS.*

E. N. PERCY†

Many engineers agree that it is only a matter of time and development before centrifugal pumps will displace the reciprocating type for most classes of work. Owing to their high speed, they occupy little space, and as they have no moving parts except the runner, there is less complication and repairs; consequently, they are more reliable, and give less trouble.

Centrifugal pumps are admirably adapted for direct connection with electric motors, steam turbines, steam or gas engines, or belt drives when high speeds are necessary. They run silently, there are no pipe shocks, nor is an air chamber necessary. If the discharge valve is closed, no harm results, as the pressure does not rise, and the load on the pump is removed; hence, like a shunt wound dynamo, it is self-regulating, only doing work in proportion to the quantity of water pumped (approximately). A battery of centrifugals can be connected in series for one duty, requiring high pressure, and in parallel for another duty requiring low pressure and great quantity. The motor and pump are always directly connected and can operate without any foundation, even at the end of a rope in a deep well. For fire service, there is no danger of bursting hose or pipes; for this reason, if for no other, there should be a special field for them in Tammany fire departments. This type is also adapted to the handling of beers, chemicals, and other liquids liable to contamination or erosion in action, as there are no valves or other details to cause trouble.

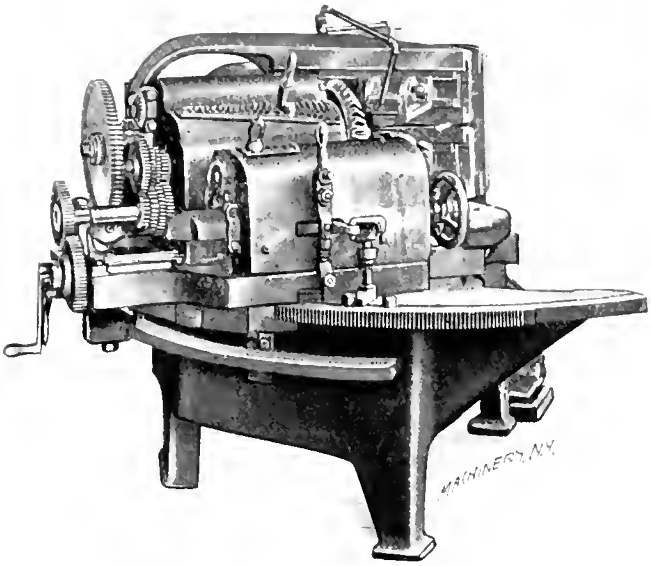

Fig. 13. The Browning Templet Bevel Gear Planer.

The common, commercial, volute pump seldom gives over 45 per cent efficiency, but can easily be designed to give 65 per cent, and be manufactured just as cheaply. A high-duty pump for a special condition will give 88 to 90 per cent efficiency, but, so far, these results have been confined to European makes, American manufacturers not securing much over 80 per cent at official trials. The multi-stage pumps are divided into two classes, the commercial and the high duty. They operate at various speeds dependent upon innumerable conditions. For the best efficiency, any centrifugal pump operates at but one speed. Pumps without guide vanes can have a fair efficiency over a very wide range of speed, owing partly to the fact that the suction column adjusts its rotation to some extent to suit the runner speed. The velocity of a high-speed pump can be reduced with only a slight falling off in the efficiency, but the low-speed type becomes inefficient very fast on being speeded up, because of the excessive eddies in the casing. With a high-duty pump provided with guide vanes, any change of speed is attended with great efficiency losses, because of the eddies between runner blades and guide vanes. If variable speed is a necessary feature, the guide blades must be movable to suit conditions, as in a variable speed water turbine. When the quantity of water varies (as by adjusting the discharge valve), as before, the plain volute pump has a fair efficiency over a wide range of variation, but the high-duty pump again suffers from eddies between the runner and guide vanes. In this case, also, it is customary to have variable guide vanes if a high efficiency for all conditions is desired. When one considers the commercial efficiency, which includes cost of repairs, reliability, spare parts, silence, and space occupied, the centrifugal pump is entitled to a high rating.

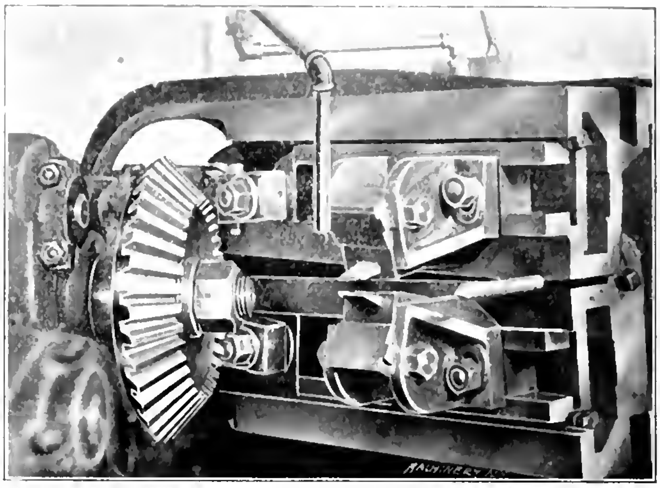

Fig. 14. Detail of the Browning Machine, showing Two Tool-holders.

Of the various powers for driving centrifugals, the electric motor, steam turbine, steam engine, and gas engine, are all far more economical than the ordinary steam pump using from 40 to 80 pounds of steam per horse-power per hour. When used in municipal waterworks service, the pumps can be run in parallel for ordinary service work, and connected in series for fires or flushing the mains. Many cities have this system, particularly in the West. When used in connection with tank supply, a float valve may be placed at the end of the discharge valve, as the pressure cannot rise when the valve closes, and the power necessary varies as the quantity of water pumped, with an additional variation due to change of efficiency.

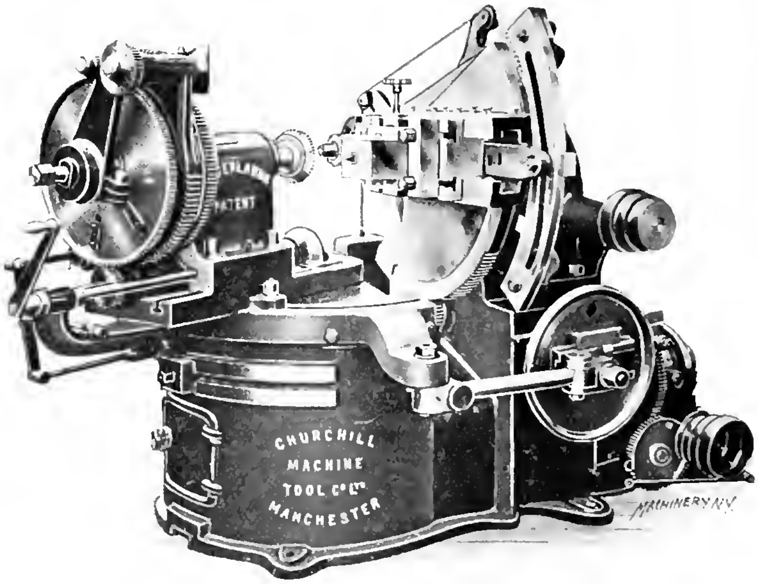

Fig. 15. The Churchill Bevel Gear Generating Machine, in which Provision is made for Modifying the Teeth to avoid Interference.

Of late, it has been customary to supply large buildings and hotels with a regular system of piping for ice water. It

* For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: Centrifugal Pumps, April and January, 1907; A New Method of Pumping Heavy Crude Fuel Oil or Other Thick Viscous Fluid, July, 1906; The Compound Pumping Engine, February, 1906; The Limit in Pumping Machinery, August, 1905; Pumping Heavy Fluids, April, 1905.

† Address: 312 West Seventy-third St., New York City.

is obvious that this must be an endless system, with constant circulation. There is no better nor more economical method than to have this maintained by a small centrifugal pump. No roof tank is necessary, although it is often used, as the pump can maintain the service, and a spare pump is cheaper than a tank, since they are so small. If a closed pressure tank is used at the bottom, the upward and downward moving columns balance, and the pump has only friction and weight of water actually used to overcome. A tank at the top gives a reserve capacity, and it may be either open or closed, but it is a source of loss by convection of heat, due to water remaining there.

One of the chief uses of centrifugals is in the irrigation of land. Their small first cost opens up a field hitherto precluded by the cost, complication, upkeep, and lack of economy of reciprocating pumps of the same capacity. Now, the farmer can, by a small gas engine or wood-burning steam engine and a centrifugal pump, irrigate his land from a nearby stream, canal or lake, and the cost is so nominal for small lifts as not to need serious consideration. The extreme height of lift for profitable irrigation seems to be around 170 to 200 feet, varying with conditions such as quality of land, cost of fuel, and value of crop. Irrigation on a large scale has been most successfully practiced by pumping, and plants up to 1,000 horse-power are in use.

Centrifugal pumps are now used in many large power plants as feed pumps, as they have many advantages over the ordinary type. There is no pipe shock or noise, and they work quietly, without air chambers, at a continuous speed, regardless of the quantity of water handled. Of course, the efficiency varies, but it is fairly good for a wide range of work, and at the worst, when driven by an electric motor or steam turbine, the centrifugal pump uses less steam than the reciprocating type. As a condenser circulating pump, the centrifugal's good points are well known. It is probable, however, that in the future, circulating pumps in large plants will be smaller and run at a higher speed, driven by an electric motor or steam turbine. For the handling of sewage, or bilge water full of ashes, coal, debris and grease, the centrifugal type of pump has no equal. In fact, many a good ship has gone down because the valves of a reciprocating pump became clogged at a critical time. This type can be operated while submerged in the bilge, the power being transmitted by a vertical shaft running to a motor or turbine placed above the pump.

As a mine sinking pump, the centrifugal has made its reputation. It is compact, being self-contained, and highly efficient. For regular mine pumping stations, the multi-stage pump, with a waterproof electric motor, needs neither engineer nor a dry station. In fact, it will run entirely submerged. Whereas the steam pumping station needed a complete engineering crew, many repairs, and a complete duplicate plant to insure safety. Deep tube wells 10 and 12 inches in diameter are now pumped by submerged multi-stage pumps driven by highly-efficient electric motors, which is preferable to the single cylinder deep well steam pump, using from 60 to 100 pounds of steam per horse-power hour, and requiring careful operation, and many repairs.

All over the city of Berlin, Germany, are numerous beautiful fountains. Near each is a small electro-centrifugal pump drawing water from the canals which cross the city in every direction, and discharging it to the fountain. They have no attendant, and are never shut down, or attended to in any way, except by an inspector who looks at them several times a week, seldom, however, doing anything to them. What reciprocating pump could perform this duty without being practically rebuilt every year or two? [The life of any pump depends, of course, greatly upon the chemical properties of, and the amount of grit in the liquid being pumped. Under favorable conditions, well-constructed reciprocating pumps will often run for years without giving any great trouble and without requiring much attention.—Editor.] In a like manner, in those parts of the country where electricity can be obtained from power lines, pumps driven by motors can be set up for irrigation or other purposes, and no attention paid to them for weeks at a time. This may not be advisable, but it is actually the case in many western farming communities.

For wrecking, salvaging and dry dock work, the centrifugal pump holds supreme sway because of its portability and cheapness. For the draining of land and marshes it has been used exclusively by the Dutch and by the engineers who have drained the Ferrarri Marshes of Northern Italy; the two greatest pieces of reclamation known to history. Of course, this refers to the time of modern pumping, since the Dutch have ceased to depend on windmills. The use of centrifugal pumps for hydraulic dredging has done much to improve our harbors and cheapen canal work. When made properly, they even endure this terrific wear, which could not even be thought of in connection with a reciprocating pump. As a lubricating pump for large systems of forced lubrication, the centrifugal maintains a constant pressure, no matter what the conditions of lubrication are, nor how often they change. In hydraulic elevator service, it is the ideal pump, because, without governors or regulating apparatus of any kind, it maintains a constant pressure, always supplying all the water necessary, up to the limit of its horse-power, and works equally well under pressure tank or open system. It could be used to advantage with hydraulic hoisting or manufacturing machinery. Steam turbine driven centrifugals have been applied to some of our most prominent fire boats, and they are now recognized by the underwriters, provided certain conditions relative to priming, etc., are met with.

To sum up, the centrifugal pump is a very modern piece of machinery, the growth and importance of which, in this country, is just beginning to be realized.

* * *

TO DETERMINE SIZE OF GAS AND OIL ENGINE CYLINDERS.

NEWTON WRIGHT.*

The determination of the size of a gas engine cylinder from the heating value of the fuel, and the pressure caused by the theoretical rise of temperature, is impractical, as the losses due to incomplete combustion, cooling effect of jacket, and incomplete expansion, cannot be estimated with any great degree of accuracy. The size is most conveniently determined from the known fuel consumption of engines of similar power and type, provided the ratio of air to gas is also known. The formulas given in this article will aid in determining the size required, in this manner. In the formulas given the notation used is as follows:

d = diameter of cylinder in inches,
s = stroke in inches,
n = revolutions per minute,
H = brake horse-power per cylinder,
c = cubic feet of gas per brake horse-power hour,
w = pounds of oil per brake horse-power hour,
r = ratio of air to gas or vapor,
r_1 = ratio of air and products of combustion (in clearance space) to gas or vapor,
k = ratio of total capacity of cylinder to piston displacement,
V = piston displacement per stroke in cubic inches,
V_1 = piston displacement in cubic inches per brake horse-power,
v = clearance volume in cubic inches,
m = ratio of diameter to stroke.

One pound of heavy oil gives about 12 cubic feet of vapor, and one pound of light oil about 6 cubic feet; consequently, in applying the following formula for the ratio of air to gas or vapor, to oil engines, 12 w and 6 w, respectively, are substituted for c. The value of the ratio r is expressed by the formula

$$r = \frac{d^2sn}{cH \times 72} - 1.$$

The ratio r varies from 2 to 3.3 for producer gas, from 7 to 12 for lighting gas, from 27 to 40 for vapor of heavy oil, and from 36 to 52 for the vapor of light oil. With the most economical engines the value of r lies between the two figures given, but is generally nearer the lower than the higher. Per-

---

* Address: 28 Greys Inn Road, London, England.

haps the average figures would be with producer gas, 2.4, lighting gas, 9; heavy oil, 30; and light oil, 40. In the two last instances, this value of the ratio would make 360 cubic feet of air per pound of heavy oil, and 240 cubic feet of air per pound of light oil.

The value of the ratio of air and products of combustion (in clearance space) to gas or vapor is expressed by the formula:

$$r_1 = \frac{d^2snk}{cH \times 72} - 1.$$

The ratio k of total capacity of cylinder to piston displacement is given in Table I.

TABLE I. RATIO OF TOTAL CYLINDER CAPACITY TO PISTON DISPLACEMENT.

Absolute Compression in Pounds per square inch.	k	Absolute Compression in Pounds per square inch.	k
30	2.65	75	1.46
45	1.86	90	1.38
60	1.58	105	1.33

The value of k is higher than it apparently would be, as the heating of the air following the compression causes the pressure to rise in a greater ratio than that due to the actual compression. When means are taken to clear the cylinder of the products of combustion, as is usual with engines working on producer gas, then r_1 will equal the ratio of pure air to gas.

The value of the piston displacement per stroke, in cubic inches, V, is expressed by the formula:

$$V = \frac{Hc\ (r+1)\ 57.6}{n}$$

The relation between the diameter of the cylinder and the other quantities affecting it, is expressed by the formula:

$$d = 4.2\sqrt{m}\ \sqrt[3]{\frac{Hc\ (r+1)}{n}}$$

The ratio of the diameter to the stroke m equals, of course, $\frac{d}{s}$, or $d = sm$. From the formula given it will be seen that if the length of stroke is given, the power of the engine will be proportional to the square of the diameter, but if the ratio of the diameter to the stroke is given, the power will be proportional to the cube of the diameter. Table II gives the usual values of m employed.

The clearance volume is determined by the formula,

$$v = V\ (k - 1) = d^2s \times 0.7854\ (k - 1).$$

The total volume of the cylinder equals $V + v = Vk$.

TABLE II. COMMON VALUES FOR QUANTITIES ENTERING IN CALCULATION OF SIZE OF GAS AND OIL ENGINE CYLINDERS.

Fuel Used.	H	c or w	n	m	V_1
Producer Gas.....	20- 50	85	170	0.6	100
	50-100	80	160	0.7	100
	over 100	75	150	0 9	100
Lighting Gas. ...	to 5	30	300	0.5	60
	5-20	25	220	0.5	66
	20-50	20	170	0.6	70
	H	w	n	m	V_1
Heavy Oil	to 5	1.2	300	0.5	87
	5-20	0.9	220	0.5	88
	20-50	0.7	170	0.6	90
Light Oil..... ...	to 1½	1.	750	0.6	19
	5	0.75	750	0.8	14

The compression varies from 35 to 80 pounds per square inch, and is usually about 75 pounds. The piston speed in feet per minute is from 400 to 700 in gas and heavy oil engines of less than 200 H.P. per cylinder, up to 1,000 in the largest engines. In light oil engines the piston speed is seldom less than 650 feet per minute, even in the smallest sizes, and more in the larger.

Assuming a consumption of 80 cubic feet of producer gas per brake horse-power, 25 cubic feet of lighting gas, 0.9 pound of heavy oil and 0.75 pound of light oil, and taking the average values of r as given in the first part of this article, the following formula may be employed for finding the diameter of the cylinders, if the ratio between the diameter and the length of stroke is given.

$$d = f\sqrt[3]{m}\ \sqrt[3]{\frac{H}{n}} = \frac{f\sqrt[3]{m}}{\sqrt[3]{\frac{n}{H}}}$$

In this formula f is a coefficient which equals 27.2 for producer gas, 26.4 for lighting gas, 29 for heavy oil, and 24 for light oil. At ordinary speed H would equal, approximately, $\frac{d^2}{5}$ for producer gas, $\frac{d^2}{4}$ for lighting gas, $\frac{d^2}{6}$ for heavy oil, and $\frac{d^2}{4}$ for light oil. These formulas, however, will not hold good for very small engines, say under 10 H.P., except for those using light oil.

The heating value of the fuel is usually as follows: Producer gas, 150 B. T. U. per cubic foot; lighting gas, 660 B. T. U. per cubic foot; heavy oil (specific gravity about 0.88), 20,000 B. T. U. per pound; light oil (specific gravity about 0.69), 28,000 B. T. U. per pound.

As has been mentioned before, one pound of heavy oil gives 12 cubic feet of vapor and one pound of light oil about 6 cubic feet, so that the heating value per cubic foot of vapor is 1,660 with heavy oil, and 4,660 with light oil.

Taking the average ratios of r as given before, the heating value of the mixture of air and gas drawn into the cylinder per cubic foot is, with producer gas 45, with lighting gas 66, with heavy oil 55, and with light oil 114. If the clearance space is allowed for, and assuming 75 pounds compression, the figures are 37, 48, 37 and 80, respectively. A theoretically perfect engine requires 2,545 B. T. U. per horse-power-hour, corresponding to a consumption of 17 cubic feet of producer gas, 3.9 cubic feet of lighting gas, 0.125 pound of heavy oil, 0.091 pound of light oil. If the efficiency of the gas producer is taken into account, minus 0.182 pound of anthracite or 0.212 pound of slack as one pound of coal, the producer gives about 62 to 70 feet of gas.

The preceding formulas refer to ordinary 4-cycle single-acting engines. For engines with several cylinders, the power, fuel consumption, etc., should be taken for one cylinder alone, and if a double-acting cylinder, the power, fuel, etc., for one end.

* * *

From a note in the *Mechanical Engineer* for December 25, 1908, it is evident that English mechanics and engineers are also feeling the need of more intimate connection between technical education and shop practice. A committee of the Northeast Coast Institution of Engineers and Shipbuilders has made the suggestion that apprentices be divided into two classes, one to be known as "ordinary apprentices" and the other as "pupils," the latter receiving rather more wages and also serving six years' apprenticeship, half of this to be passed in the works and the other half at college. For "ordinary apprentices" it was recommended that preference should be given to those with the highest leaving certificates at the elementary day school, where the committee recommend youths intending to qualify as artisans should receive, when possible, some instruction in elementary science, and that each year they would be given marks for examinations, time-keeping, good conduct, industry, and progress, bonuses being given for exceeding a certain number of marks. The pupil class will be trained to recruit the ranks of draughtsmen, managers, superintendents, employers, etc. Those who have passed a three years' course in engineering at a university college and obtained a certificate from it, would be taken as pupils for a three years' course, and in other cases workshop experience and college study would be combined for a period of six years, the pay to be higher after the first year's college course. Ordinary apprentices would be promoted to the pupil class on passing suitable examinations, during the course of their apprenticeship.

PACKING MACHINE TOOLS FOR EXPORT.

Machinery for export must be packed in a much more thorough manner than is necessary for domestic shipping, if it passes unharmed the rough handling it inevitably receives. It is generally sufficient for domestic shipment to crate a machine simply, as it probably will not be turned over or roughly handled in the course of transportation, and even may not leave the car on which it was loaded until it reaches its destination. In the case of foreign shipment the condition is entirely different. It is shifted from one vehicle to another many times in its course and is very unceremoniously handled. A box containing a machine tool worth thousands of dollars is of no more importance to a stevedore than one containing dog biscuit. Even if carefully handled, there is the effect of storms at sea to be considered. The pitching and rolling of a vessel in seaway may cause great damage to a machine improperly packed in its box. All machinery for foreign shipment must be braced in its boxing in such a way that it will not shift position or throw great loads on slender parts even when lowered into the hold of the steamer with the machine on end or upside down.

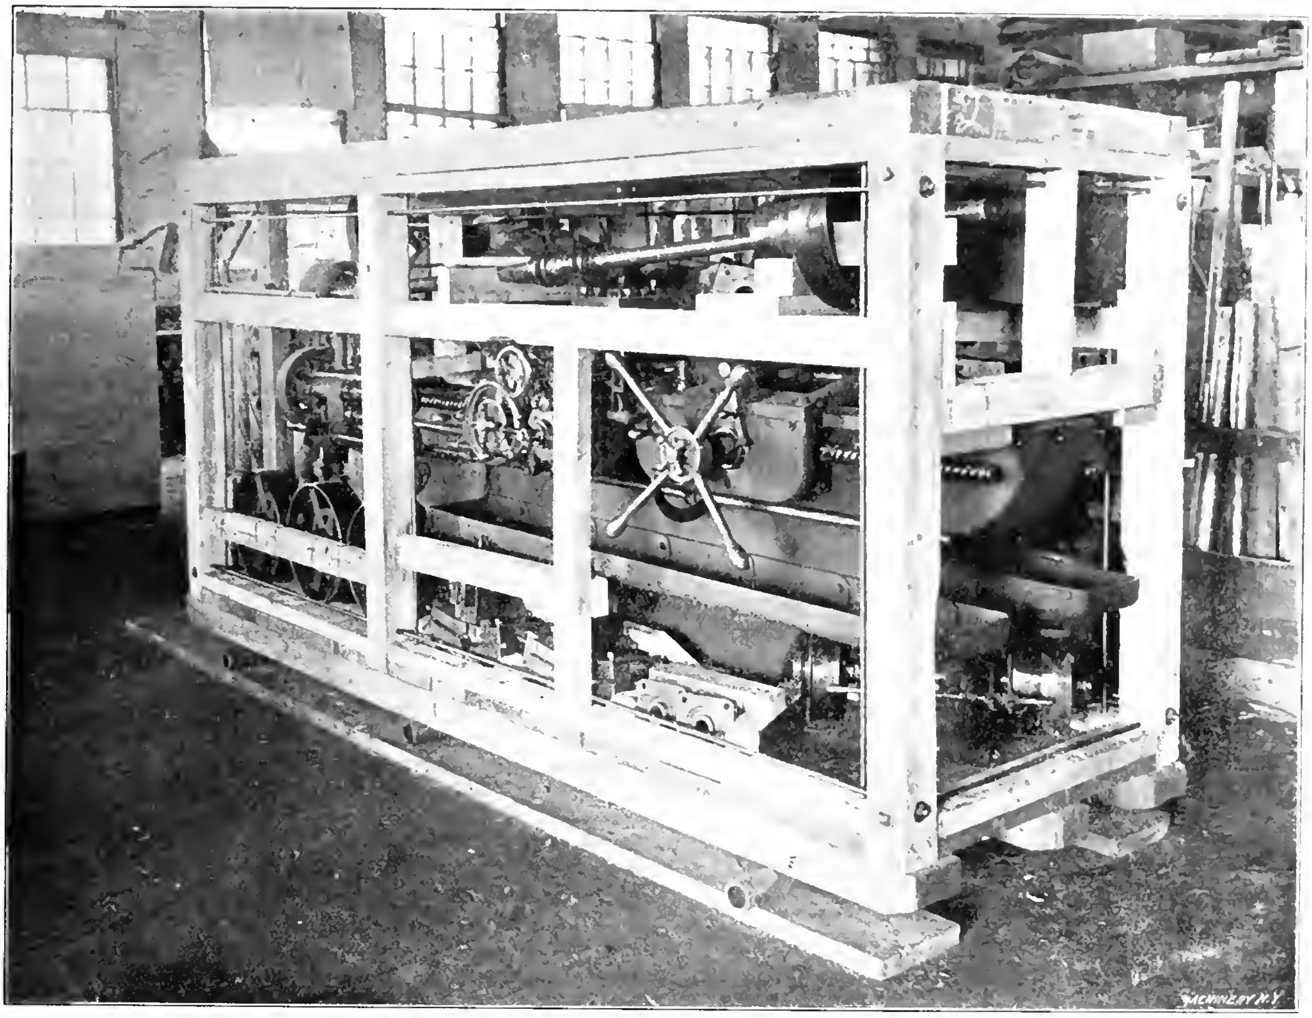

Fig. 1. Framing of Export Case for Gisholt Turret Lathe. Note Size of Framing, and Through-bolts tying it together.

Many American machine tool builders have boxed their machines very poorly, the result being that when received by European agents, parts were found broken, and the machines in a generally bad condition. Oftentimes the breakage of a small part has delayed putting the machine into use, weeks or even months, the consequence being that the customer is dissatisfied with the delay, and often sales have been lost by the breakage of a trifling small part which the agent was unable to promptly replace. The subject of packing machinery for export was very ably handled in a paper contributed by Mr. Paul Roux to the American Chamber of Commerce, Paris (see MACHINERY, April, 1904) in which our manufacturers were warned of the bad effect on foreign customers, produced by lax practice in preparing for foreign shipment. But some American builders had learned the lesson thoroughly long before that time and for years have packed their machines in a way that leaves little for criticism.

The accompanying photographs illustrate the very thorough and substantial way in which machine tools built by the Gisholt Machine Co., Madison, Wis., are prepared for foreign shipment. The company has developed the practice illustrated, through experience, and since it began following this method of boxing and packing, it has virtually eliminated all complaint regarding bad condition of machines received by its customers across the water.

Fig. 1 shows a Gisholt turret lathe in the strong frame made for foreign shipment, on which the outside covering of boards has not yet been nailed. It will be noticed that the very substantial framing is tied together by long ½-inch bolts, thus strongly reinforcing the joining of the timbers at the corners. The posts are made of 4 x 6-inch hemlock, and the remainder of the frame of 4 x 4-inch hemlock. The flooring is made of 2 x 10-inch hemlock and the skidding of 4 x 6-inch No. 2 hemlock. For boarding the outside of the case, No. 2 shiplap is used.

Figs. 2 and 3 are two views of a case containing the bed, table, feed box, head-stock, shields, etc., of a 42-inch Gisholt boring mill. The same specifications in regard to posts, overhead work, skids and boarding used for boxing the turret lathe, apply to the boring mill. Fig. 4 shows a case containing the top rail, down slides and cross-rail of the same machine, while Fig. 5 shows a case containing the housings. In these casings the use of ½-inch through-bolts is not found necessary as the weight of the parts is not so great as to rack apart the nailing of the timbers.

In Fig. 6 two machines completely boxed and loaded on a car ready to move out of the shop are shown. All bright parts of the machines are thoroughly slushed with No. 98 "Cosmic" slushing compound, while the tops of the machines are covered with tar paper. Then on top of the completely enclosed case is fastened a layer of waterproof paper lined with burlap, thus making a tight roof and insuring the machines from

becoming wet when exposed to storms on wharves. Some manufacturers have overdone the waterproofing act by lining the case throughout with tarred paper. Such a lining prevents circulation of air and causes dampness to collect which rusts finished surfaces even though protected with slushing compounds.

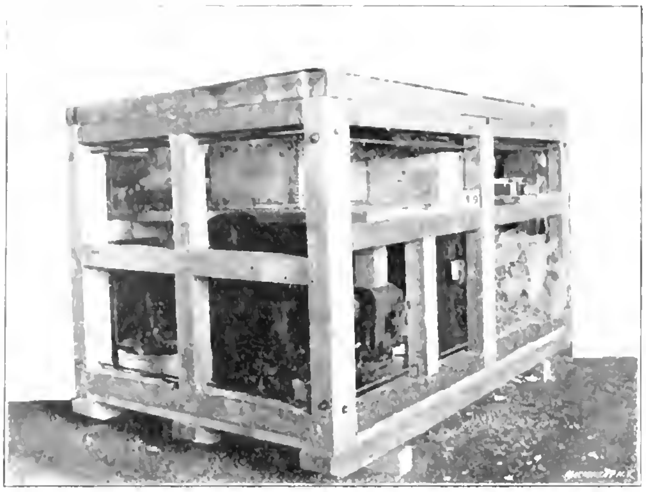

Fig. 2. Framing of Export Case for Gisholt 42-inch Boring Mill—Bed, Table, Feed-box, Head-stock, etc.

Special note should be taken of the thorough way in which the accessory parts are cleated down, and the manner in which heavy parts are supported by the framing. The proper preparation of a heavy machine so as to withstand foreign shipment is costly of time, labor and lumber, and much thought should be given to the design of package. Much can be learned in the latter regard from a careful study of these illustrations. It must be remembered that in lowering a machine into the hold of a steamer it is quite possible that the box will be suspended with the machine upside down, or what may be worse, from one end if it is too long to go down the hatchways horizontally. No slender part should be in contact with the thin boarding, as a blow or heavy pressure may be transmitted to the part with bad effect. The dropping of a case is not an unknown accident, and, of course, no framework sustaining a heavy machine will withstand a drop of many feet, but a drop of a few feet should not be disastrous, and is not likely to be, if boxed as here illustrated. Following is a summary of the principal points that should be observed in packing machines for export:

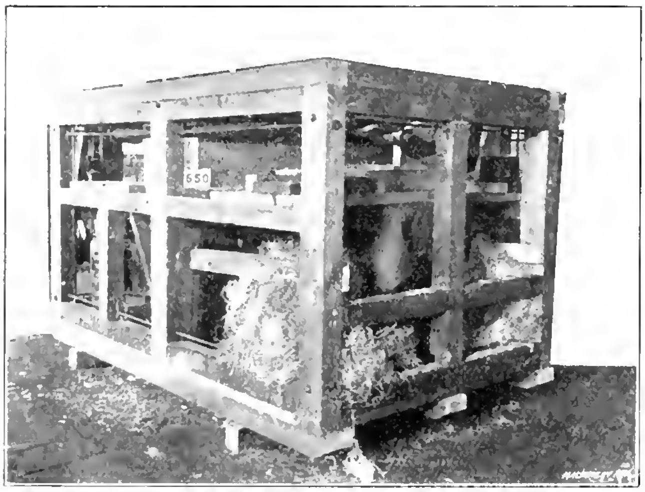

Fig. 3. Framing of Export Case for Gisholt 42-inch Boring Mill—Bed, Table, Feed-box, Head-stock, etc.

1.—Dismount all projecting slender parts to save space and to prevent breakage by side pressure. Saving of space is important as 40 cubic feet is reckoned a ton even if the actual weight is less.

2.—Avoid packages weighing more than 4½ tons if possible. The freight rate is much higher for packages exceeding this limit than for lesser weights. Keep all weights less than two tons if it can be accomplished without making assembly too difficult.

3.—In dismounting machines take into consideration ignorance of the parties receiving it, and avoid as much as possible dismounting parts that require careful adjustment for the successful working of the machine.

4.—Fill all the screw holes with wood or waste soaked in slushing oil, to prevent filling with dirt and rust.

5.—Tag all parts removed, giving their position or use on the machine.

6.—Prepare a list of all the detached parts to accompany the machine, which will show if any part has been lost in transit or custom house examination. Assembled drawings or photographs are desirable also, to facilitate erection.

7.—Cover all finished parts with a reliable slushing oil to prevent rusting during transit. The salt air and dampness of the sea voyage will attack unprotected finished parts to an extent almost unbelievable by one having known only the protection needed for land transport.

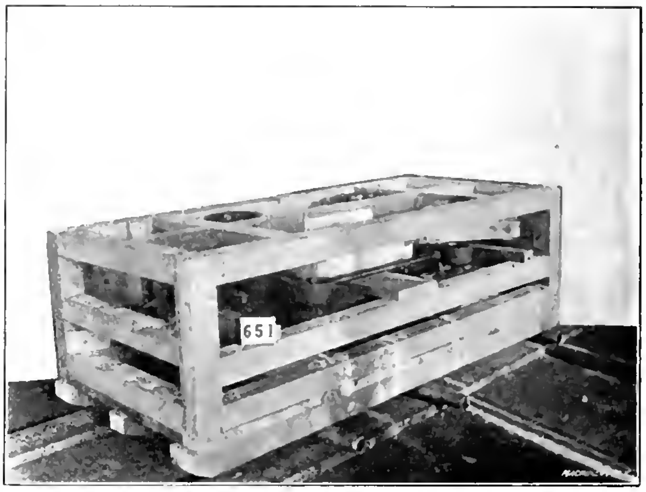

Fig. 4. Framing of Export Case for 42-inch Gisholt Boring Mill—Top-rail, Down-slides and Cross-rail.

8.—Build the package with strong skids, floor and framework, reinforced by through-bolts, if large, heavy machines are to be shipped without dismounting the frames from the legs.

9.—Support all heavy overhanging parts with cross girts from side frames, and pack accessory parts so that they cannot change position even if the case is overturned.

10.—Provide a waterproof roof and board the sides so as to resist driving storms of rain or snow. Leave an opening 12 x 18 inches in one side, the cover of which can readily be removed for custom house examination. Mark the screws holding the panel so that they will readily be found and removed without damaging the case.

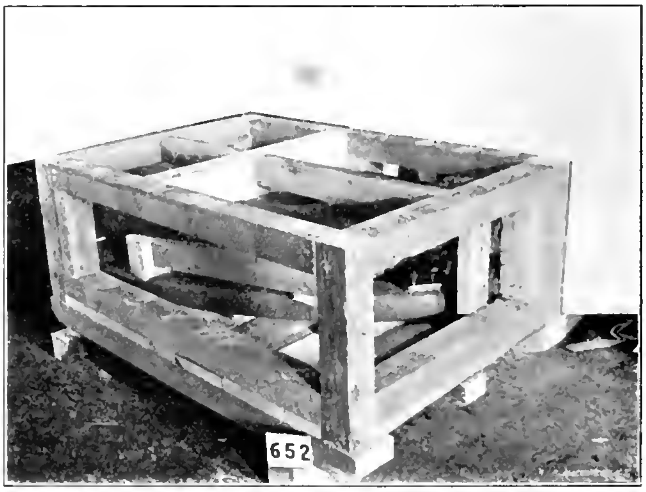

Fig. 5. Framing of Export Case for 42-inch Gisholt Boring Mill—Housings.

11.—Mark the case with the gross and net weight, volume in cubic feet, port of destination, names of consignee and shipper, name, number and capacity of machine; also designate the top or bottom and the nails or screws that should be first removed in unpacking.

DISTINCTIVE COLORS FOR PIPING IN A MANUFACTURING PLANT.*

OSCAR E. PERRIGO.†

There has recently been a good deal of discussion on the subject of painting the piping of a power plant in distinctive colors for the purpose of identifying the use of the various lines of pipe. The subject has appeared to be of sufficient importance to attract the attention of the members of the American Society of Mechanical Engineers, and a proposition has been made to standardize a system of colors which it is assumed should be somewhat suggestive of the use of the pipes and easily memorized by even the dullest intellect in the plant.

For many years the writer has been an advocate of the principle of making use of the well-known peculiarity in the minds of men to quickly recognize colors and their significance in preference to any amount of printed or written directions that can be given. Thus, in the pattern-shop a certain set of distinctive colors was given to patterns to indicate the metal of which they were to be cast, and to indicate what part of a pattern was to be cast in metal and what parts were the cores and the core-prints. In one establishment which had all its castings made outside the plant, much difficulty and annoyance had been experienced by having patterns sent to the wrong foundry, or ordered of the wrong metal. The result of the method of using distinctive colors worked so well that in seven years' use not a single casting was sent to the wrong foundry or made of the wrong metal. This seemed to prove the practical value of the system.

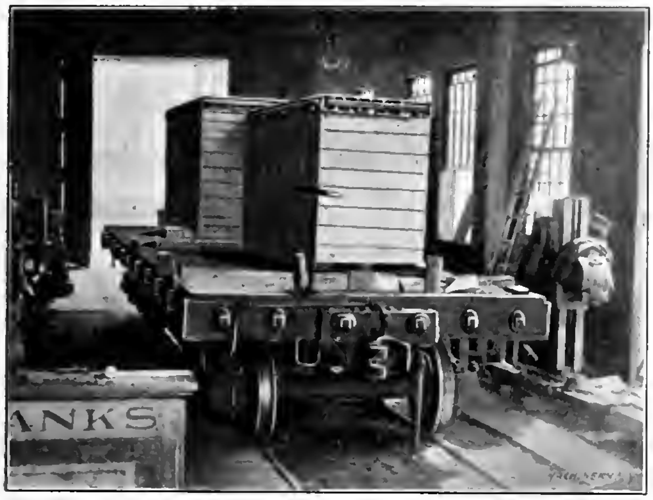

Fig. 6. Two Machines completely boxed and loaded on Car Ready for Shipment.

In the shop and office systems, the cards and blanks used had their distinctive colors, indicating their individual purposes, or the departments in which they were used. The men soon learned the signification of the colors, with no instruction whatever. Cards and blanks were habitually referred to by their colors rather than by the titles printed at the top. The work of sorting, arranging, and of generally handling them was greatly lessened and the question of efficiency favorably affected.

In the year 1891 the writer took charge of a manufacturing plant that had been started in "the good old times" (about 1850) in one small building, and which had been remodeled and added to at various times as the necessities of the business required, until it comprised no less than thirteen buildings and additions. There had been no general plan by which this work of development had proceeded, but each successive addition had been made to meet the emergencies of the hour and without much consideration for the future needs of the business. The result, so far as shafting, piping, transportation facilities, etc., were concerned, was much complication and a perplexing growth representing a maximum of expense and a minimum of efficiency. To bring something like order out of the chaos of piping, was a task that can be better appreciated by a man who has had a similar problem to solve, than by any amount of written description. Most of the piping had been done by outside workmen, and at various times, each of whom seemed to have endeavored to get as much piping and as many fittings into his particular job as possible, without reference to the necessities of the case or to previous or future conditions. Consequently, the systems of piping for steam, water, gas, and the fire protection system of sprinkling, were in an almost hopeless tangle, and generally two or three times as much piping put up as was needed. The sprinkling system was really the only piping in the plant that was put up according to a regularly formulated plan, and was, of course, distinguishable by the constantly recurring sprinkler heads upon all the smaller overhead pipes. As a preliminary to revising this piping system (excepting the sprinkler system), a comprehensive plan was worked out and workmen regularly employed by the company began the changes in accordance with it. These changes were continued until the entire piping system (except the sprinkler pipes) was completed according to the plan. When this work was begun, a great deal of difficulty was experienced in tracing out the various lines of piping, and on one occasion when a plug was removed from a tee for the purpose of making an extension to the gas lighting system, a jet of water convinced the gas fitter that he was on the wrong line of piping. Several incidents (or accidents) of this kind led the writer to use distinctive colors to identify the different lines of piping. Accordingly, after considering the question thoroughly, he adopted the following system of colors.

Red: For sprinkler pipes and all water pipes connected to the fire pump and used for fire purposes.

Green: For all other water pipes.

Blue: For all gas piping.

Brown: For all heating coils and the piping leading to them.

Black: For all other steam pipes.

When the men started the work of painting the pipes, and the scheme became known around the plant, there were a great many free opinions expressed as to the sane condition of the superintendent's mind. There was much wagging of wise heads among "the old timers," and a good many jokes by the "smart Alecs," as to what kind of a scheme would happen next; but in a few weeks the novelty of the innovation wore off and the sober second thoughts of the makers of shop opinions brought about a realizing sense of the fitness of the scheme to the purposes for which it was intended, and like the scheme for distinctive colors for patterns, and for distinctive colors for cards, blanks, etc., the practical utility of the system was readily conceded.

In the years of practical experience since that time, each trial of the system of identification by means of distinctive colors has still further strengthened the opinion that it is a very valuable and practically useful scheme, and that there are an infinite number of uses to which it can be profitably put in the organization and routine systems of any manufacturing plant.

* * *

Some interesting particulars of gears made from a special composition termed "Unica," which appears to constitute a new departure in silent power transmission, are given in our European contemporaries. These gears are made principally from compressed cotton, and tests carried out at the Royal Testing Institute in Berlin show that their resistance to indentation is 45 per cent greater than German rawhide at 1,120 pounds pressure per square inch, and that they offer 100 per cent greater resistance to displacement than rawhide at maximum pressure. Other advantages of the gears are stated to be that they are not affected by oil, and are cheaper than other types of silent gears. They can be key-seated the same as ordinary metal gears without fear of failure, and without the necessity of using bushings. The ultimate breaking stress sustained by the teeth of gears made from this material was shown by the experiments to be 51 per cent over that of German rawhide pinions and 27 per cent above that of vulcanized fiber pinions. It is stated that in strength the gears equal cast iron gears.

LATHE KINKS.

PAUL W. ABBOTT *

I once worked in a place where I was doing a medium grade of tool work, where there was no milling machine or drill press which I could use, so that it devolved upon me to do these two operations in the lathe the greater part of the time. Some of the schemes for doing this work, and the regular lathe work, will be presented in the following article.

The lathe used was a 16-inch Prentice with a first-class taper attachment, and it had the following equipment, the most of which I designed and made: One 12-inch three-jawed universal chuck, one 10-inch four-jawed combination chuck, and two drill chucks, one for rough use and the other kept for small, special jobs that necessitated a true running chuck. These chucks were mounted on hollow tool steel plugs, so that a bar of stock up to the capacity of the chuck could be run through and worked on. There was also one pair of special 60-degree cone centers used for nothing but the best work; one pair 60-degree cone cutters for ordinary work; one pair 90-degree cone centers (both hardened), used for rough, hurried work which I centered with a center punch; one long 60-degree cone center, projecting about 4 inches from the chuck, to be used on a piece of work that projected beyond the arbor or inside of a hole; two 60-degree half-cone centers for the tail-stock, one cut clear to center for squaring small work, and one cut down within 3/16 inch of center for heavier work; two pair 60-degree cone centers which were turned down; one pair to ½ inch and one pair to 5/16 inch diameter for getting inside of small holes; and one pair of centers for wood turning, of which I had a little now and then. As there was quite a little work on samples which were pointed 90 degrees, there was also a pair of 90-degree hollow centers, and three sizes of half-hollow centers for the tail-stock. Some of the work had round ends highly polished, and for that there was a steel center with a brass plug inserted in the end, which could be hand-tooled out to fit the work. All of the centers were draw-polished on the taper, and the head-stock centers were highly polished on the end that projected from center hole, while the tail-stock centers were left black. Thus they could be distinguished at a glance.

The collection of lathe tools consisted of about 300 of all kinds, shapes and sizes which were suitable for work ranging from 1/16 inch to 10 inches diameter. There was a set of Armstrong regular turners for holding high-speed steel bits, which I used altogether on regular turning. For drilling there were Nos. 1, 2, and 3 Morse sockets fitted to the lathe, and the following rigs: For regular plain drilling there was a plate, as shown in Fig. 1, which fitted the tail-stock spindle snugly, the work being supported by hand or blocked up on the bed of the lathe or carriage. For drilling round work, there was a V-block (Fig. 2), which was used with the plate shown in Fig. 1, the work being supported by hand. For drilling such jobs as shown in Fig. 3, or anything irregular in shape, an angle iron *A* was bolted on the side of the cross slide (Fig. 4), and the work *B* to be drilled strapped onto it. Any angle could be obtained in this way, and in drilling a row of holes it was particularly handy as the cross slide could be run along to first one hole and then the other. When drilling such work as a large box tool which was too large to mount on the angle iron, the cross slide was removed and the work strapped onto the ways of the cross slide as shown in Fig. 5. For drilling round work such as collars, I had a number of pieces of cold rolled steel of different diameters, from which one was selected to fit the hole in the collar, which was then drilled by using the V-block on the tail-stock spindle.

For milling jobs I had a number of arbors and a varied assortment of cutters. One of the best rigs, and one which no tool-maker should be without, was a 9-inch slitting saw, 1/16 inch thick, which was kept mounted on an arbor all the time with the dog on the arbor, ready to put in the lathe at a minute's notice. Another useful fixture consisted of a flat block of cast iron about 6 inches long, 4 inches wide, and 1½ inch thick, having two 90-degree V's in it at right angles to each other, and a number of tapped holes. This block, which was bolted to the top of the cross slide, and moved with it, was put to numberless uses. If I wanted a flat handle, such as shown in Fig. 6, did I wait for a forging? Not I!—simply reached under the bench and dug out a piece of soft steel the right thickness, laid off the right shape on it, strapped it to the block, and sawed it out to shape; the whole operation taking about five minutes. The saw ran at approximately 200 feet per minute (it had fine teeth, about 14 to the inch), and it was fed through a ⅜-inch flat stock at the rate of 2 inches per minute. If I wanted to cut off a piece of bar stock, I never went to the shaper to do it; I could saw a piece off with this rig while I was getting the shaper ready. A few of the pieces for which this rig was used are shown in Figs. 7, 8 and 9. If a number of pieces were to be cut from the bar it was strapped down loosely in the V-groove, and a stop put on the outside of the block to bring the pieces all the same length. The carriage was then locked and the pieces sawed. One inch cold rolled stock could be cut off at the rate of one piece per minute. Lard oil was used as a lubricant. When cutting brass the saw ran at 500 feet per minute. For milling such jobs as the heads of special cap-screws or squared ends on drill chuck wrenches, the rig shown in Fig. 10, which was mounted on the cross slide, was used. For this fixture there was a set of cast-iron bushings with holes varying by sixteenths of an inch for different sizes of work. I used to

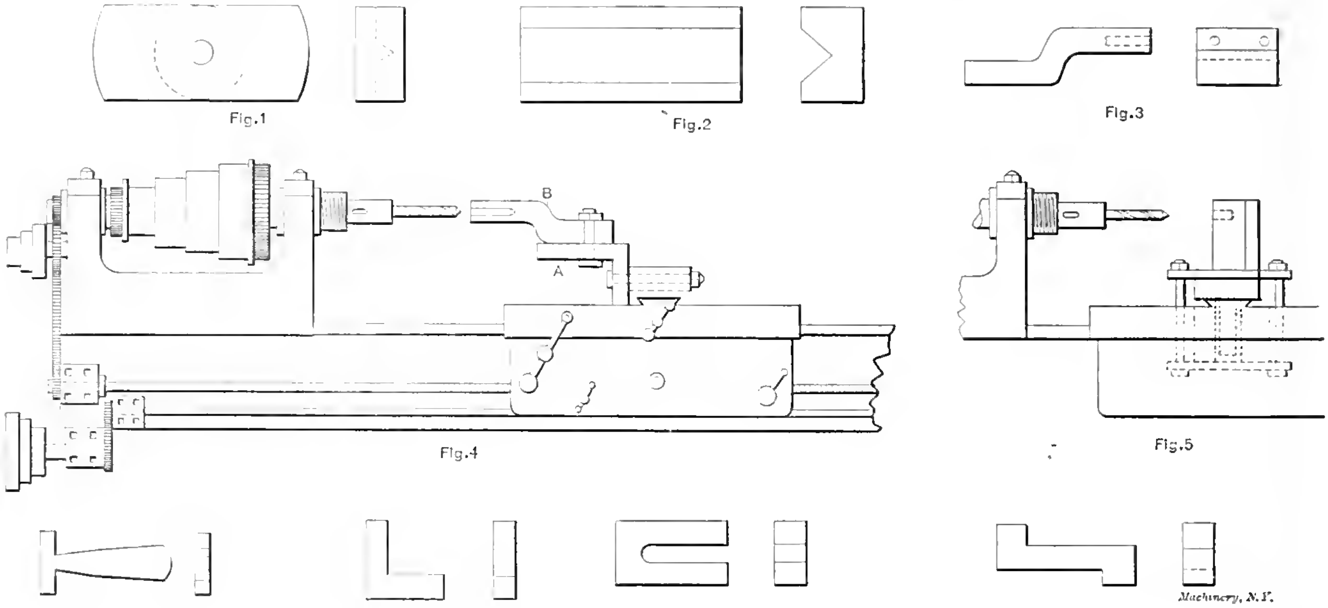

Fig.1 Fig.2 Fig.3 Fig.4 Fig.5 Fig.6 Fig.7 Fig.8 Fig.9

Figs. 1 to 9. Tools for, and Examples of, Work done on the Lathe.

---

* 18 Waterford Street, Lowell, Mass.

have some bushings to make, similar to the one shown at *C*, which had to be cut into four equal parts. For doing this job there was a squared bushing *D* and the arbor *E*. The squared bushing was inserted in the body of the fixture in place of the round one; the square headed set-screws removed, and a thumb-screw having a flat end put in. The arbor *E* was inserted in the squared bushing, and the screw tightened down on it. The bushing to be slit was slipped onto the arbor, and the counterbored washer *F* tightened against the end. The jig was blocked up to such a height that the arbor *E*, where the bushing went on, just touched the saw, passing underneath it, the saw running backward. The flat sides on the bushing *D* served as an index for the four cuts as the thumb-screw was tightened down on each side. Split collets were also sawed in this jig, and short end mills and countersinks were fluted with it. Such a job as milling the face of the small cam, shown in Fig. 11, was done by strapping the V-block (Fig. 2) on the cross slide with the V lengthwise of the lathe, and strapping the arbor, holding the cam in the V so the arbor could be turned with a wrench on the end. Then with an end mill held in the drill chuck, and getting the proper depth of cut by feeding in the cross slide, which when in far enough was locked, the arbor was revolved and the piece milled to the shape required, except the sharp corner, which was afterward filed.

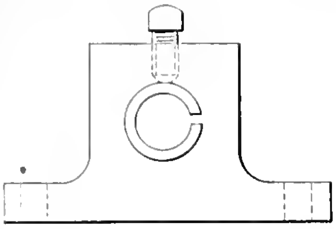

Fig.10

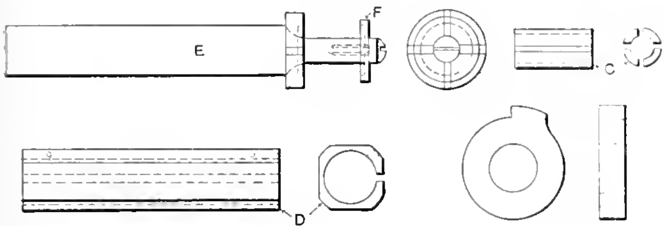

Machinery, N.Y.
Fig.11

Figs. 10 and 11. Fixture for Milling on the Lathe and Examples of Work.

For boring jobs I had the universal and combination chucks, a 16-inch face-plate, and a 6-inch four-jawed, independent, reversible-jaw chuck for small eccentric work, and a 4 x 6-inch angle iron. Some of my boring jobs were as small as ⅛-inch diameter, and others as large as 10 inches diameter. The boring on the angle iron was of the usual nature—boxes, bearings, etc., for repairs on machines. When pieces were too large for the face-plate they were strapped to the carriage and a boring bar used. When boring holes in the ends of long shafts, the angle iron was mounted on the side of the cross slide as in drilling, and the shaft was strapped in the V-groove in the angle iron. A drill was first used, and then a small boring tool which was held in the drill chuck. The boring tool is shown in Fig. 12. This feature of having 90-degree V's planed in the angle iron is a valuable one where there is any round work handled on the angle iron.

In connection with the cutting of small pitch threads, I always used carborundum slip stones to resharpen the thread tool before taking the final finishing cuts; in this way it was not necessary to remove the tool and disturb its setting. Slip stones of a medium grade of coarseness will remove 0.002 or 0.003 inch from a small surface in no time. These were also used on repair work. When reaming odd size holes, if the reamer was cutting a little large it could be stoned 0.002 inch under size in two minutes. For straight lathe work I had a number of features for facilitating the speed at which it could be done. There were three rests for the lathe: the regular center rest, a follow rest, and a rest for light work (Fig. 13) which fastened to the tail-stock spindle. For the center rest I had five sets of jaws; one set for small work down to 3/16 inch diameter; one set of shorter jaws for the usual run of work, one set still shorter for work up to the full capacity of the rest; one set of jaws that were tapered off to 3/16 inch square on their ends, for taper work; one set of steel jaws 5/16 inch thick to go in between shoulders or other narrow places. Thus there were sets of jaws for all the work that came along, and there was no waiting to file jaws to take in a large piece of work and then find them too short for the next small work that came. The slots in the rest were numbered and the jaws were numbered to correspond, so that the latter always lined up correctly. On the jaws a center line was marked so that as they wore away and had to be filed off on the sides to make them narrower on their points, they could be filed to the center line and always be lined up with the center line of the lathe. The follow rest, which was of the usual type, had several sets of jaws for different sizes of work. The rest shown in Fig. 13 is not very common, but is mighty handy on small work. The arms *G* are adjustable on the shaft, and the jaws *H* are of brass and are also adjustable.

The feed on this lathe was thrown in by a T-handle *J* which could be turned either way, and also thrown out by revolving in the same direction. When turning a long piece in the lathe a bar was fastened to the bed of the lathe, as shown in Fig. 14, and in that an adjustable rod *K* which, when the feed handle struck it, would throw the feed out. This was very handy, as I could be doing something else while turning a long piece.

I used to have a number of long, square threaded screws of mild steel to make 1¾ inch diameter, three threads per inch. When doing square threading an Armstrong tool-holder was used for holding ⅜-inch square tool bits; these bits were made of Novo steel. There was one tool for roughing and one for finishing, 0.005 inch being left on each side of the thread to remove with the finishing tool.

As there was no compound rest for the lathe, when doing angular work other means had to be provided. For angles up to 10 degrees, measured from a line at right angles to the ways, setting the tail-stock over would do. For angles up to 15 degrees, measured from a line parallel to the ways, the taper attachment was used, but for angles of larger degree, another scheme was adopted. The carriage feed and the cross feed could both be thrown in together, which gave an angle of about 45 degrees. This angle could be varied either way by setting the tail-stock over or by connecting up the taper attachment. This was applied in a very practical manner to the making of some 90-degree inserted tooth countersinks, 5 inches in diameter. I used this method for turning the 90-degree nose of the countersink, and boring the 90-degree steel cone which fitted the nose, which was afterward cut up into sections for holding the teeth. Having no indexing attachment on the shaper, the graduating was all done in the lathe with the gearing, using a sharp-pointed tool in the tool-post, and then transferring the work to the shaper and working to the lines. When cutting off a piece on an arbor, I always set my calipers to about 0.005 inch over the size of the arbor, and then, holding the calipers in the slot made by the cutting-off tool, cut away freely until the calipers slipped over the work. This is only a little kink, but it often saves cutting into the arbor. There are various ways of fix-

Figs. 12 to 15. Automatic Feed Stop and Miscellaneous Lathe Toole.

ing the ends of centers, but the best way I know of is shown in Fig. 15. A center finished like this will stand any amount of banging without injuring the fit in the center hole. Some of these kinks may not be new to all, but they are all good ones, and time savers.

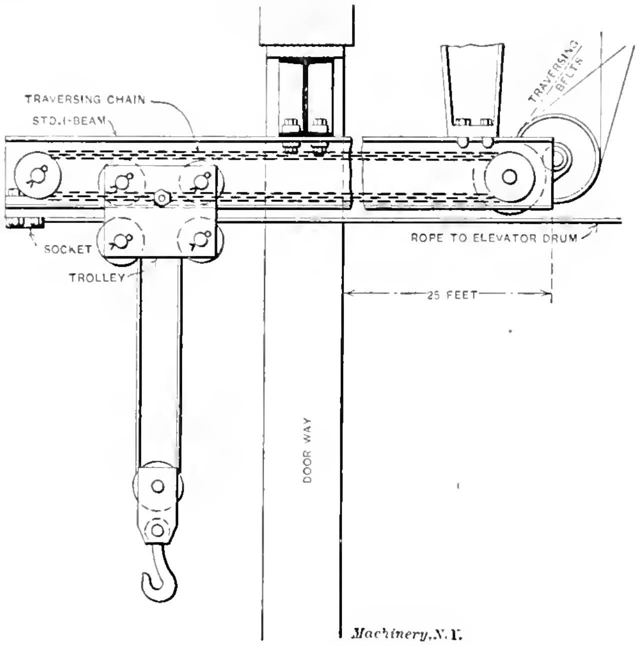
A CONVENIENT OUTSIDE SHOP HOIST.

The shop of E. E. Bartlett, of Boston, the builder of the Greenerd arbor press, is located on the sixth floor of a factory building. As the elevator service is not particularly convenient, and as the castings for the larger sizes of the arbor presses are quite heavy, they are hoisted up the outside of the building and in through a door onto the floor of the shop. The same arrangement is used for lowering the finished work. This is a very common practice. The ordinary rig consists of a wooden beam projecting over the doorway for a few feet and provided with an eye-bolt to which a block and tackle is rigged, which is operated by anything that comes handy. For hoisting a bale of hay with such an arrangement to the second story of a stable, a horse is hitched to the end of the rope; in manufacturing establishments the horse is sometimes used, but the hauling is more often done with some homemade winding arrangement.



Machinery,N.Y.

A Convenient Hoist for Handling Material through an Outside Doorway in an Upper Floor.

Mr. Bartlett has improved on the primitive construction in a way that gives him little reason to regret the inefficiency of the elevator. The arrangement is shown diagrammatically in the accompanying line engraving. A steel I-beam, properly proportioned, is firmly suspended beneath the arch of the door-way, projecting outdoors for a sufficient distance to allow the material to clear the sides of the building, and extending inward for 25 feet or so over a shipping and receiving floor. On the under flanges of this I-beam runs a trolley, provided with two idler sheaves. Over these passes a wire rope, from which, by means of a block and hook, the load is suspended as shown. The outer end of this rope is fastened to the outer end of the I-beam, while the inner end is led back to a regular commercial form of elevator hoist provided with the usual stops to prevent overwinding, and having the usual arrangement of shifting belts for raising or lowering the load as required. The controlling ropes for this elevator hoist are brought to a point near a window beside the doorway, where the operator can have a full view of the operation, both indoors and out.

The trolley is connected with a chain running over the idler at the outer end of the beam and over a sprocket at the inner end. This sprocket is connected by gearing with tight and loose reversing pulleys, whose belt shifter is operated by cords which are also led to the operator's position by the window. It will be seen that with this familiar arrangement of trolley and hoisting rope, the load may be raised or lowered and traversed, together or separately, the two motions being independent of each other. The operator at the window raises the load from the truck below until it reaches the level of the doorway, then runs the trolley in by power until it reaches the desired position over the receiving floor, when it is lowered and released. One great advantage of this arrangement, from the standpoint of safety, is the avoiding of the necessity for leaning out through the door to pull the load in; a frequent cause of accidents is thus avoided. Another advantage is the convenience, in shipping, of being able to take work from the floor and deposit it in the wagon, without requiring the intermediate operation of shifting on rollers into the elevator, and from the elevator to the truck. The whole arrangement is very simple, and may be made almost entirely from commercial parts. For hoisting loose castings a basket is used, made of boiler iron.

* * *

EXPERIMENTS WITH ROPE AND BELT DRIVES.

Some experiments have been undertaken by the Technical Institute at Charlottenburg, Germany, in order to establish definitely the loss of energy in transmitting power by means of belts and ropes. These experiments indicate that the capacity of belts for transmitting power at high velocity is considerably higher than given by ordinary formulas and calculating methods. It appears from the experiments that it is an advantage in belt drives to use large pulley diameters, and consequently high peripheral velocity. Considerably better results are obtained if the pulleys are made from wood for diameters less than 24 inches. An idler for obtaining the required tension, placed close to the small pulley and having a diameter at least 50 per cent greater than this pulley, does not reduce the efficiency of the drive in any appreciable degree when the belt speed is not greater than 100 feet per second. An idler for producing proper tension and for providing larger angle of contact on the smaller pulley is therefore to be recommended in belt drives of high ratio between the sizes of the pulleys.

The friction in the bearings is considerably greater for rope drives than for belt drives, because ropes must be under higher tension than belts, all other conditions being equal. The efficiency of rope drives decreases considerably for high speeds, while it increases for belt drives. When high peripheral velocity is required it is therefore advisable to use belts rather than ropes. In the case of rope drives the efficiency is also reduced when the diameter of the pulley or sheave is reduced, due to the power required for bending the rope, whereas the diameter of pulley in belt drives is of very little consequence, within rather large limits. The highest efficiency obtained during the tests referred to was 98 per cent with the belt drive, all conditions being ideal. Power transmission by means of a single rope, gave 97 per cent as the highest efficiency; using two ropes side by side, made the highest efficiency 95 per cent; and only 90 per cent efficiency was obtained with four ropes side by side. The efficiency in the case of rope drives thus decreases about in proportion to the number of ropes employed. The figures quoted give the actual efficiency of the drive, the friction losses in the bearings being subtracted. The latter are also greater in the case of ropes than in the case of belts, due to the higher tension required in rope drives. While idlers in the case of belt drives did not appreciably decrease the efficiency, in the case of rope drives it was found that idler sheaves decreased the efficiency considerably.

* * *

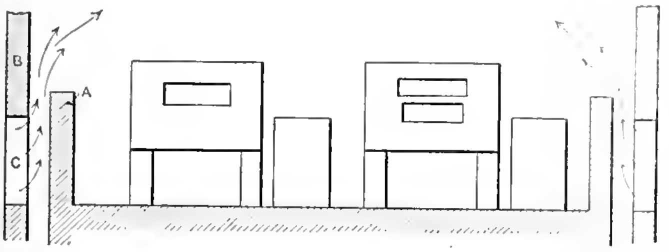
A scheme for securing efficient industrial education which undoubtedly could, in a modified form, be worked to advantage in many of our industrial centers in the United States, has been adopted by a number of English firms. It appears that some municipalities maintain public evening schools especially adapted to the needs of apprentices, but as the expenses for these evening schools are rather too high to be borne directly by the municipality, if efficient instruction is to be given, the local firms have agreed to pay a certain sum for the instruction of each of their respective apprentices who joins an evening class, and monthly reports are forwarded the firms as to the attendance and progress of the students.

THE MANUFACTURE OF TAPS—2.

In the January issue, the turning, threading, squaring, fluting, chamfering, and relieving of taps, as practiced in the manufacture of these tools by the Wells Bros. Co., Greenfield, Mass., was treated in detail. It is proposed in the present and concluding article on the manufacture of taps to treat of the hardening and other operations still remaining to be performed on the taps, and also to refer briefly to some of the many interesting features of the shop equipment and systems used in the works of the Wells Bros. Co.

Hardening.

The hardening of taps and dies in this plant is carried on according to the most modern methods, and several features have been introduced which are of particular interest. The hardening room is completely dark except for what little daylight comes in through the ventilators in the ceiling. There is an advantage in having this room dark as it is possible for the hardener to judge exactly the heat of the pieces to be hardened, by their color. It would seem that a hardening room without windows would be rather uncomfortable, but the ventilation is of the best, and the arrangement for securing efficient ventilation without letting in the light is indicated diagrammatically in Fig. 20. The hardening room proper may be said to consist of a concrete tank *A* having walls extending up about 3 feet from the floor. Outside of these walls are the actual outside walls *B* of the building, which are provided with openings or windows *C* below the level of the top of the walls *A*. From these windows the air circulates through the room, escaping through ventilators in the ceiling.



Machinery,N.Y.

Fig. 20. Diagrammatical Sketch of Arrangement of Hardening Room.

This system of ventilation evidently is unusually efficient, as the hardening room was much cooler than a great many others which the writer has known, in which the windows for ventilation and light were provided directly in the walls. It is evident that it is permissible to have the windows constantly open and secure better ventilation in a case where the arrangement is as indicated in Fig. 20, because the cold air does not strike the furnace directly, nor does the draft inconvenience the operators, as is often the case when ordinary windows in a hardening room are opened.

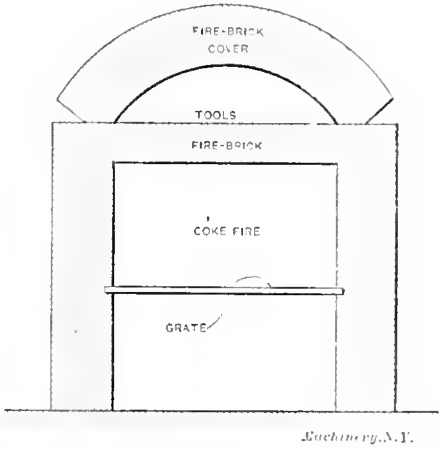
The furnaces, which are of the company's own design, are heated by oil fuel. An underground tank is provided outside of the works, having a capacity of 6,000 gallons. From this the oil is pumped to a small tank where it is under pressure and from where it goes to the various furnaces. The surplus oil returns to the big tank by a return pipe. All piping is under the concrete floor in the hardening room. There are two regular hardening furnaces installed in the works, one for large and one for small work. No lead pots filled with molten lead are used for ordinary hardening, as it is considered that the method of hardening in lead is a poor one, and that in order to obtain satisfactory results more modern methods must be employed. The hardening furnace for small work is provided with ten tubes or pipes 1½ inch in diameter and 14 inches long. These tubes pass directly through the furnace and the outside walls of the furnace frame, and are open at the front end. The flames from the burners strike the outside of that part of these tubes which is inside the furnace. The pipe used is ordinary gas pipe, and burns out in from four to six weeks.

The work is placed in half circular shells and pushed into the tubes where it is heated slowly and very uniformly. The operator observes when the work has reached the correct hardening temperature, then he removes the half circular shell with the work from the tube, and dumps it directly into the hardening bath which consists of ordinary brine. It has been found that this method of hardening is superior to any that has been tried in the works, and that the taps come out of the hardening bath with a remarkably even texture. Taps up to five-eighths inch diameter are hardened in this manner.

Larger taps are hardened in a furnace where the oil fuel strikes cast iron plates on which the work rests. The work is heated very slowly. By distributing the flame from the burner in a certain way, it is possible to heat the furnace and the cast iron plate at one end much more than at the other. The work is first put in at the cooler end of the furnace, and gradually moved over to the hottest part, and when it has been in long enough to insure a uniform heat throughout the work, even on large pieces, it is removed and quenched, as usual.

Some taps, like bit brace taps, for instance, are not turned up from the solid stock but are drop forged. These drop forgings must be annealed before the taps are turned to the correct size. The annealing is done in an ordinary annealing furnace, the work being packed with cast iron chips in cast iron boxes and a cover of cast iron placed on the boxes. These boxes are placed in the furnace in the morning and the fire is kept going for ten hours. The boxes are then removed from the furnace the next morning.

Some interesting things seen in the hardening room which do not have direct bearing on the manufacture of taps, may here be mentioned. One is the method for obtaining the mottled effect which the company produces on die-stocks and several other tools having large polished surfaces. In order to obtain a fine mottled effect on the steel, the object to be treated is first highly polished and then very carefully cleaned from all oil in hot soda solution. It is then slowly heated to a temperature of from 150 to 200 degrees by placing it on the hot fire-brick covering the top of the furnace. When heated to the degree mentioned, the steel is put in a pot of heated cyanide of potassium and brought to a dark red heat. It is then dipped into clear water and vigorously moved about in this. Unless the work is moved about when cooling off in the water, the mottled effect desired will not be obtained.



Machinery,N.Y.

Fig. 21. Diagrammatical Section of Hardening Furnace for High-speed Steel.

Gages are not hardened by heating in the furnace the same as regular tools, but are pack hardened. The gages to be hardened are packed in ordinary ground bone in cast iron boxes covered with fire clay on top, and then heated for about three hours.

For hardening high-speed steel, a special furnace, shown diagrammatically in Fig. 21, is employed. For obtaining the heat required, coke and an air blast are employed. Small work is heated from three to four minutes and quenched in linseed oil mixed with ordinary salt; as much salt as the oil will dissolve is used.

Long taps which require straightening are heated to a straw temper and then placed under a straightening press having two cast iron blocks in which the tap rests at the ends. A screw with a block bearing on the tap is then used for obtaining the required pressure for straightening the tap. All taps are tempered in oil, and the temper is drawn to a temperature of from 430 to 450 degrees F.

Polishing the Taps.

[illegible] the shank of the tap is polished. After hardening the [illegible] again returned to the polishing room where [illegible] polished in the flutes by means of a small [illegible] of semi-circular cross-section. The taps are [illegible] burred between the threads with a piece of [illegible] hoop iron, which is caused by hand to slide [illegible] between the teeth, the tap meanwhile being revolved on centers. After this burring operation the taps are cleaned [illegible] threads by a wire brush revolving at high speed. Then the shank and the end and corners of the square are polished by hand.

A view of the polishing room is shown in Fig. 22. All polishing and grinding is done by hand; the polishing room is unusually free from dust owing to the fact that every wheel is provided with a sheet-steel hood connecting with an exhaust system under the floor. The arrangement is shown plainly in Fig. 23, which also shows a machine of rather ancient design, it having been built in 1877. The most interesting thing about this machine is that it is provided simply with ordinary cast iron boxes carefully protected from dust by dust caps, and while it has been in constant use for the last thirty-two years, the boxes are still in good condition. This indicates the possibilities of regular cast iron boxes for journals running at high-speed, provided the boxes are carefully protected from grit and dust.

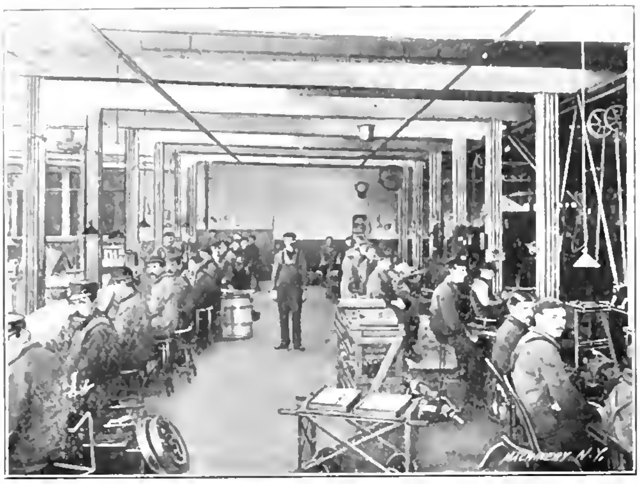


Fig. 22. Grinding Department—A Common Form of Shop Truck used in the Shops is shown in the Foreground.

Tools for Inspecting the Taps.

The taps are now ready for the inspection department, a view of which is shown in Fig. 24. It should be mentioned in this connection, however, that between each operation of any consequence all tools go to the inspection department to be inspected before the next operation on the tools is performed. In the inspection department the system of gages developed by the Wells Bros. Co., examples of which are shown in Figs. 19 (January issue) and 25, play an important part. Fig. 25 shows two thread micrometer gages for measuring the angle diameters of taps; these micrometers are provided with large dials at the measuring screw end of the device, the dials being graduated so that 0.0001 inch can be easily read off, this amount being equivalent to 3/64 inch on the periphery of the dial. These thread micrometers are made according to the principle developed by the company, having the two measuring points offset half of the pitch so that each point enters directly into a thread in the tap to be measured. In the foreground is shown a block holding a number of measuring points which can be substituted in these measuring instruments for different pitches and classes of threads.

On the right-hand side in Fig. 25 are shown two thread micrometers mounted in convenient holders, which are provided with points for measuring the angle diameters of threads, the anvil point being adjustable for different pitches, the same as in the larger instruments. In the same illustration is also shown an interesting gage for measuring the [illegible] and width of the flat of Acme standard thread tools. In Fig. 19 are shown the regular working gages employed in the works and in the inspection room. We have already referred to the limit gages *A* and *B* for measuring diameters of plain work. It will be seen that these gages are also made with sharp points, as shown at *C*, for measuring the angle diameter of threads. This system of gages, as well as some of those shown in Fig. 25, has previously been described in MACHINERY in the August and September, 1907, issues. For measuring the lead, gages as shown at *D*, Fig. 19, are used.

The company is at the present time preparing to place on the market a system of limit gages which have been used in the works for some time, of which one example is shown at *E*, Fig. 19, the female gages being placed in the box shown, and the male gages being seen in front of the box. The feature of these gages is that each gage is surrounded by a hard rubber ring on the outside, one being black and one being red. The black color indicates the maximum limit gage and the red color the minimum gage, the red color being the "danger signal." This same indicating system is followed in regard to the handles of the plug gages. The advantage of such visible indications of the maximum and minimum gage, which obviate the necessity of looking for the stamping on the gages, is evident.

The system of setting the limit gages of the type shown at *C*, Fig. 19, is of considerable interest. In order to make it possible to set the gages easily to any predetermined limits, a special threaded plug is provided, having a very slight taper. At a certain place on this plug the exact standard size is indicated by a line. The taper for each plug is so selected that the next thread below the size line marked is 0.001 inch less in diameter than the standard diameter at the line, the second thread, 0.002 inch less, and so forth; the first thread above the size line is, of course, 0.001 inch larger in diameter than this dimension. By adjusting the maximum and minimum limits of the gages to this taper plug, the gages can evidently be set to any limits varying by 0.001 inch, and if special care is used, limits as close as 0.0005 may be obtained. The same system, of course, can also be used for the setting of the plain limit gages *A* and *B* in Fig. 19, a plain plug with size lines being used.

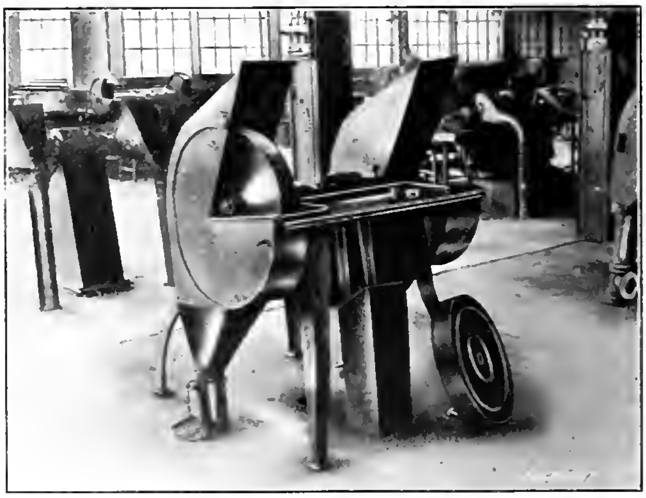

Fig. 23. An Old Grinder built in 1877 which still gives Efficient Service. Note also System used for Exhausting the Dust due to Grinding.

The Stock Room.

After the inspection the taps go into the stock-room, where the smaller ones are put away in drawers, as shown in the foreground of Fig. 26. The larger taps are put away on open shelves. All the racks and shelves are made of metal, and the shelves are adjustable for height on principles similar to those employed in adjustable shelve bookcases. This gives great flexibility to the storage system. The stock-room is also unusually light, due to the fact that there are no solid partitions such as are necessary when the shelves are made from wood. On each of the drawers in which the smaller taps are contained, the kind, size, and pitch of the tap is marked, and also the minimum and maximum number of taps which ought to be kept in stock. When the storekeeper finds that the number of taps of a certain kind is running down towards the minimum limit, he puts in an order for a new supply of

this kind of taps. In this way a full supply of all sizes and pitches are assured without any elaborate system of bookkeeping.

Some Features of Interest in the Shop.

There are many features in the shop equipment and the systems employed, which are seldom seen in other plants. One of the first things which the observer will notice is the liberal use made of concrete. Not only are the floor in the shop and the larger machine foundations made of concrete, but many smaller machines are provided with concrete supports instead of cast iron legs, and it is stated that the cost of concrete used for this purpose is only from one-fourth to one-fifth that of iron legs. Concrete is also used largely for supports for work benches, and in the shipping room the writer saw a large bench made entirely out of concrete, intended to be used for nailing boxes; the noise commonly present in the shipping room, due to the hammer blows in nailing boxes and crates and the vibrations in the benches and floors, are largely eliminated in this shipping room, due to the fact that there are no vibrations in the supporting bench or floor, and it appears from a comparison with other places within the writer's experience that the larger proportion of the noise is due not to the nailing operation itself, but to the fact that the box or crate is supported on a flimsy and vibrating support.

All tools are stored in the shop in cabinets with sliding glass doors, and the benches in front of these cabinets are covered with linoleum. It has been found that it is not only cheaper to keep the benches thus covered, if a neat appearance is valued, than it would be to try to keep a wooden bench in fairly good condition, but it is also much easier to keep clean. All cutters are placed on wooden pegs mounted in blocks, and on the end of each block is given the sizes of the cutters and the purpose for which they are intended.

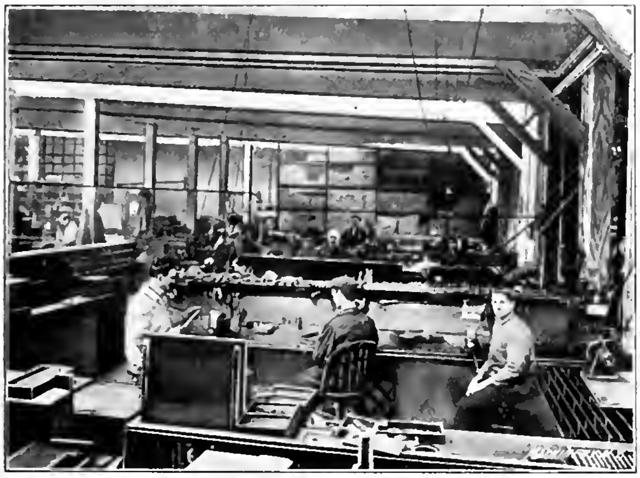

Fig 24. Inspection Department.

Each foreman in the shop is supplied wtih a volume of blueprints bound in a loose leaf binder, and he is also provided with a loose leaf binder for all special instructions given to his department from the superintendent's office. All gages are turned in to the inspection department once a week to be inspected and adjusted.

Besides the regular stock-room, a storeroom is also provided for work in progress. All work goes to this storeroom between each operation, and as mentioned before, it is then inspected if the operation warrants this. On regular taps only the threading and finishing is inspected, there being practically no chance for mistakes in the other operations inasmuch as the operators are provided with limit gages which determine whether the work is made as required. One of the features in the shop which saves a large amount of handling of the material, and makes its transportation from one part of the shop to another convenient, is the use of box trucks of the type shown in Fig. 27. This truck is practically an iron truck provided with a wood lining, and it rests on four wheels, one at each end and one on each side, as shown. When the work has been placed in the truck after having been finished in one department, it is transported to the storeroom for unfinished work, and remains in the truck until it is sent to the department where the next operation is to be performed. It is then taken out of the truck as it is wanted for the machines, and when the operation is performed it is placed in another truck ready to go back to the storeroom again; in this way any superfluous amount of handling the material is avoided. These box trucks at the same time provide good means for storage of the articles.

In the same illustration is also shown one of the very convenient benches used all over the shop. It will be noticed that it consists mainly of an iron frame provided with two wooden shelves. All over the shop one finds trucks and stands of various types built up with iron frames, Mr. Wells being a great believer in "iron furniture" on account of its strength and durability. The interesting feature about this work bench, however, is that it has no sliding drawers, but is provided with two cast iron semi-circular trays which are mounted on a stud at the center of the circle, and when the material contained in the trays is wanted, all that is required is to swing the tray out so that the contents are exposed. It is clear that in this way the whole contents of the tray will become visible when the tray is swung out completely, whereas in the case of a drawer, it is not usually possible to pull it out far enough to see the complete contents, particularly when heavy tools are stored away in it. Besides, the difficulty of trying to pull out a drawer containing heavy tools and making it slide freely is well known. In the engraving, Fig. 27, the upper tray is shown closed, while the lower one is shown swung out so that about three-quarters of the contents are exposed to view.

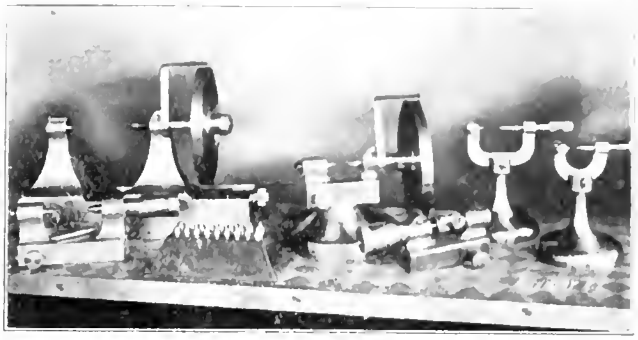

Fig. 25. A Set of Thread Micrometer Gages of the Wells Bros Co.'s Type, used in Inspecting Taps.

The equipment in the shop is highly specialized. In a general way one might say that there are very few standard machine tools, and there are few machines of modern make. This, however, in no way interferes with the efficiency of the shop, for it is plainly in evidence that a simple machine designed exclusively for performing one specific operation is a far better investment, and far more efficient for the work it is intended to do in specialized manufacture, than would be one of the modern universal machines which in many respects are largely tool-room machines. It is Mr. Wells' opinion that in most classes of manufacture the highest efficiency can be reached by simple improvements of the ordinary design of machine tools rather than by departing too far from the old line of tools and trying to introduce new features which

Fig. 26. A "Street" in the Stock-room where the Finished Work is Stored.

are seldom or never required in ordinary manufacture. There are many machines in the shop which were built twenty or more years ago which are still in use and which perform the work they are used upon fully as efficiently as would a standard modern machine tool, but it is understood that these conditions are true only in cases where the manufacture is highly specialized as in the case of making taps and dies.

Being a one-story shop and provided with skylights, it is exceptionally well lighted, a feature which is also evidenced by the appearance of the half-tones, the photographs for which were taken on a very dark and foggy day with no direct sunlight whatever.

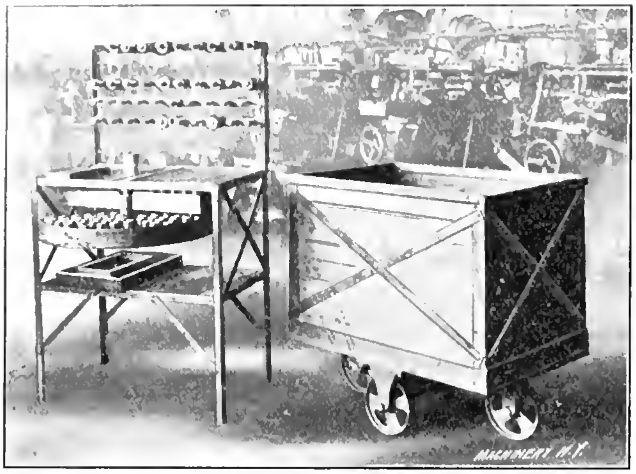

Fig. 27. A Work Bench with Handy "Drawers" and a Storage Truck used Extensively in the Shops.

After having noted the methods at present employed in the making of taps in a highly specialized tap manufacturing plant, it may be interesting to refer to the methods which Mr. Wells and his brother first employed when they started in making taps thirty-three years ago. Special machinery, and even the now common types of standard machines, were then not as common as now, and when manufacturing on a small scale in particular, some methods which to-day would be considered rather crude, were employed. Mr. Wells tells of how they used to cut off the tap blanks in the blacksmith shop from the rough stock, one man wielding the sledge while another held the cold chisel. The threading was all done in ordinary lathes with chasers, Mr. Wells being the first man who employed chasers for thread cutting at the Wiley & Russel Co.'s Works in Greenfield in 1874. The fluting at that time was done in a small milling machine where one tap was fluted at a time, one man being required for each machine to feed the table by hand. At first the tempering of the taps was done in an oil stove. Little by little, as the shop grew, these methods were superseded by more efficient ones, until at the present time the manufacture is placed on the efficient basis outlined by the present description of the plant and the methods.

HOW TO GET A JOB.

A. P. PRESS.

Well, the hard times have come and gone again and the boys are out hunting for jobs. Now, there is a lot of difference between getting a job and holding it. Some fellows are natural job-getters, and others are job-keepers; and when the job-keeper really loses his job, he is "up against it for fair." I have done lots of job hunting, and I have had the jobs hunting for me; and there is a big difference between the two kinds of sport.

In most of the big factories, nowadays, the hiring and sacking is done by a hiring clerk, who doesn't know a tool-maker from a power-press hand. When the foreman of a department wants half a dozen men he orders them the same as he would the same number of files from the stock-room, and after he gets them he sorts them out, keeps what he wants, and lets the rest go. Now, this is all very well for the shop, but it's kind of hard on the fellow who is doing the hunting. And so a few words to him may help him bag his game:

First, be sure what you can do and do *well*. Go after a job in that line, and if it is not there, take the next place. If a man comes to me and tells me he knows how to break stone, and that he can break them quickly, then I have some encouragement to try him, for the man that can do one thing well can learn to do another well, provided it is in his capacity to do it at all. Don't tell me that you can do anything, for of all answers to an inquiry as to what a man can do, that's the most discouraging; in fact, it isn't any use to talk with the applicant further.

Second, don't run in a hard-luck story about your wife and seven small children, because if the boss is "onto his job" it won't help your case a mite; he isn't running a free soup house but he is trying to "deliver the goods" and not have the freight charges too high. If you are hard up, he may give you a dollar, but he won't give you a job.

When you want a job just ask the boss flat if he wants a good vise hand, or whatever your "best hold" is; tell him what pay you want, and that you will go in and work and work quickly, and if you are not worth the price to just drop you and there will be no hard feelings. If he has a job to give you can get it.

Third, if you are an old fellow and wear glasses, put them on before you go in; then you won't feel "streaked" when you get on the job and have to wear them. I well remember the last job that I went for; I heard the boss coming up the corridor and I put them on in a hurry. He came in, talked a minute and said he was looking for a man with plenty of experience and asked if I would go on as foreman. Well, I guessed I would, and I did and made good.

Now, a word about cheek—not gall—just cheek. The boss saw a new man sweeping up the shop, so he said: "When did you come in?" "Yesterday, sor." "Who hired you?" "The man over there, sor," said the sweeper, pointing to the other sweeper down at the end of the room. "Well, how's this, Tom?" said the "super," calling up the old hand. "Well, sor, had more work than I could do, and so I put him on." "Well, I'll be d—," said the super, but he went into the office and had a good laugh over it and ended by putting him on the books.

Lately, the graft mania that we have had for the last few years has had its effect in some of the shops, and there has been a lot of what I would call "foreman grafting" done—mostly in the big shops. The foreman will charge a man, say, $5 for his job, and then collect it on the installment plan. There is one thing worse than to give a man a dollar for a job, and that is to take it, for the moment that you do that you put yourself in the other man's power. The case to which I refer came up lately; the man paid his $5, came in and worked a few days, and then, not liking it, went to the office and stated the case and wanted to know whether, if he got through, he could get his $5 back again. There was "something doing" right away.

* * *

According to the *Brass World*, the best spring metals (alloys) are those which do not contain zinc. When zinc is present crystallization is more apt to occur.

JIGS AND FIXTURES—11.

EXAMPLES OF BORING JIGS.

EINAR MORIN *

In the January issue of MACHINERY the fundamental principles of boring jigs were outlined. In the present installment a number of applications of these principles to boring jigs that have been designed for shop use will be shown.

In Fig. 126 are shown two views of a small jig supported directly on the work to be bored. This jig is used for boring out a cross-slide carriage, and is located on the work by the dove-tail slide and held in place by the two set-screws *A*. The two bushings *B* are driven into the solid part of the jig and the two corresponding bushings *C* are placed in the loose leaf *D* which is removed when the jig is placed in position on, or removed from, the work. The two set-screws *A* do not bear directly on the side of the carriage but are provided with brass or steel shoes as shown in Fig. 130, where *E* is the shoe. The leaf *D* cannot be attached permanently to the jig and simply swung out of the way when the jig is located on the work, because it could not be swung in place after the jig is applied on account of the small clearance in the cross-slide carriage. The leaf is therefore made loose, which is an objectionable feature, but lugs have been carried up on the casting on both sides of the leaf as shown, to give good support; these lugs are carefully finished to fit the leaf, and the latter is located and held in place by ground plugs.

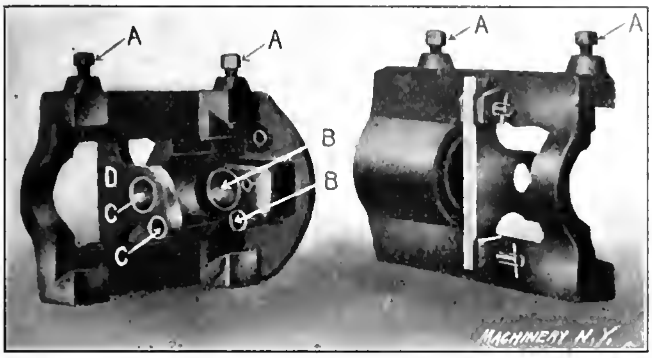

Fig. 126. Example of Small Boring Jig, with Removable Leaf for Holding Guiding Bushings.

In Fig. 127 is shown a boring jig which receives the work *A* between two uprights. The work in this case is the tail-stock of a lathe where two holes *B* and *C* are to be bored out. The bottom surface of the tail-stock is finished before boring, and is located on the finished bottom of the jig by means of a key and keyway. The keyway is cut in the jig and is a little wider than the key in the work, and the set-screws *D* bring the key against one side of the keyway, that side being in accurate relation to the hole *B* to be bored in the tail-stock. Longitudinally the work is located by a stop pin, against which it is brought up by a set-screw from the opposite side. The tail-stock is held to the jig by bolts *E* exactly as it is held on the lathe bed.

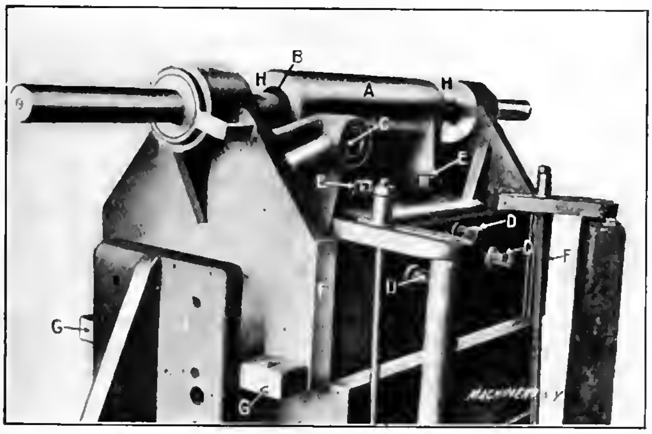

Fig. 127. Common Type of Medium Size Boring Jig.

The placing of the set-screws *D* at different heights is one of the features of the jig; this makes it possible for the jig to take tail-stocks of various heights for different sizes of lathes, raising blocks being used for the smaller sizes. The raising blocks are located exactly as the tail-stock itself, so that the work placed on them will come in the same relative position to the uprights of the jig whether the work rests directly on the jig bottom or on the raising pieces. The two finished strips *F* are provided for facilitating the making of the jig, and the lugs *G* for the clamping down of the jig to the boring machine. The jig, however, can also be clamped to the boring machine table as shown in the illustration. At *H* is a liberal clearance between the work and the jig, allowing ample room for insertion of facing cutters, reamers, and boring tools. Ribs are provided for strengthening the jig, as shown.

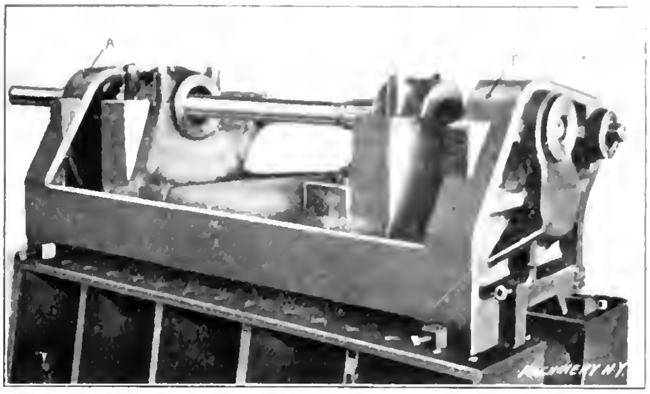

Fig. 128. Large Size Boring Jig made from a Solid Casting

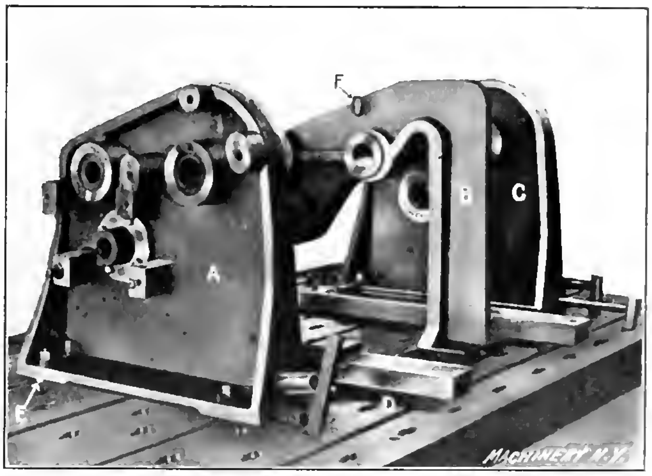

Fig. 129. Boring Jig consisting of Base-plate and Separate Removable Upright carrying the Guide Bushings.

The half-tone Fig. 128 shows a large size boring jig made from a solid casting. In this case the work to be bored out is the head of a lathe. It is located and clamped to the jig in a similar way as that mentioned for the tail-stock; clamping it to the jig in the same way that it is fastened to the lathe bed insures that the effects of possible spring will be less noticeable. Opinions differ as to whether it is good practice to make up a jig of the size shown in one piece, the distance between the standards *A* and *B* being from four to five feet, or whether it would be better to make loose members located on a base-plate as shown in Fig. 129. The writer advocates the making of one piece jigs of as large sizes as possible because, with loose members as shown in Fig. 129, there is no assurance that the standards are located correctly in relation to each other or to the work to be bored, and it involves more or less work to get the jig in order. The jig

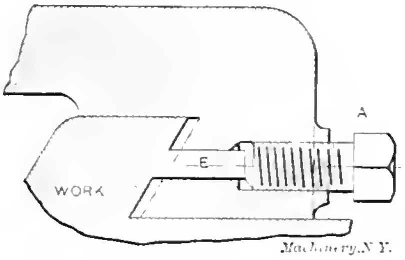

Fig. 130. Means for Holding Work against Locating Side of Dove-tail Slide of Boring Jig in Fig. 126.

---

* Address: Borlänge, Sweden.

in Fig. 128 does not need to be as heavy as would be inferred from the illustration, because a large portion of the bottom can be cored out.

The boring jig illustrated in Fig. 129 consists of four parts; the upright members A, B, and C, and the base-plate D, which may be used for all jigs of similar construction. This type of boring jig is used only for very large work. In the case illustrated, large lathe heads are to be bored. The work is located on the base-plate between the two members A and C. The member B is only used when the distance between A and C is very long, so that an auxiliary support for the boring bar is required, or when some obstacle prevents the bar from passing through the work from one of the outside members to the other. As a rule these members are located on the base-plate by a tongue fitting into one of the slots as shown at E. The members are brought as close as possible to the work, sufficient space, of course, being permitted for the cutting tools to be inserted. The standards are cored out and ribbed and lugs provided so as to give the bearing bushings long and substantial support. Good results will be obtained with this type of jigs provided they are carefully set upon the base-plate. At F in the member B is shown a boss; this is provided with a tapped hole for a hook or eye-bolt for facilitating the moving of the jig member by an overhead crane. The other members have tapped holes on the top for the same purpose.

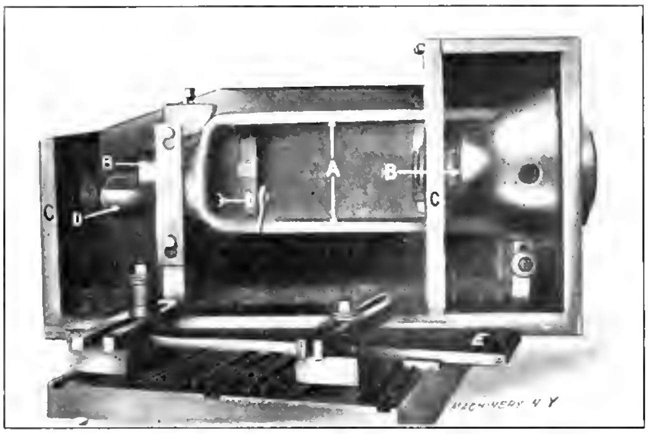

Fig. 131. Wedge-piece for aligning Work for Boring Holes with the Axes at an Angle.

The jigs in Figs. 126, 127, and 128 are ordinarily used on boring lathes, but the one shown in Fig. 129 may also be used in combination with a portable driving and feeding arrangement, one type of which is shown in Fig. 135. The lugs and finished bosses on the side of jig member A, which do not carry bushings, are used for connection to this drive and feed mechanism.

Fig. 133 shows a boring jig of the loose member type provided with motor drive for the boring bars. The members are mounted on the base A, located by the tongue B, and clamped down by T-bolts. The work C, a lathe head, is placed on the extension piece D. The boring bar is driven from the motor by means of a worm and worm-wheel, the bar being [illegible] is shown in Fig. 135. In this engraving, A represents the work, B and C the jig members, D the motor which is connected to the pulley E, which, in turn, through a worm-shaft F and the worm-wheel W, drives the boring bar G; this latter is keyed to, but at the same time is a sliding fit in, the worm-wheel. The bar is fed forward by the feed-screw H which passes through the stationary nut J fastened to the base-plate. The motion of the screw is actuated from the bar itself through a train of gears. The gear K is keyed to the screw and driven by the gear L which is mounted on the same stud as the star-wheel M which is turned by the pin N attached to the connecting head O; this latter rotates with the boring bar, but the screw H is a free-running fit in O, and simply has a thrust washer at its end to take the feed thrust. More or less feed can be arranged for by using more than one pin in the connecting head. The pin or pins can be pulled back when the feed is not required. The gears and star-wheel are mounted in the bracket P which follows the bar and which is prevented from turning by the rod R fastened to the bracket. The bar can be pushed back by using a wrench or crank at the end of the feed screw.

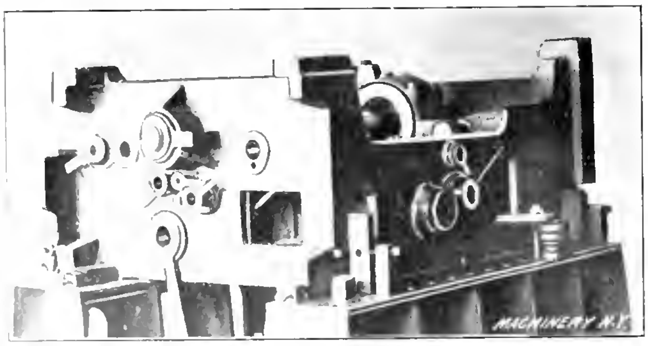

Fig. 132. Combined Drilling and Boring Jig used with a Horizontal Drilling and Boring Machine.

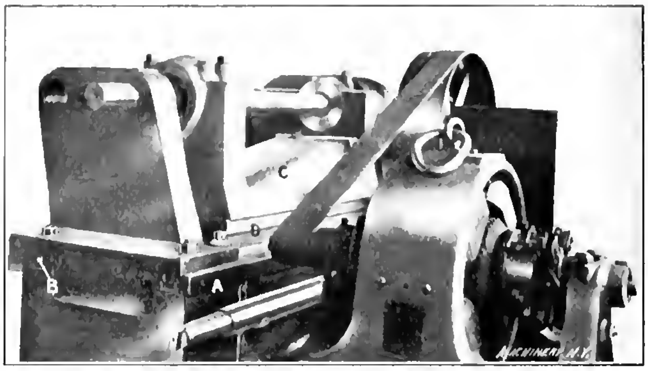

Fig. 133. Boring Jig with Portable Motor-driven Drive

The feed arrangement shown, has proved very serviceable and reliable. A separate and portable drive, of the type indicated, is quite necessary for large boring jigs as there are few machines large enough in the ordinary shop to handle such heavy work.

In Fig. 131 is shown a boring jig for boring out the top frame A of radial drills. The design of the jig is simple but effective; the hole B is parallel with the finished side C of the jig and is bored out after the jig has been brought up square against a parallel and strapped to the machine table. The hole D is bored at an angle with the hole B, and the setting of the jig for the boring out of this hole is facilitated by providing a wedge-shaped piece E of such an angle that the jig will be set in the proper position when moved up against the wedge. If universal joints are used for connecting the boring bar with the driving spindle, the setting of the work at an angle could be omitted, although it is preferable even when using universal joints to have the boring bars as nearly as possible in line with the spindle. This eliminates a great deal of the eccentric stress, especially when taking a heavy cut with coarse feed.

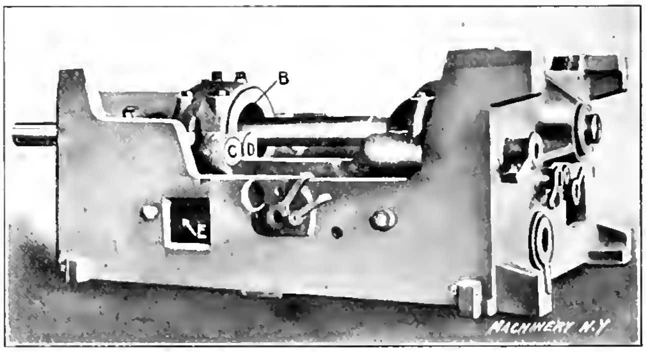

Fig. 134. Another View of the Jig in Fig. 132. Note that Holes are drilled or bored from All Sides.

Boring operations are sometimes carried out using parts of the machine itself as guiding means for the boring bars, and in some instances it is very essential that boring operations be performed in this way in order to obtain perfect alignment. In Fig. 136 is shown a line engraving of a machine bed with the head-stock solid with the bed. In the top view is shown a method for boring out a hole at B by the use of two jigs C and D which are located on the V's of the machine and held down by hook bolts. If the hole B only passes

through the part *E* of the head this would be the preferable way of boring it. In some instances, however, the hole *B* may be required to be in alignment with the holes in a carriage or in a bracket as at *F* and *G*. These holes, of course, can then be used to great advantage as guiding means. Should the holes be too large to fit the boring bar, cast iron bushings can be made to fit the holes and the bar. In the elevation and end view of Fig. 136 is shown how a cross-slide carriage and apron *I*, which has a hole *J* in line with the holes in bearings *K*, *L*, and *M*, and travels between *K* and *L*, can be bored out by using the brackets *K*, *L*, and *M* to guide the boring bar. By keying the traveling part *I* close to the bracket during the boring operation, as illustrated, accurate results will be obtained. It is evident that two of the bearings could be bored out by using the finished bearing and the traveling part *I* as guiding means. Arrangements of this kind usually save expensive tools, and often give better results.

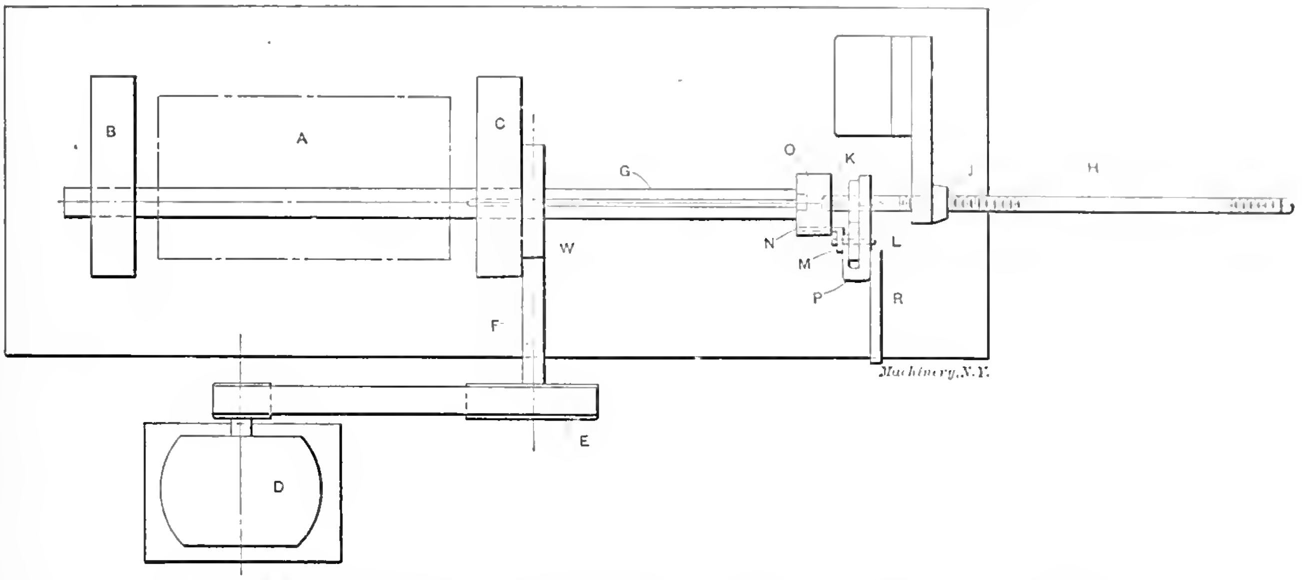

Fig. 135. Diagrammatical Outline of Arrangement of the Drive and Feed of the Boring-bar of Jig in Fig 133.

Combination Drill and Boring Jig.

Jigs for performing both drilling and boring operations are frequently used to great advantage. In designing such jigs, however, judgment must be displayed not to arrange for combination jigs when the operations can be more easily performed in two separate jigs. Sometimes it is advisable to have a jig for the boring alone, and then to use the bored holes for locating the work in a separate drill jig. In other cases it may be better to do the drilling first and locate the work for the boring operations from the drilled holes. The designer should decide which method would be preferable, considering, in the first place, the factors of the time required and the accuracy of the work. To give any definite rules for this work is not possible, but it may be said that combination jigs should be used only when the drilled and bored holes are somewhat near the same diameters. When the holes are of widely different diameters two jigs are preferable. If a few screw-holes of small diameter for holding a collar or bracket, for instance, located around a large bored hole, were to be drilled with the same jig used for the large hole, the jig when used on a small drill press would be entirely too heavy to manipulate. It is likely that in such a case a small separate drill jig could be attached directly to the work. In other cases, however, it will prove a distinct saving to combine the boring and drilling jig in one.

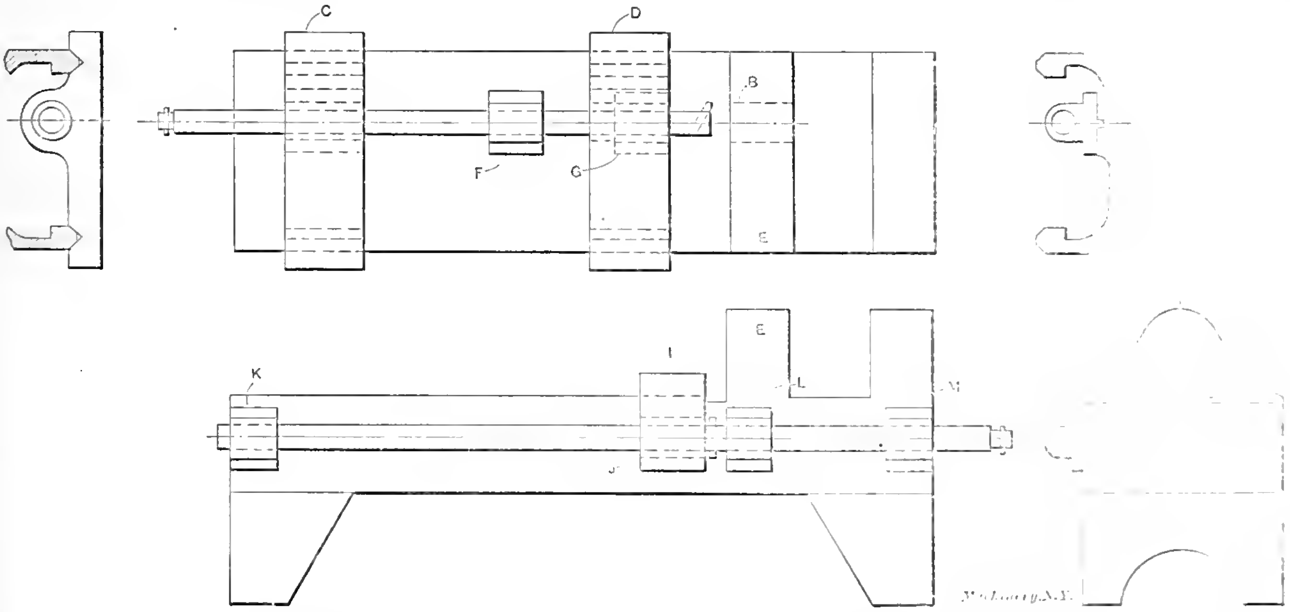

Fig. 136. Examples of Boring where Parts of the Machine being built are used as Guiding Means.

In Figs. 132 and 134 is shown a combination drill and boring jig of large size. The work *A* in Fig. 134 is a head-stock for a lathe with a number of holes to be drilled. The large holes *B* at both ends of the head-stock are cored as usual, and allow the boring bar to enter for taking the roughing cut. The holes at *C* and *D* are opened up by drills previous to the boring operation. As there is considerable distance between the end of the head-stock and the uprights of the jig, long bushings are used to give the drill a good bearing close to the work. The small holes which are drilled and reamed are shown in Fig. 132. Both the drilling and boring operations may be performed on a horizontal boring and drilling machine. As the horizontal drilling and boring machines usually have adjustments in all directions, the only moving of the jig necessary is to turn it around for drilling the holes on the opposite sides.

SHOP PHOTOGRAPHY.[*]

H. P. FAIRFIELD[†]

I have read with much interest the article by H. C. Estep on "Shop Photography," which was published in the December issue of MACHINERY. He speaks of his experience with films and makes a statement about glass plates and halation which has not been borne out in my case or in any case of which I know. Negatives entirely free from halation are as easily and truly made upon glass plates as upon films. The only condition necessary is to give the proper exposure. If this is done, a perfect negative results which is free from deep shadows, halations or false high lights on any good make of glass plates or films. Proper exposure must, as in any case, be reinforced by exact and scientific development, and this can be obtained by using the tanks and developer powders sold by the Eastman Co. Mr. Estep's article conveys the idea that the so-called films are peculiarly free from halation troubles. My point is that there are no differences in this respect, whether using glass plates or films, and that when given the right amount of exposure and scientific development, either will give a perfect negative free from halation under the most adverse conditions. While the proper amount of exposure given a plate is not the whole of photography, by any means, it is a considerable factor in any case and perhaps the hardest single item to correctly gage. Mr. Estep's method of teaching exposure by obtaining a "standard" is along the lines of the best practice.

As to what causes halation, I do not know, but I have figured it out that its *effect* is made *visible* on the negative by over-development when trying to bring out detail in the shadows, as the darker parts of the picture are termed. Take, as an example, an interior with windows on one or even two sides, of which it is desired that a view be taken looking directly at these, as shown in Fig. 1. The camera is thus facing the source from which all the illumination is coming and all objects in front of the camera have their deepest shadows facing the lens. The operator is naturally misled by the glare from the windows in his eyes, and forgets that the shadow sides of the objects (machines for example) are reflecting into his eyes, or the lens, very little light indeed. Under this influence he invariably misjudges the time of exposure, undertiming the plate or film and really obtaining no image of the shadow areas on the sensitive plate. When the plate or film is placed in a normal developing solution, the windows and adjacent areas being strongly lighted, develop, as it is termed, in their proper time, while the darker or shadow areas have not reflected sufficient light to affect the sensitive plate or film, enough to register a distinct image in the time it takes to develop the strongly lighted areas. Usually, in such cases as this, the operator prolongs development with the hope that he can get something to show where, practically speaking, the light has made no impression upon the plate. Pushing development in this manner builds up or thickens the strongly lighted areas on the negative, and, in the case of windows and adjacent strongly lighted areas, obliterates practically all the detail. If the operator can be made to believe, at the beginning, that such a plate is hopeless, and if he will discard it and obtain one with a correct exposure, much will be gained. Dr. John Nicol, who for years has been editor-in-chief of the *American Amateur Photographer*, has repeated a thousand times in that publication this motto: "Expose for the shadows—the high lights will take care of themselves." The sensitized coating of the negative, upon which the light impresses the image, is alike in like grades for either plates or films. The usual supports for the coating are glass plates in one case and a flexible support of celluloid or paper in the other, the coating remaining the same, and exposure being the same whichever is used.

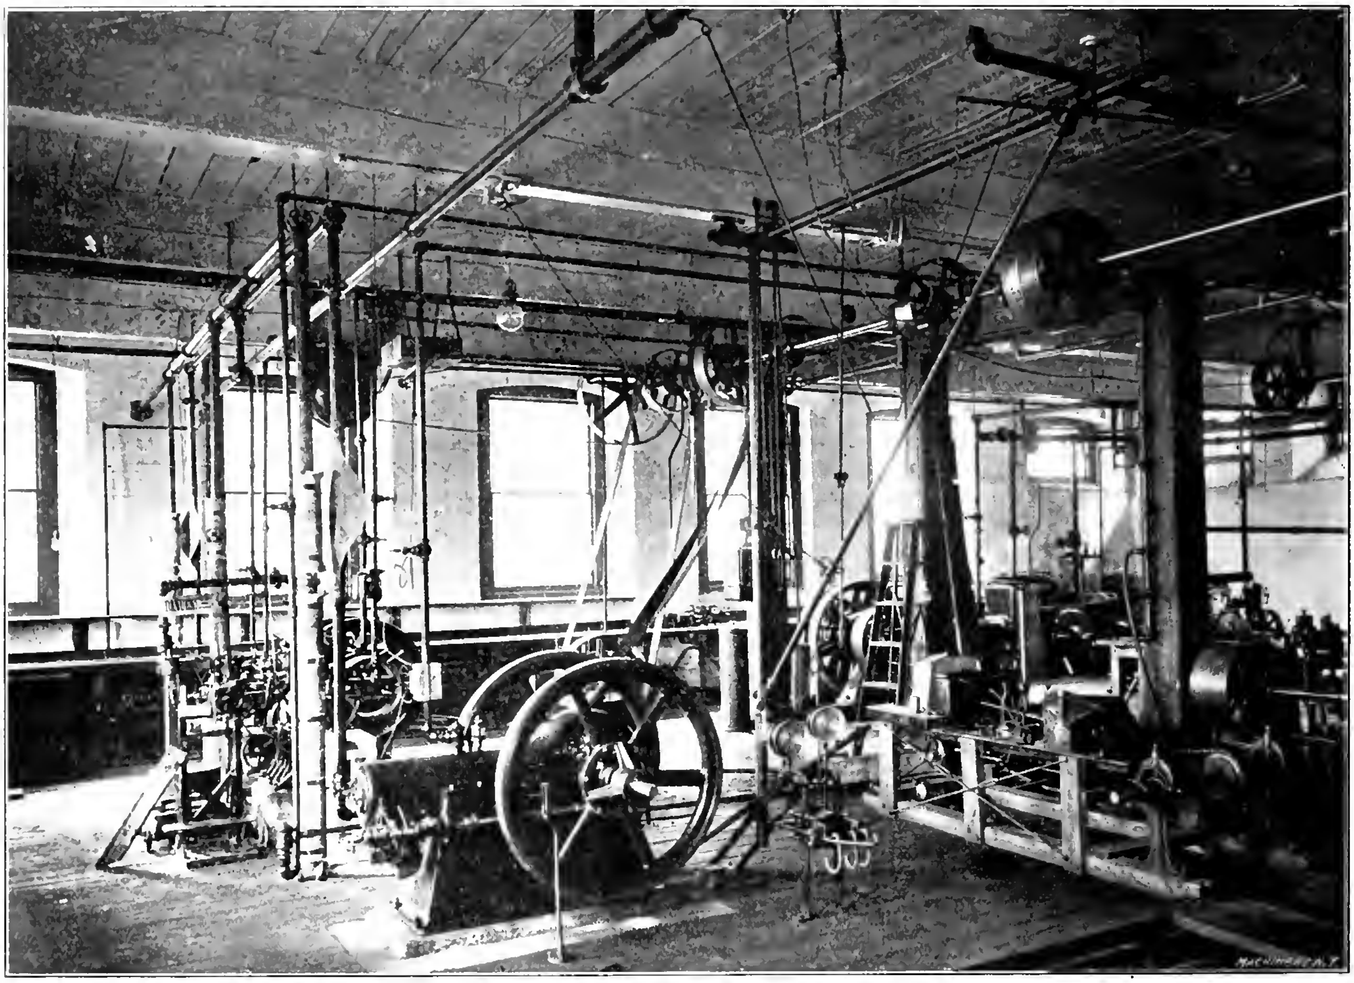

Fig. 1. Type of Interior which is often Under-exposed, the Exposure being made for the High Lights instead of the Shadows.

A word as to what I mean by scientific development. Several firms, notably the Eastman Co., have carried on elaborate experiments to learn all that could be learned regard-

---

[*] For additional information on this subject, see the following articles previously published in MACHINERY: Industrial Photography, [illegible], 1909; Shop Photography, December, 1908; Correcting Perspective in Photography, February, 1908, and other articles there [illegible].

[†] [illegible] Worcester Polytechnic Institute, Worcester, Mass.

ing the action of developers and the correct timing of development. This has been done under the direction of expert chemists and manipulators, and when under such conditions results are published, they can be taken as reliable. The tank method of development can be performed in an ordinary tray, but is more neatly and pleasantly done in one of the modern plate or film tanks. The principle is this: Given a developer of a certain strength, its action on the plate should be limited to a definite interval of time. Action continued beyond this stated time not only does not result in any increase of detail, but actually thickens, halates and fogs the results thus far obtained. Experiments scientifically carried out have determined what this time should be for various developers when in solution as directed. Given such a known developer, some suitable sort of a tank to hold the plates and solution, means for measuring time, a thermometer for indicating temperatures, and all there is in the negative must be obtained. An accurately and properly timed exposure, a developing solution of known strength, at a correct degree of temperature allowed to act upon the negative a scientifically determined period of time is "It." In Fig. 2 is shown a half-tone reproduction of a print taken from a 5x7 negative made during a bright sunshiny day on a standard glass plate of the ordinary sort, unbacked or doctored in any manner. The plate was developed in the Eastman plate tank. The windows shown are of Southern exposure and were left exactly as shown in the picture.

Fig. 2. Negative made on a Standard Glass Plate during a Bright Sunny Day. Note Absence of Halation.

Fig. 3. Another Splendid Interior in which Every Detail is brought out without Halation around the Windows.

To anyone taking up the work, I would say that the best apparatus, materials and supplies are none too good; therefore get the best that can be afforded. This is especially true in lenses. No one using a modern Goerz or Zeiss anastigmat will ever use any other if he has the price. An anastigmat lens has nothing to do directly with halation, but is recommended as essential to the best technical work as its corrections are more perfect than the so-termed rectilinear lens. Indirectly, as such a lens can be used at a larger aperture than the cheaper lens, its use often results in a better timed negative and therefore greater freedom from "soot and whitewash." While it is a pleasure to use almost any camera outfit, the best is none too good if serious work is contemplated.

While I wish to make the point that there is no halation necessary if exposure and development are properly timed, it is seldom that the operator's judgment tells him just what is best in the exposure. For this reason, it is always wise to avoid conditions which are likely to give adverse results.

* * *

"DON'TS" FOR THE BLACKSMITH.

GEORGE T COLES *

Don't be afraid to strike the iron while it's hot.

Don't take two heats to do what you ought to do in one.

Don't hang hot tongs in the tong-rack.

Don't use a hot chisel to cut cold stock.

Don't use a cold chisel as a hammer—it may fly off the handle and hurt somebody.

Don't abuse your helper—it isn't his fault all the time.

Don't forget to make your bolt-heads standard size.

Don't use your hand hammer for a bob punch—it's dangerous.

Don't borrow your neighbor's tools—make your own.

Don't alter your tongs for every job; make new ones—it pays.

Don't forget to fix your tongs when you break them.

Don't forget to use the square—your eye won't do.

Don't watch the other fellow's fire—attend to your own.

Don't watch the "boss"—watch your fire.

Don't forget to see that your tools fit your anvil—it saves time.

Don't work with hot tongs; cool them off—you'll be surprised at the results.

Don't forget that a little salt in your fire helps things wonderfully, sometimes.

Don't forget to anneal your flatters and fullers once in a while—it's time well spent.

Don't use a high carbon steel for your tools; a cheap grade is better and lasts longer.

Don't forget to take your time hardening a die—it pays.

Don't get the corners of the die hotter than the body—if you do they may come off.

Don't hammer cold steel—it's hard work, and besides, it's bad for the steel.

Don't have any "cold sets" in your forgings—cut them out before they do harm.

Don't abuse the dies of the steam hammer—your work will look bad.

Don't roll your work at the steam hammer—'twill make it hollow.

Don't be reckless around the steam hammer—it's dangerous.

Don't forget that the scale around the steam hammer is the best flux for welding.

Don't use your flatter or fuller at the steam hammer—it's dangerous.

Don't scrap the short ends—they come handy sometimes.

Don't forget to take the frost out of the steam hammer the first thing in the morning.

Don't forget to give her (the steam hammer) steam slowly first thing in the morning.

Don't forget to let her (steam hammer) run open for a few minutes first thing in the morning.

Don't forget to use a little graphite and cylinder oil on the guides—it make the hammer run easier.

Don't forget to oil up the hammer once in a while, and remember that an automatic oiler is best.

Don't forget that a steam trap is the latest attachment to a steam hammer.

Don't nick and break good carbon steel when making tools—it injures the steel.

Don't melt lead or babbitt in your fire if you expect to do any welding—it will cause trouble.

Don't forget when forging to allow 10 per cent for waste.

Don't criticise the other fellow's work—do your own quickly and well.

MACHINERY
DESIGN CONSTRUCTION—OPERATION.
PUBLISHED MONTHLY BY
THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

FEBRUARY, 1909.

PAID CIRCULATION FOR JANUARY, 1909, 21,865 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE EXPERIENCE OF PURCHASING AGENTS.

The recent experience of a foundry company in marketing a specialty is an example of present-day problems in distribution, and as the facts involved throw some light on the results produced by removing the purchasing department of an industrial undertaking too far from the influence of the mechanical department, it may be worth while placing on record. The foundry firm in question is making a special casting used on railway cars, which is made in such a manner that a great deal of the work in fitting is saved when the part is applied to the car. In obtaining orders for these castings, it has been found that it is very easy to introduce them with small companies where the master mechanic directs the purchase of materials; but when it comes to the large companies which have special purchasing agents, who as a rule are unfamiliar with mechanical requirements, it has been found difficult to introduce this product of the company. The casting spoken of is of a very special type, is cast in a somewhat different manner from ordinary castings, and must therefore necessarily be more expensive, pound for pound, than are regular castings. The purchasing agent who lacks mechanical experience, however, measures the value of castings simply by the weight, and expects to pay so much per pound for castings, irrespective of the manner in which they are produced and the purpose for which they are intended. The mechanical man, on the other hand, especially if he be in charge, and responsible for the economical results obtained, would immediately realize, in a case such as here referred to, that the casting, as made, possessed a distinctive value because of saving a considerable amount of labor expense and trouble in fitting to the car in the shop.

This example illustrates one of the defects in the organization of large industrial concerns where the influence of mechanically trained men is not directly felt in the business office, and where the management, therefore, is entirely in the hands of men whose whole training has been confined to office work and to whom mechanical features have not the same significance as to men who have been trained in the productive departments. At the present time, undoubtedly, this defect of administration is growing, due to the formation of large corporations which replace the smaller individual concerns. In the former, the man of business training, as a rule, entirely overshadows the mechanic, and this is by no means always to the best interest of the firm. Many thousands of dollars are lost yearly by large industrial concerns on account of the lack of appreciation of mechanical requirements in the purchasing department.

* * *

HABITS OF WORK.

Several years ago the writer visited a well-known engineering school, and naturally included the machine shop or "mechanical laboratory," in which the students were instructed in the elements of machine construction and operation. The class at work at the time was building a universal grinding machine from castings furnished by the manufacturer. Among the parts being machined was the platen, which was being planed by one of the "boys." He was "nursing" the job by taking an insignificant cut with an almost microscopic feed. At the rate the planing was proceeding, half a dozen cuts would have been required to finish the surface, and the time of each cut would have been about three times the normal.

In response to a comment that the cut and the feed were rather below the average machine shop practice, the guide volunteered the information that the boy was employing this expedient to keep the machine going until the instructor could reach him, without endangering the job. It was apparently the common practice to proceed in this leisurely manner in order to avoid mistakes. The instructor thus could keep in close touch with the state of each boy's job, and nothing was likely to go far astray between his visits. The plan, of course, was commendable from one point of view: that is, avoiding mistakes and spoiling work, but it was a very serious defect, as any practical mechanic will immediately concede. While the boys received practical instruction in the manipulation of machine tools and production of finished machine parts, they did not acquire another kind of instruction in a matter equally as important, and that is, speed of performance.

A graduate from this or any other engineering school conducted in a similar way, would find in going into a manufacturing plant that he was in a strange world. The changed conditions would virtually make him a stranger to the work with which he should be quite familiar. He would be unable to do commercial work satisfactorily until he had acquired considerable experience, and would be incompetent to direct the work, even as a sub-foreman, simply because he has no conception of commercial speeds.

A more serious fault of such methods of instruction is that the learner cannot do his work as well as though it were done at his best speed. This may seem strange to those who have not given the matter thought, but it is a fact confirmed by numerous observations that the best work is that done rapidly and with care. In mass production it is much easier to make 99 out of 100 parts meet all the requirements of a rigid inspection system than if each part were made slowly and individually. In passing, it may be remarked that mass production is one part of the secret of the extraordinary accuracy of the Swedish gages that have excited the wonder and admiration of the whole mechanical world.

The value of habits of industry acquired under the system of training that teaches quickness and dexterity as well as skill, is admirably treated by Mr. Gantt in his paper "Training Workmen," read before the December meeting of the American Society of Mechanical Engineers. "Habits of work are comparable with habits of thought in engineering," and inferentially an engineer's training should include the right habits of work as well as the right habits of thought if he is to direct industrial operations.

* * *

From observations of manufacturing cost in many machine shops, Mr. James Hartness, president of the Jones & Lamson Machine Co., Springfield, Vermont, has concluded that for the purpose of estimate, it may be taken that one-third the cost is labor, one-third material, and one-third shop burden. Lathe work is usually one-half the machining or one-sixth the total cost of production.

MACHINE TOOLS AND THE TARIFF.

The advanced development of the machine tool industry in this country, and the use of ingenious cost-saving appliances as well as the greater skill and productiveness of American workmen, have enabled our manufacturers of certain kinds of tools, which are turned out in large lots, to so reduce costs that they have been able to market a considerable portion of their product abroad in competition with foreign machines, which until recently have been produced in small lots only. This class of American manufactures would be the least affected by a moderate reduction in our tariff; but very heavy tools which are made largely of cast iron, many of them special tools, need more protection. There are many cheap and cumbersome machines made by English, German and other European manufacturers, which could hardly be sold in this country at any price; but, on the other hand, most of our best tools are now accurately copied by foreign makers; and, unless our manufacturers were protected, could be sold in this country at prices which would completely demoralize the American machine tool industry. Progressive foreign manufacturers recognize the superiority of American methods and are rapidly adopting them; and all they really need to compete on even terms with our own manufacturers, anywhere, is a larger market, which means larger production.

For fifteen or twenty years American machine tools have been sold all over Europe in competition with foreign makes, at virtually the same prices as in this country; and our export trade increased rapidly up to 1907. During that year, although we had then begun to feel the effects of foreign imitations, most of our leading machine tool builders were from six months to a year behind in their deliveries. The development of our machine tool industry has never been so great as during the period above referred to, and within that time the number of manufacturers and the output increased three or four fold. The steady and rapid development of this industry naturally resulted in stronger competition among our manufacturers, and in remarkable development in the capacity of our machine tools. No sooner did one manufacturer place an improved machine on the market, than his competitor set to work to better it; and often produced one at the same price which would turn out more work at less cost. The automatic screw machine is a type of labor-saving tool of distinctly American origin. One of these machines easily turns out from five to twenty times the product of an ordinary engine lathe, at a cost for direct labor attendance, in some cases, of less than one-tenth that of the latter. Many other machines of the screw-machine type have been perfected, which have completely revolutionized the manufacture of small parts, effecting savings fully as great. Almost without exception these machines are being copied by European makers, who, of course, are under no expense for originating, developing and perfecting them, yet under a lower duty they could and would undersell the originators in this market, on account of the difference in the cost of labor. How great this difference is is shown by the following tables:

Foreign.	Machinists.	Tool-makers.	Handy-men.
Italy	8 to 12	12 to 16	9 to 10
Switzerland	15	20	10 to 12
Germany—			
Munich	13	17	10
Saxony and the Rhine Valley.	15	20	11 to 12
Berlin	14.5 to 17	19 to 22	11 to 13
Magdeburg	14.5	19	8.5 to 10
Great Britain	15.5	20	9
France	Machine tool industry still in its infancy.		
United States.			
New York City	33	39 to 44	16 to 28
Philadelphia, Pa.	31 to 37	32	16
Providence, R. I.*	26	28 to 35	18 to 25
Hartford, Conn.	32	37	20
Cleveland, O.	25 to 30	30 to 35	18 to 25
Cincinnati, O.	27	32	20 to 30
Milwaukee, Wis.	25 to 40	30 to 40	17½ to 25

* On piecework these rates may be increased 30 to 40 per cent.

The United States will always be the greatest market for our machine tools, and while the cultivation of foreign trade should continue to be of prime importance, in considering the tariff on such products we must be careful not to sacrifice the kernel for what might prove to be the husk.

MACHINERY'S EDUCATIONAL WORK.

The editorial policy of a journal like Machinery takes cognizance of the several important functions the publication performs in its relations to a multitude of readers, among whom there is a wide disparity in age, experience and ability. Machinery is a trade journal, publishing the general news of the trade it represents, which is one function. It is a technical journal, presenting the technical news of the trade, which is another. It is a forum for the discussion of questions of importance to the trade, technical and commercial. It is also a journal of education for students of machine design and shop practice, and we state without hesitation that this function is the most important of all, and is the one which chiefly characterizes and distinguishes Machinery.

The school of engineering likely to graduate men best equipped for the practice of engineering is the one which, in teaching fundamental principles, does not fail to train its students in the ability to detect these amidst unfamiliar details and in novel and unforeseen circumstances. When a man can do this, and can apply the fundamental principles of his vocation to creative work, he is trained. This is what technical schools are for, and this is the ultimate distinction between the trained and untrained man. One gropes for his principles, finally reaching them through costly experiment; the other goes straight to the heart of the matter, sees the principle and applies it.

In this sense Machinery is essentially a school of engineering. Every accurate and adequate account of a piece of mechanical work done in field and shop and drafting-room, is a lesson in mechanical practice and an elucidation of the principles involved. All experience is educational, or would be, if properly classified and logically arranged. Machinery collects, as it were, the mechanical experience of the month, discards what is unimportant or merely incidental, condenses and classifies the remainder, and endeavors to so arrange and adapt the matter that it becomes logically and properly a permanent part of the body of approved mechanical knowledge. This important educational function of the technical journal is well recognized by educators, one of whom happily designated Machinery as "a progressive textbook for mechanics."

And in the sense that Machinery is a progressive textbook, there is a weight of responsibility to a great body of readers, including men at the very top of the engineering profession, who read to keep in touch with the latest developments, expecting to find them reliably chronicled here; and that much greater number of machinists and draftsmen who also wish to keep up to date, but to whom an account of the latest developments would, in many instances, be of little educational value unless presented in such a manner as to supply any deficiencies in technical education or practical experience. Take for example the series "Jigs and Fixtures" now appearing, in which the treatment of the subject is very characteristic of Machinery. These articles are published primarily to describe the general practice, which presents many interesting and valuable features. Yet the whole subject is reviewed, the principles formulated; and when completed the series will comprise a complete treatise on jig and fixture design brought up to date. The series of articles on shop construction, which began with September, is another good example of this educational work. The problem of shop construction is analyzed, the general rules and principles clearly stated, and then, specifically, the actual details of construction for a plant of a certain size, intended to produce at low cost.

The Shop Operation Sheets which teach shop practice and incidentally the principles, are examples of this practical educational method, further exemplified in the "jig" method of instruction used so successfully by Mr. Renshaw, the originator, in his school in Cincinnati. The "jig" idea fits in well with our educational system and has been adopted here to be developed and given wider usefulness in conjunction with the rest of our educational material and equipment which includes Machinery, the Reference Series, Data Sheets and Shop Operation Sheets.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

It is stated in the *Daily Consular Reports* that the centenary of the re-establishment of national independence in Holland will be celebrated by a world's fair to be held at The Hague in 1913. It is stated that the grounds for the exposition have already been secured and a guarantee fund provided.

An application of the Lumière process of color photography, which appears to be both interesting and valuable, is described in a recent issue of the *Revue de Métallurgie*, where a number of microphotographs made in color by this process, are reproduced. The structure of metals is much more strikingly represented than with the usual black and white prints.

It is stated in the *Horseless Age* that the following composition is used extensively for typewriter levers: copper 57 per cent, nickel 20 per cent, zinc 20 per cent, and aluminum 3 per cent. These parts, even when the nickel on the surface is worn off, never rust. The alloy is very hard, but may be bent to a considerable extent without breaking.

According to the *Railway and Engineering Review*, experiments have been undertaken for several years with concrete ties in Italy, and the Italian government has now ordered 300,000 of these ties, or enough to lay about 100 miles of track. The ties are reinforced with small round iron rods and weigh 286 pounds each, of which 28 pounds is metal. The cost of the ties is $1.20 each. The ties will have creosoted oak bearing blocks.

The forests of the United States, according to reports of the Forest Service, now cover approximately 550,000,000 acres, while the original forests covered at least 850,000,000 acres. The government owns about one-quarter of the total forest area, which contains one-fifth of all the timber now standing. Those timber lands which are owned privately are generally more valuable than those of the government, but are far less carefully managed.

The first commercial wireless telegraph station conducted by the British post-office in connection with the regular British telegraph service, was opened on December 11 at Bolt Head, South Devon, on a height 430 feet above sea level. The range of the station is 250 miles, and it can be used for communication with all ships at sea fitted with wireless apparatus, as well as with the channel islands, in the event of interruption of the communication by the regular cables.

A brown color can be produced on all kinds of metals by the following process, described in the *Brass World*. The work to be treated is first bronze plated by a regular bronze solution of copper and zinc. When a good deposit has been produced, the article is rinsed and immersed in a solution of 2 ounces of liver of sulphur to one gallon of water. This solution is used cold. When the desired color has been obtained, the work is again rinsed and then scratch brushed. In this manner the whole surface is shaded down to a brown color.

An interesting use of electric light has been made by the city authorities in Chicago. The street sweepers on the more important boulevards in the city found their work hampered and rendered dangerous at night by carriages and automobiles. In order to relieve the danger, each man is provided with an electric lamp attached to his helmet, and fed from a storage battery in the sweeper's pocket. The entire outfit weighs less than a pound and, according to the *Scientific American*, the lamp will burn ten hours without recharging the batteries.

For several months the United States wireless telegraph station at San Francisco has received calls supposed to have come from Japan, where one of the most powerful wireless telegraphic apparatus in the world is installed. The distance the messages have been transmitted is 4,700 miles. Although the operators at San Francisco have been unable to reply owing to the smaller size of their apparatus, it seems probable that it will be possible before long to establish direct communication across the Pacific Ocean. The instance referred to marks a record for the transmission of wireless messages.

The price of aluminum has fallen considerably during the past year and according to *Chemiker Zeitung*, the price in Germany during the latter part of the past year was only 150 Mark per 100 kilograms, which is at the rate of only 16 cents per pound. It is interesting to notice how the price of aluminum has declined since 1855. According to the source mentioned the price in 1855 was $106.00 per pound; in 1856, $32.00; in 1857, $10.60; in 1886, $7.10; in 1888, $5.00; in 1890, $1.52; in 1891, $0.83; in 1895, $0.32; in 1900, $0.22; in 1905-1906, $0.40; in 1907, $0.43; in 1908, $0.16.

We are accustomed to speaking of the workless as "the unemployed," but the *San Francisco Star* long ago brought into use a truer word—"disemployed." For the merely unemployed, we need have no especial sympathy if they are poor, nor any extraordinary respect if they are rich; for "unemployment" means no more than idleness. But "disemployment" connotes all the agony of the worker in a period of hard times, when he can find no work to do. And as this condition comes from social maladjustment, the resulting lack of employment is best expressed as *dis*employment. It is enforced unemployment.—*The Public.*

In a talk before the Sphinx Club, New York, November 10, Dr. Harvey Wiley, Chief of the Chemical Bureau, Department of Agriculture, made a statement in regard to trade-marks that is worth the attention of all manufacturers using trade-marks. The Court of Appeals, District of Columbia, has handed down a decision in regard to trade-marks and advertising that will tend to check misrepresentation. The court will not protect any trade-mark about which false statements are made in advertising. If a manufacturer labels his goods properly and advertises them falsely, then by the decision of the court, he is not protected in his trade-mark rights.

Bare aluminum wire may safely be used in coils without any insulation except between successive layers, owing to the existence of a film of oxide on the surface of the aluminum. The film in its natural state, says the *Scientific American*, will resist 0.5 volt; but by exposing it to the air at a temperature of about 100 degrees C. it is possible to get rid of the hydrates contained in the film, and thus increase its resistance so that it will withstand a high voltage. The insulation between the layers of the coil should be non-hydroscopic, and the coils should be covered with insulating paint to prevent moisture from entering.

The United States Steel Corporation, recognizing the great economic loss caused by accidents to life and limb, is instituting a system of accident prevention, safeguards for machinery, and inspection of same in all its plants. It issued a call to all managers of plants for suggestions for methods and safeguards and received in response about 2,500 ideas. A very large proportion of these ideas was accepted, about 2,300 being found feasible. The managers of the corporation recognized the fact that it is not sufficient to install safeguards and methods designed to prevent accidents alone, but that it is also necessary to provide an efficient inspection system by which these safeguards and methods would be maintained. It is a sorrowful fact that workmen themselves are the greatest enemies of accident preventive devices, especially when they interfere in the slightest with machine operation. Another point affecting safety appliances that is important in a corporation having constituent plants operated in competi-

tion as are those of the U. S. Steel Corporation, is that the individual plants are not charged directly for the cost of maintenance, which is charged to administration expense. Under such arrangement no superintendent feels that his mill is being taxed for a feature that could be avoided and which he might fiercely antagonize were it charged directly against him. Charging this expense against a general overhead fund alters the complexion of the charge entirely, from the individual manager's viewpoint. It is gratifying to note that America's greatest corporation has recognized its responsibility in reducing the appalling loss of life and maiming of employes in industrial work. Its example should be very helpful in leading other concerns to give the matter the attention that its importance demands.

TRAIN DISPATCHING BY TELEPHONE.

The Atchison, Topeka & Santa Fé Railroad has announced that it will soon operate its entire main line, from Chicago to the Pacific Coast, by telephone instead of by telegraph. Contracts have already been let for a part of the needed installation, which will cost about $2,000,000. The Union Pacific has already installed 123 miles of telephone betwen North Platte, Neb., and Sidney. The New York Central has been dispatching by telephone between Albany and Syracuse, and is extending the system to Buffalo. The Erie has been for some time doing the greater part of its dispatching in the New York suburban district this way. The Great Northern is installing a thousand miles of 'phones, and the Pennsylvania is trying out this system.

The availability of the telephone for train dispatching was discovered when the railroads found that an immense volume of complex business was being successfully handled by telephone between city freight offices, receiving docks, and freight yards, involving the telephoning of contents of way bills and slips containing many figures. When the National and State laws limiting the working hours of railroad telegraphers to nine and eight hours, put added operating expenses on the roads, and the unions would not agree to the employment of apprentices to help keep down the cost, the railroads began to try out the telephone in dispatching, with the result that it is coming into general use. Any person of ordinary intelligence can send and receive orders by telephone, and some of the best tower men to-day are disabled trainmen put at this work.

There is no question of safety involved. The universal use of block signals has taken from train dispatching the work of preventing collisions, and dispatching is now purely the management of traffic. The telephone has been found more efficient than the telegraph for this.—*New York Times.*

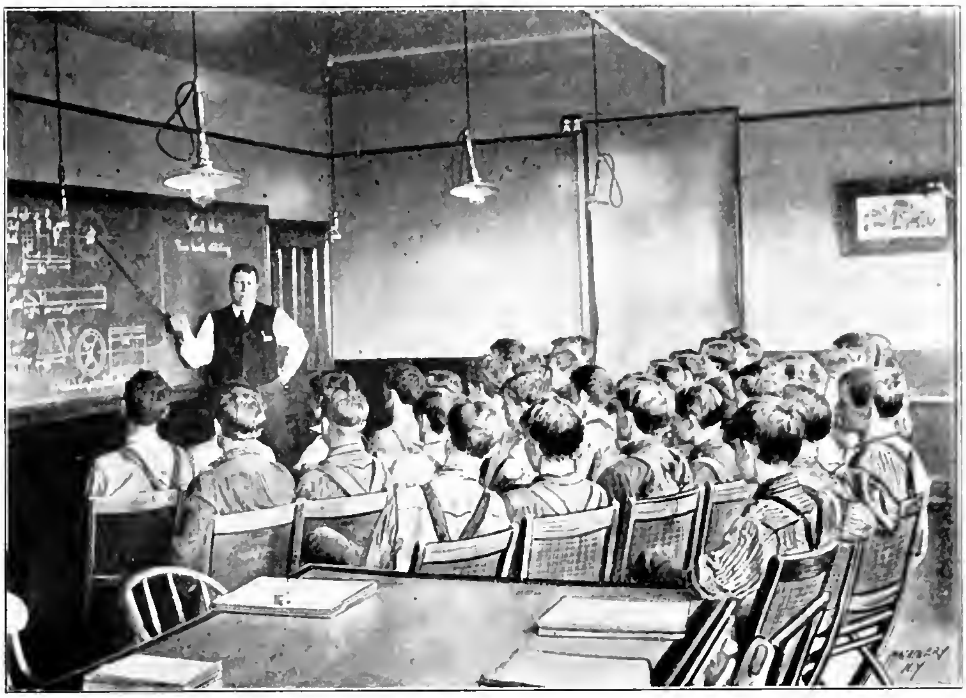
EDUCATING APPRENTICES AT DRIFTON.

In an article on educating apprentices, contributed to *Mining Men* (September, 1908) by Mr. William Lloyd, superintendent of the Lehigh Valley Coal Co.'s shops at Drifton, Pa., the author wrote in part as follows:

"I have found by experience that in a force of about forty apprentices there are about 25 per cent who will avail themselves of the usual opportunities for self-education, about 50 per cent can be persuaded by their employers to attend night school—if the employers are progressive enough in educational matters to make some effort in that direction—and the other 25 per cent cannot be prevailed upon to take these advantages under any circumstances. It was just to take care of the last mentioned that gave me the first thought of our school. About two years ago I had the honor of being appointed on the board of directors of the Mining and Mechanical Institute of Freeland, that splendid school for boys and men which was founded by the late Eckley B. Coxe. It was through my connection with this school that I was enabled to more fully realize the advantages of a school for the boys at the shop.

"In building up our force of apprentices I made it a rule to have each one promise to attend the night school at the Mining and Mechanical Institute. I found that some were regular pupils already, and there were some who could be persuaded to attend, while—as I said above—a certain percentage would not take this splendid opportunity to better their condition. One reason I found for some not wishing to start, was that their early education had been almost entirely neglected, so at the ages of sixteen or seventeen years they were ashamed to start; thus the only solution was compulsory education; in other words, we make going to our school a part of their work, for which they are paid.

"Years ago my experience with mechanics in nearly all trades convinced me that there is a very small percentage who can make an intelligent free-hand sketch, so we started by making free-hand sketching one of the leading features in our school; and it is remarkable what talent some of the boys show in this study. I know of no trade in which a man is not better off if able to intelligently put his ideas on paper. Therefore, in the near future we expect to teach the boys to write letters such as a mechanic is called on to send to the works when out erecting machinery. This I know to be very important, for a great deal of time is lost and serious mistakes sometimes occur, because such letters do not intelligently convey the man's ideas to the shop superintendent.



Instructing Apprentices at the Lehigh Valley Coal Co.'s Shops, Drifton, Pa.

"We have started on a plan of lectures by the foremen of the different departments. Our idea in doing this is that the apprentices of each department may thus have some knowledge of how and why some things are done in the other departments. Besides this, we intend to give the boys special instructions pertaining to their respective trades. For instance, the machinist apprentice will be instructed in the principles of valve setting, lining up and erecting machinery, etc.; the foundry apprentice will be instructed in the principles of mixing and melting iron and other metal combinations that go in engine and pump construction, also the reasons why different sand is used in some jobs and not in others.

"The question may be asked: 'Does it pay to take this interest in the boys?' I have always believed that it would, and I am now sure that it does. We not only get more and better work out of the boys while they stay with us, but we feel when they leave that we have done our best to make good men of them, and that we are sending out mechanics who are above the average."

TOOL-HOLDER ADJUSTABLE FOR HEIGHT.

La Machine Moderne for January 1, 1909, illustrates and describes a simple tool-holder of adjustable height, which appears to be of very convenient design. It is made in two forms, as shown in Figs. 1 and 2; the first has a spring holder for the blade, while in the second case the blade is grasped solidly, this being the only difference in the two tools.

This device consists of three members: an outer sleeve *A* split as shown for clamping; an inner sleeve *B*, bored eccentrically, and also split for clamping the tool-holder proper *C*, which is hollow, to permit carrying long bars of cutting steel. In adjusting the tool for height, it is loosened in the tool-post, and sleeve *B* is rotated by a spanner wrench or pin inserted in the holes drilled in the periphery of its flange. The rotating of this sleeve raises or lowers its eccentric bore, and thus raises or lowers the tool-holder contained in it to the proper height. All the members are clamped together and set by the tool-post screw.

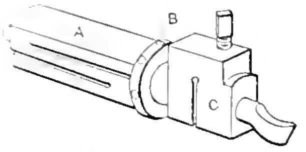


Fig. 1. Spring Tool-holder, of Adjustable Height.

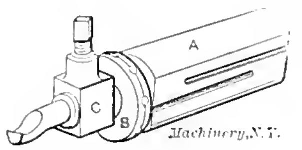

Fig. 2. Similar Tool, with Blade solidly held.

The point of the blade may be fashioned as a turning tool, side tool, threading tool, etc. The device appears to be especially useful for threading on small work, where the center adjustment should be made with great care. The fact that the tool-holder itself can be rotated to any angle, may be taken advantage of in steep pitch screws to set the cutting tools at the proper angle to give equal top rake on both cutting edges. The device may also be conveniently used for centering drills, reamers, boring tools, etc., with the axis of the lathe.

THE APPLICATION OF MOTORS TO MACHINE TOOLS.

Dexter S. Kimball, in *The Sibley Journal of Engineering*. March, 1908.

The introduction of electrical distribution and the electric motor gave to engineers of large plants a solution to a problem that had for a long time been very troublesome. The old method of power distribution with its wide belts and large shafts was quickly recognized as far inferior to the new method of distributing power electrically, running the various lines of small shafting by motors belted to them. By an easy extension of this system the larger tools were soon belted to their own individual motors, and the advantages so gained were evident to all, and up to this point engineers were fairly well agreed. But engineers soon came forward with the claim that great economy could be obtained by attaching a motor to every tool, and doing away with all belts and line-shafts. On this point, however, opinions were not so unanimous, and a discussion arose as to the relative merits of the two systems, and many tests were made to determine which was the most economical way, these comparisons generally being drawn between the so-called *group system* and *individual motor system*. It was clearly shown that conditions exist where either or both systems have a place, and that again conditions may exist where neither are desirable, as in cases where heavy machinery is to be operated close to the prime mover. The plant must be very small and compact, however, when electric distribution cannot be used to advantage, and in large plants it is indispensable. It is also now conceded, by engineers in general, that large and portable tools can be best driven by individual motors.

That the individual drive has not met with more favor was due in the past mainly to two causes, *viz.*, imperpect motors, and the general attitude of machine tool builders. When motors were first introduced in this work, electrical designers had not studied the peculiar problems presented, and as a consequence the first motors were not very satisfactory. The machine tool builder, on the other hand, saw at once that the motor was going to impose a new set of conditions on these machines, compelling him eventually to alter his patterns; and many makers naturally did much to discourage what some of them characterized as a fad.

As might be expected, the combinations designed under these circumstances were fearful and wonderful. A standard gas engine fastened to an ordinary carriage would not make a very good automobile; yet in comparison it would show up well with some of these early efforts. These difficulties, however, are now being rapidly overcome, and it is possible to buy almost any machine tool, motor driven in some way, although not always in a very desirable manner.

The engineer confronted with the problem of connecting up his electrical system of distribution to his medium size and small machines will be governed largely by the following considerations in making his decision as to the method to be used: 1. First cost of installation. 2. Maintenance and depreciation. 3. Provision for extension. 4. Sectional operation. 5. Flexibility as to location of tools. 6. Efficiency of system. 7. Positive application of power.

It may be well to consider these points in detail.

1. Without question the first cost of individual driving is considerably greater than group driving, and unless it can be shown that the individual drive has great advantages in other ways which offset this important item, it should not be considered. This is often a very difficult thing to do, and first cost will remain a drawback to the motor drive for small tools till different conditions of manufacturing reduce the costs considerably from where they stand at present.

2. On the second point we have as yet not a great deal of data that the writer is aware of; but his experience has been that the cost of maintenance and the depreciation was somewhat less in group driving. In the group drive the great item of expense is that of belting, which is costly and wears out rapidly; on the other hand, when motors do need repairing the repairs are costly, so that, on the whole, there does not seem to be much choice. Reliable data on this point would be of great service.

3. Regarding the third point, the individual drive has all the advantage. No system has ever been devised that provides so easily for extension. Changes in arrangement are also more quickly and easily made with the individual drive.

4. Here, again, the advantage is all with the individual drive, particularly with large tools which may be required to run overtime. Further, the breaking down of an individual motor does not affect but the one tool.

5. On this point the individual drive has an advantage that is particularly important. Machines so driven can be placed wherever desired, and in case of large tools, ideal conditions are obtained for overhead handling devices. In the case of small tools, greater convenience can be obtained, and tools can be placed in the middle of the room without cutting out the light. Incidentally, the elimination of belts greatly decreases the dust.

6. It has been found by actual measurement that there is little to choose between group and individual driving as far as efficiency is concerned.

7. The seventh and last point is the one on which the individual drive has its greatest claim to superiority, and which has done more for the individual drive than anything else. It was soon found that where motors were directly geared to the machine, a greater output was possible on account of the elimination of the slip in the belt, and the consequent driving of the work up to the limit of the cutting tool. This, of course, greatly reduces the time of the operation, and, as the cost of the time is two-thirds the total cost of the product, it is easy to see what a saving could be effected. The introduction of the new high-speed steels added still more to the necessity of positive driving, and it has been well demonstrated that where heavy cuts are to be taken the positively geared motor will show a great saving of time over the belt drive.

Herein, also, lies the solution of the problem so confusing at present to the engineer who is trying to find out just how far he can carry the individual motor drive idea and make it pay. In the case of large tools it will be seen at once that the solution is plain, and a careful consideration will show that the individual drive can be successfully used down to

a point *where a belt of convenient size will have no trouble in driving the cutting tool up to its limit.* Rules which fix some particular limit to the minimum size of motor to be used, or the minimum size of machine to which a motor should be attached are very misleading, as it depends entirely on what the tool is intended to do. For instance, a group of 16-inch lathes in one shop may be required to only take off a very light chip, and a group drive is satisfactory. In another shop these lathes may do heavy work, so that a motor drive will pay handsomely. There is no trouble, as a rule, in driving small drill presses up to the limit of the drill by means of group drive, and these are driven successfully in this manner; the same being true of small tools in general. At present it will not pay, outside of the advantages of better light and cleaner surroundings, to drive vêry small tools individually.

Summarizing what has been said above, we may state our conclusions as follows:

	Group Drive.	Individual.
1. First cost	Considerably less	
2. Maintenance and depreciation	Probably less	
3. Provision for extension...		Much superior
4. Sectional operation.......		Much superior
5. Flexibility as to location..		Much superior
6. Efficiency of system......	No great difference	
7. Positive application of power		Much superior

Having decided what tools to drive individually and what to group drive, the next question is the matter of motors and the methods of connecting them to the machines. Here, again, a great difference of opinion exists. In order to get a clear idea of what is needed in a motor for this work it will be well to look at the requirements of the tools themselves.

Machine tools may for this purpose be classified into the following groups:

(a) Machines requiring a constant speed. In this class come punches, shears, fans for ventilating purposes, and also the shafting of group drives. The torque may vary with the demand for power.

(b) Variable speed machines requiring maximum power at minimum speed. In this class are lathes, boring mills, and most machine tools where automatic regulation is needed. Here the cutting speeds are practically constant for a given metal, but the cuts are larger on the larger work.

(c) Variable speed tools requiring heavy starting torque, as cranes, sheet iron rolls, etc., where regulation of speed is by hand.

(d) Machines requiring a torque increasing with the speed, as blowers and fans which give variable blast. This class is rather unimportant.

Of course there is no trouble in meeting the requirements of the constant speed machines, but the problem of variable speed is difficult. If a good mechanical speed changing device were to be had, the problem would be easy to solve; but so far none has been produced that will answer the purpose. Many have been made that will give any speed between the limits of the mechanism, but they all depend on friction, and hence to carry the work required must in most cases be very large and cumbersome; while those that are positive in their action give only several speeds between the limits. Of the latter type a number are now on the market which can be used with success in many places.

When the electrical side of the problem is considered, a choice of two distinct systems of distribution is presented, namely, the alternating current, and the direct current systems, both of which have a place under proper circumstances in this work.

It may be said at the outset that when the alternating current system of distribution can be used, it is preferable, as the wiring is smaller in a large system, and the generators and motors simpler and more reliable. It has, however, its limitations, as will be seen, as far as machine tool driving is concerned.

The alternating current system offers two kinds of motors, the synchronous and the induction motor. The first is not self-starting and, except in a few cases, has no place in machine tool driving. Where heavy line-shafts are to be run for some length of time and provision can be made for starting, a synchronous motor is an excellent thing in connection with induction motors, as it tends to steady the line and help the power factor. In small sizes, however, it is not suitable for machine tool driving.

The induction motor is self-starting, and, like the synchronous motor, tends to run at constant speed. It is by its nature not a variable speed machine, although it can be made so in several ways, none of which, however, have so far proved adequate to the demands of machine tool driving. It has been successfully used on cranes and similar devices, the speed variations being obtained by putting resistance in the secondary, and variable speed induction motors are now on the market controlled in this manner. One plant at least has been fitted out with induction motors, where several changes of speed were obtained by varying the frequency, with fair success. But as yet, the induction motor cannot be considered as equal to the direct current motor for variable speed work, though considerable experimental work is now being done that may change the situation.

If the plant under consideration is to contain constant speed machines principally, the induction motor in connection with a mechanical speed-changing device will generally prove to be the best, and where all the machinery is of constant speed type it is much preferable.

The direct current system offers three kinds of motors, their combined characteristics covering much more closely the requirements of the case than do those of the alternating motor, and there is little doubt as to the greater adaptability of the system for general machine tool driving. These motors are: 1. Series wound motors. 2. Compound wound motors. 3. Shunt wound motors.

The series motor is a variable speed motor with great starting torque. It can be controlled throughout its whole range of speed and would seem at first glance to be almost ideal for lathes and boring mills. It is, however, very uneconomical, as the control is obtained by resistance in its circuit. It also requires an expensive controller on account of the heavy current to be handled and must be controlled by hand, as its speed varies inversely with the load, and under light loads it will run away. It is an excellent motor for cranes, elevators, sheet iron bending rolls, etc., and occupies a very important place in the equipment. It therefore covers the requirements of the tools under class (c).

The compound wound motor is suitable where small variations of speed are needed coupled with a large starting torque. It will, of course, give constant speed when set for any set of conditions within its range.

The shunt motor is, in its standard form, a constant speed motor. When set to run at a given speed it will not vary appreciably under varying load up to its capacity. It can be made to vary its speed in a number of ways, those which are most used being one of the following three: by varying the current in the armature; by varying the strength of the field; and by varying the voltage applied to the armature terminals.

These characteristics make the shunt wound motor most suitable of any for the purposes of machine tool driving and by means of these methods of control, either singly or in combination with each other or in combination with gearing, most of such work is now accomplished.

Summarizing the above conclusions, we may state them as follows:

Class of Machine.	Alternating Current Motors.	Direct Current Motors.
Constant speed torque varying with load.	Induction motor. Synchronous motor.	Shunt or Compound wound motor.
Variable speed, maximum work at minimum speed, automatic regulation.	Induction motor with mechanical speed changing device.	Shunt wound motor with or without change gears.
Variable speed. Heavy starting torque. Hand regulation.	Induction motor.	Series wound motor.
Variable speed, torque increasing with speed.		Comp. wound motor.

FRENCH COMBINED HORIZONTAL AND VERTICAL MILLING MACHINE.

La Machine Moderne in the issue of January 1, 1909, described a new milling machine recently brought out by the Société Française de Machines-Outil, the new French machine tool building firm of which we have made mention from time to time. Like the Ingersoll combined horizontal and vertical milling machine (described in the new tools department of the March, 1908, issue of MACHINERY), this tool is provided with two spindles, one vertical and the other horizontal, which may be used separately or simultaneously, though there appears to be no provision made for axial adjustment of the spindles.

"One of the refinements much sought after in the construction of milling machines is a combination of two spindles, one vertical and the other horizontal, permitting the easy transformation of the machine from a vertical to a horizontal miller, or *vice versa* as occasion requires.

"Different solutions of this problem have been offered. Among others, certain American builders make an attachment carrying a vertical spindle, which can be mounted on the horizontal spindle; but when so used the horizontal spindle is out of commission. Furthermore, each change in the method of operation necessitates the mounting or dismounting of the attachment, which, in order to be portable, is generally of light construction.

"To escape these inconveniences, the Société Francaise de Machines-Outils has designed the machine shown in Figs. 1 to 8, which only requires a simple rotation of the vertical head to change from vertical to horizontal milling. It should be noticed also that when the vertical head is turned back out of the way it presents a particularly strong support for the arbor in the case of horizontal milling. Among the different kinds of machine tools, in the design of a milling machine especially should a new company take account of the established reputation of certain foreign makes at present on the market, and of the difficulty of turning in its own direction the prejudices of the French consumer. The builders have, therefore, laid out a definite catalogue of the desirable qualities of such a machine, which can be summed up in the following list: First, rigid construction; second, easy manipulation; third, silent and positive drive; fourth, single drive for the spindle and the feeds; fifth, change of feed independent of the change of speed of the spindle; sixth, a large number of spindle speeds and rates of feed; seventh, large bearing surfaces; eighth, careful workmanship.

"The drive, which is of the single pulley variety, transmits to the spindle 16 speeds in geometrical progression, by means of trains of gearing shifted by a hand-wheel, whose eight positions each give eight speeds; these can be doubled by the operation of a lever whose central position stops the machine. The speeds are indicated on a dial in full view of the operator. The proper speed for the spindle can be found by consulting a diagram furnished by the builders. All the mechanism for changing the speeds is contained within the column, and the different speeds are applicable both to the horizontal and vertical spindles. The vertical spindle can be disengaged when it is not desired to use it.

"This machine is furnished in the plain and universal forms —that is to say, with or without a swiveling table. The table is carried by a cross slide or saddle, which is supported on a strong knee, sliding vertically on large bearings at the front of the column.

"The feed mechanism is constructed with a change gear device similar in construction to that of the speed change— that is to say, 16 feeds can be obtained by the manipulation of a hand-wheel and levers, as seen in the illustration. The feeds, horizontal, cross, and vertical, are independent of the spindle and are reversible. The drive of the feed gear box is derived from the main drive. The different movements have automatic stops throughout in all directions, as well as positive stops for hand feeding. All the feed screws are provided with graduated dials. The knee, as well as the saddle and table, can be locked in any position by screws independent of the gib screws. A safety coupling is provided to prevent the breakage of important parts in the case of abnormal stress.

"The screw for the vertical adjustment of the knee is of the telescopic form, to obviate the necessity for cutting an opening in the floor. Especial care has been taken in the lubrication of the working parts within the column. The driving and feeding mechanisms, all of the bearings therein contained, and those of the spindle, are oiled by a pump which draws its supply from a reservoir in the base of the machine. The supply of lubricant for the cutters is furnished in a similar way, by means of a second pump and reservoir, separate from the first.

"Mention should also be made of the care taken to have all the mechanism accessible, for the sake of facility in cleaning and repairing. The engravings shown herewith (Figs. 3 to 8) show clearly the variety of work to which the swiveling head lends itself, including as it does, the particularly interesting operation of helical milling on a plain machine. This machine is being built in several styles and sizes."

STRESSES IN WIRE ROPES DUE TO BENDING.

Abstract of Paper by R. W. Chapman, in the Proceedings of the Australasian Institute of Mining Engineers.

Unwin states that a wire rope used over a pulley or sheave is subjected to three different stresses. Firstly, there is the longitudinal tension due to the weight suspended by the rope and the weight of the rope itself; secondly, the tension and compression stresses in the part of the rope resting on the pulley, due to the bending of the rope in a curve; and in the third place, there is a stress due to the centrifugal action at that part of the belt which is bent over the pulley. This last stress, of course, can be disregarded whenever the speed with which the belt moves over the pulley is moderate. The author of the paper here abstracted examines in detail the stresses due to bending only.

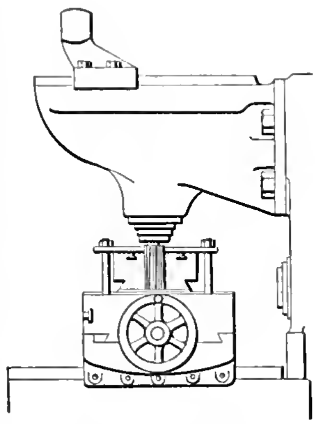

Fig. 3. Machine arranged for Plain Vertical Milling.

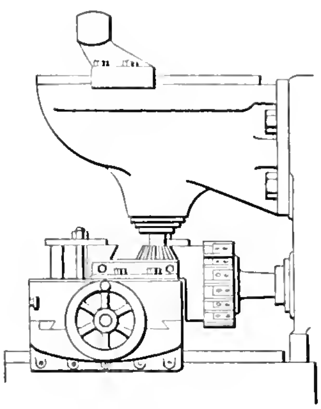

Fig. 4. Machine using Vertical and Horizontal Spindles Simultaneously.

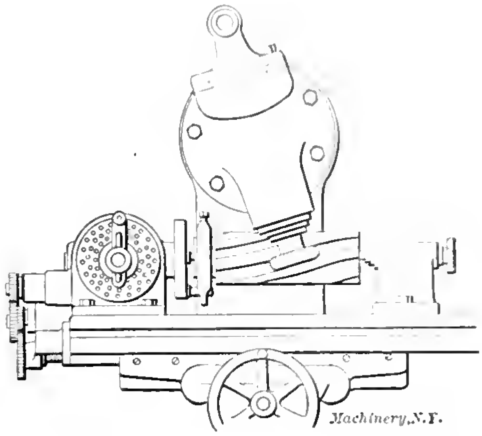

Fig. 5. Vertical Head Swiveled for Helical Milling.

The difficulties met with by investigators in trying to ascertain exactly the stresses in wire ropes bent over sheaves, is due to the fact of the complex structure of the wire rope, being made up, as it is, of spirally twisted strands, which in turn are composed of spirally twisted wires, it being difficult to say exactly what happens when this doubly twisted structure is wound around the drum or sheave. The difficulty is generally evaded in ordinary practice by the simple device of adopting a large factor of safety for a rope, usually one from eight to ten, a factor which experience has shown is sufficiently large to cover the bending strains set up when the rope is passed over sheaves of ordinary size. When, however, we add the stress due to the bending of the rope to the stress produced by direct pull, we find that the actual factor of safety is usually more nearly four than ten, and often the bending stresses in the rope are so large compared with the simple tensile stresses that neglecting them may lead to disastrous results.

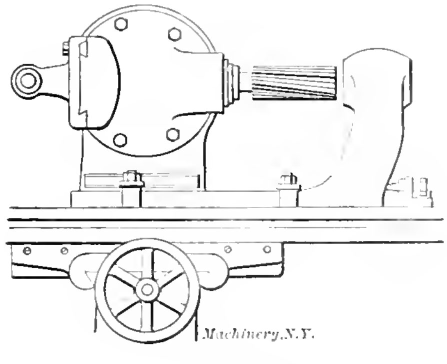

Fig. 8. Head Swiveled to Horizontal Position for Reaming, etc.

Empirical Rules for Size of Sheaves.

It has always been recognized that the bending of a wire rope over too small a sheave injures the rope, but as it is also desirable to reduce the size of the sheaves to a minimum for constructional reasons, the diameters of the sheaves are commonly made as small as is considered permissible. Various empirical rules have been given by different makers and writers for determining the minimum size of drum over which a rope may be wound. One maker states that the diameter of sheaves and drums should be about 30 times the circumference of the ropes used. Another rule says that the diameter of the sheave in feet should be $0.7C^2$, where C is the circumference of the rope in inches. Mr. H. W. Hughes in "Text-Book of Coal-Mining" states that the diameter of the pulley should not be less than 100 times that of the rope wire. Another writer gives the rule that there should be one foot diameter of pulley for each ⅛ inch diameter of rope; or, for instance, an 8-foot pulley for a one-inch rope. All these rules, however, are imperfect, because they take no account of the size of the component wires, and from practical experience we know that the smaller the diameter of the wires, the more flexible is the rope and the smaller may be the diameter of the sheave over which it may be bent.

A rule, to be of any reasonable value, should take into account the gage of the wire composing the rope. Such a rule is given by Mr. Bucknall Smith, in the *Mining Journal*, June 6, 1896, where he states that the diameter of the smallest pulley permissible should be at least 800 times the gage of the wire used. J. B. Richards, in *Mines and Minerals*, April, 1904, however, states that records show that the proper diameter of a sheave should be 115 times the diameter of a rope having 19 wires to a strand, and 185 times the diameter of a rope having 7 wires to a strand. Finally, another rule is given, deduced from practice, stating that a 6-strand, 7-wire rope requires a pulley whose diameter is equal to ten multiplied by the rope circumference squared; and a 6-strand, 19-wire rope requires a pulley whose diameter is equal to four multiplied by the square of the rope circumference. It will be noticed that there is a considerable variation of opinion expressed in the above rules, and while they may be useful for deciding approximately upon what experience has shown to be the proper size of pulleys to use for a given class of rope, they do not aid in determining the actual stresses placed on the rope by bending over pulleys of any given diameter.

Formula for Stresses in Wire Ropes due to Bending.

The author of the paper here abstracted therefore sets out to deduce mathematically a formula, giving the stresses caused by bending ropes over sheaves of given diameters, and he comes to the conclusion that the stress in pounds per square inch set up in a wire rope equals

$$\frac{E\,d}{D}\cos^2 a \cos^2 \beta$$

in which formula

E = modulus of elasticity of material, from which the wire is made,

d = diameter of component wire, in inches,

D = diameter of sheave, in inches,

a = angle made by the component wires with the axis of the strand, usually about 18 degrees,

β = angle made by the strands in the rope with the axis of the rope, usually about 18 degrees.

[It will be found that the values obtained by the use of this formula are considerably greater than those obtained by Mr. James F. Howe in the article on "Bending Stresses in Wire Rope" in the June, 1907, issue of MACHINERY, engineering edition. The difference is due to the fact that Mr. Howe simply assumes a rather low constant modulus of elasticity for the rope as a whole, while the author of the present paper introduces the actual angles made by the wires and strands, thus, it would seem, arriving at a more definite and correct result.—EDITOR.]

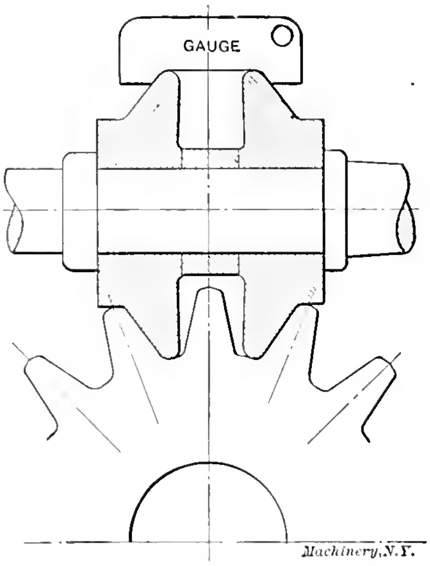
CHAIN DRIVES.

The advantages of chain drives as compared with belt drives, for certain service have frequently been pointed out. The chain drive is positive, and high tension of the chain is not required to make it grip the sprocket, as in the case with belts on pulleys. There is, therefore, an entire absence of slip, and the power is used more economically. Chain drives can also be made to occupy less space than a belt drive, and give efficient service at center distances too short for belts but too long for gearing. The troubles met with in belts in hot or damp places, are also well known to all mechanics. These difficulties are eliminated in the chain drive. One objection to chain drives has been that they are noisy, but the noise can be largely obviated by properly designing the chain and the sprocket. The size of the sprocket is a question which influences the noise of the drive. Other things being equal, the smaller the number of teeth, the greater the noise made by the drive. The action of the chain is smoother and more uniform on a large sprocket than on a small one. This principle applies to all chain gearing and should be taken into consideration when laying out a drive. In extreme cases a sprocket with only seven or eight teeth may be used with a roller chain, but eleven or twelve teeth should be considered as the minimum in all cases where smooth running is essential. Generally, even the best designed driving chains, such as the Renold silent chain, should not run more than 1,250 feet per minute. When this limit is passed some special means of lubrication should be adopted. The roller chain is generally used for speeds from 600 to 900 feet per minute; and the block chain for speeds up to 600 feet. When designing a chain drive, inclined or horizontal positions should be chosen, with the tight side of the chain on the top.



Testing the Setting of the Cutters for Cutting the Teeth in a Renold Silent Chain Gear.

In the accompanying Data Sheet Supplement, formulas are given for obtaining the various quantities in regard to length of chain, diameter of sprocket, etc., required in determining upon a chain drive, both for the Renold silent chain, the roller chain and the block chain. The highest ratios desirable between the driving and driven sprockets are, for the silent chain, 1 to 6, and for the roller and block types 1 to 7½. The maximum and minimum number of teeth advisable are for silent chain 15 and 90, for roller chain 8 and 70 and for the block chain 6 and 60. The pitch of the chain is measured from center to center of rivets, the pitch of the wheel being approximately at the tops of the teeth. An odd or "hunting" tooth should be used in the pinion when possible in order to distribute the wear evenly on the sprocket teeth. It is advisable to have the center, on which one of the sprockets is mounted, adjustable, in order to be able to keep the chain at the right tension.

Ordinary chain drives should be lubricated at least once a week, and the lubricant should be free from any tendency to gum. A thin oil may be used first to penetrate the joints, and then a thicker oil that will not be thrown off by the centrifugal force. The lubricant is best applied with a brush to the inner side of the chain while running the chain slowly on its sprockets. The chain should be lubricated oftener than once a week when used under severe conditions, as in the case of constant running night and day, fluctuating loads, when running in dusty places, etc.

It is interesting to note the manner in which the teeth in the sprockets for the Renold silent chain are cut. The tooth space is first cut from the solid blank by a stocking cutter. The teeth are then finished by cutters working in pairs, as shown in the accompanying illustration. For the same pitch three different pairs of cutters are required. These cutters are very nearly the same in form, the only difference being that they make the tooth slightly deeper for the smaller wheels. The cutters are set to a gage, as indicated in the illustration. The center line of the gage should be set exactly central with the sprocket to be cut. When cutting steel or phosphor bronze, and especially if the teeth are cut from the solid directly by the finishing cutters, it is advisable to set the dividing head so as to cut alternate teeth, or even teeth further apart than every second tooth, the inaccuracy due to local heating being thereby avoided.

Tables will also be found in the Supplement for malleable chains as made by the C. O. Bartlett & Snow Co., Cleveland, O. A table is also given for the shape of the teeth in the sprockets, for the various numbers of chain.

* * *

The following case-hardening mixture is recommended in the *American Engineer and Railroad Journal.* Put in a two-inch layer of charcoal, broken into about one-inch pieces, and pack it down in the bottom of the box used for the case-hardening. Then sprinkle about one pound of common salt over the charcoal, and one pound of pulverized sal soda over the salt. Then one pound of powdered resin is placed over the sal soda, and one pound of black oxide manganese over the resin. The material to be case-hardened is now laid on this, care being taken not to place the pieces too close together or too close to the sides of the box. Between the pieces, charcoal is filled in and well packed, care being taken to have about two inches of charcoal between the different pieces, if they be large. Now the sprinkling of the compounds on the work is repeated in reverse order, so that a two-inch layer of charcoal is placed on the top of the box. Sprinkle a little salt on the top of the charcoal, then put the cover on the box, calk with clay, and place the box in the furnace from ten to fifteen hours, heating it to a bright red. Then cool it in cold, clear water.

ELECTRICAL WELDING.

In a recent issue of MACHINERY (October, 1908) was shown a photograph of a number of examples of high-speed steel tools electrically welded in the shops of the Thomson Electric Welding Co., of Lynn, Mass. Little or nothing was said about the process itself or the range of its application. This article has been prepared in the belief that there is enough of interest and importance in electric welding to make a more detailed description of it profitable. While the process was invented several years ago, improvements are constantly being made in its application.

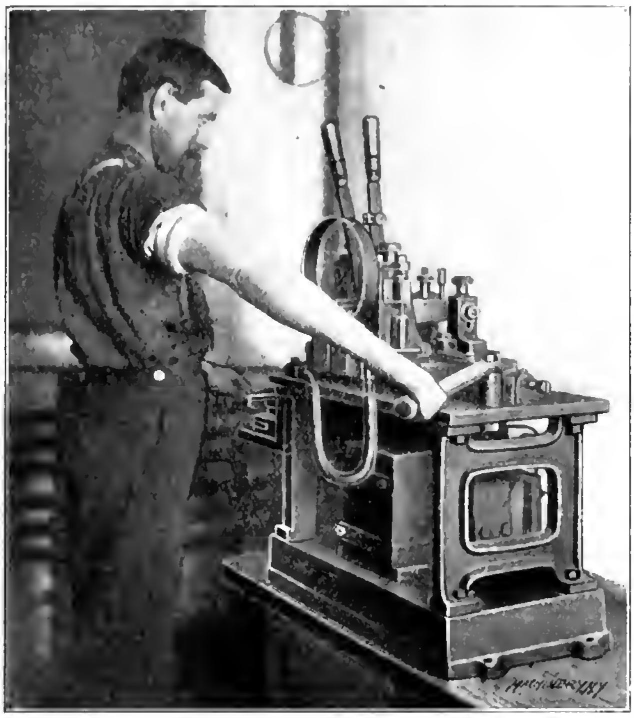


Fig. 1. Welding a Steel Ring in a Hand-power Machine; Section, 1 1-2 x 1-16 inch; Current, 10,000 Watts per 1 1-2 second.

The Principle of Electrical Welding.

The process consists, primarily, in holding the pieces to be welded between clamps, which form the terminals for an electrical circuit of very high amperage. When the surfaces to be welded are brought into contact with each other, these parts, themselves, complete the circuit, the current being transmitted directly through the work. The current strength is such that the resistance to its passage at the point of contact generates a welding heat. If the surfaces are not finished so that they come squarely into contact with each other, the reduced conducting section where the contact is made will heat rapidly to a high temperature, and flow, allowing the two parts to be pressed together into closer contact, until the whole area is at a welding heat. The heating action is thus progressive, being generally from the inside of the metal out, instead of being from the outside in, as with all other heating processes.

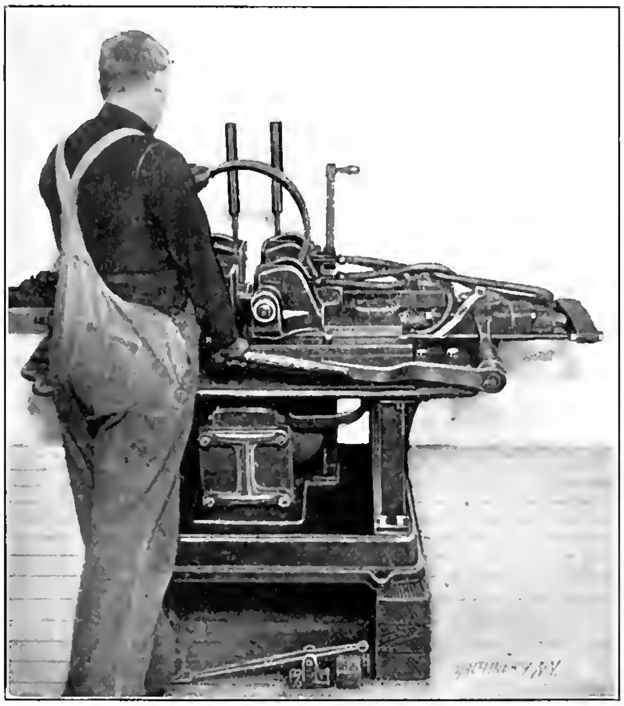

Fig. 2. A Large Machine, operated Hydraulically. Section welded, 3 x 5-8 inch; Current, 70 K.W. for 50 seconds.

Simple Welding Machines for General Use.

A simple type of machine for this process, adapted particularly to the welding of hoops, is shown in Fig. 1. The machine consists of a transformer; the electrodes between which the two ends of the work to be welded are clamped; means for pressing together the surfaces to be welded; and the necessary electrical connections, switches, etc.

The purpose of the transformer, which is mounted in the base of the machine, is to change the high potential alternating current as it is received from the shop dynamo or the commercial circuit, to the low potential, high amperage current required for welding. As it is the strength of the current in amperes that taxes the capacity of the conductor, it is necessary to transform the current into one of high amperage (and consequently low voltage) in order to over-tax the conductor at the point where it is to be heated to the desired temperature for welding. The two secondary terminals of this transformer form the support for the clamping device in the jaws of which the ends of the hoop to be welded are held. Each of these jaws is clamped to the work by cams operated by the handles shown projecting upward at the top of the machine. The two jaws are, of course, insulated from each other, so that the only path for the current is through the work.

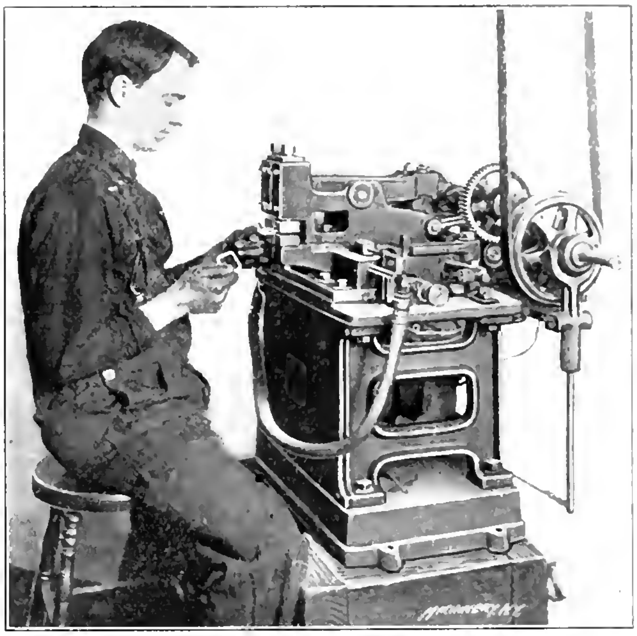

Fig. 3. A Small Automatic Machine for Welding Belt and Harness Buckles, etc.

The lever at the right hand of the operator is used for pressing the two ends of the work together. The current being thrown on, heat develops at the point of contact, owing to the high resistance to the passage of the current found there. As these points of contact are softened, the continued pressure applied by the workman forces the parts closer together, bringing them into more intimate contact. The heat developed finally so softens the work that its resistance to the pressure applied by the operator is suddenly relieved, the soft metal being squeezed out from between the joints as the jaws come together. It is important at this juncture to shut off the current immediately, to prevent over-heating and burning. This is done by an adjustable micrometer stop which, by making an electrical contact and energizing a magnet, throws open a switch in the primary circuit. The clamps are then loosened and the work removed. These various operations are matters of seconds only, and on work of me-

dium size the output is practically limited only by the rapidity of the operator's movements.

The machine just described might be spoken of as being, in a measure, a general purpose machine. Another general purpose machine for larger work is shown in Fig. 2. This is adapted either to the welding of hoops, as shown in the engraving, or the welding together of rods, bars, and general machine parts. It is adapted to work so large as to make direct hand operation impracticable for pressing the two ends of the work together. For this reason a hydraulic jack is incorporated in the machine. The workman is shown with his right hand grasping the pump lever of this jack. The release valve is seen mounted on top of the cylinder. The clamping jaws are each operated by two levers, one for opening and closing them through a considerable range of movement, and a second one for firmly tightening the work under great pressure. A fixed stop is provided on an extension arm at the left to furnish an abutment for the work against the pressure of the jack when welding bars, rods, etc. In this machine, owing to the size of the sections to be welded, the heating action is somewhat slower, so that the operator can throw off the current with the foot switch shown, when the pieces reach a welding heat. In the case of the small work used on the previous machine, the heating is so rapid that the switch has to be thrown automatically to prevent burning the metal. In both of these machines the parts in contact with the work are water cooled.

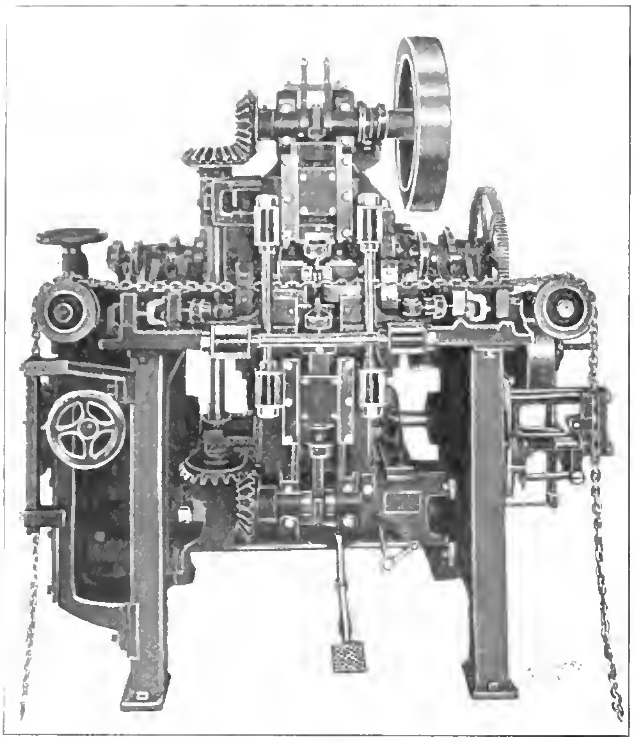

Fig. 4. Front View of Automatic Machine for Welding Chain Links.

Advantages and Disadvantages of the Process.

For work to which it is applicable (and its range of work is surprisingly large) the electrical welding process presents certain well-defined advantages. In the first place, as has been described, the heating is from the interior of the work out, instead of from the exterior inward, as is the case with any outside application of heat by coke fire, gas furnace, or similar means. This gives assurance that the whole section will be properly heated and properly welded. This is not possible in the case of large sections heated from the outside. Uniformity of heating is assured by the fact that if at any point the temperature is higher than at other points of contact between the parts, the increased heat increases the resistance, forcing the current into the cooler sections, and thus equalizing the temperature until it is uniform throughout the whole area. The process is almost instantaneous on small sections, and on larger work requires but the merest fraction of the time required with the old processes. The metal, while heating, is in the full view of the operator, instead of being concealed by flame or fuel. The weld is homogeneous, being of the same material throughout, uniting in intimate contact. By suitable electric controllers the metal can be held at any temperature desired for any length of time, and the heat increased and decreased as well.

The method applies to a great range of kinds and forms of metal, including those which could not hitherto be effectually brazed. Metals of widely dissimilar character can also be united. The process is under close control, so far as accuracy of dimensions is concerned, owing to the fact that the parts are kept in accurate alignment by the clamps, which may be given any shape necessary to hold regular or special work. Another point of importance is the extreme economy in the use of heat. This is localized at the point desired, and very little of it is lost by radiation, or is used in heating anything else except the work. The apparatus is clean and free from dust and dirt in its operation. There is, as well, no blistering or scaling of the work, the heat being confined to the welded joint. The slight fin or swelling produced at the junction may easily be broken or ground off, leaving a smooth, flawless surface. The current may be generated by dynamos, specially designed for the purpose, installed in the shop, or may be taken from a city light supply, if the latter is of the alternating current type, at from 100 to 400 volts.

The disadvantages which might be mentioned in connection with the process are chiefly those which are closely connected with the advantages. One of them is the great rapidity of action of the machine, which would tend to keep it idle the greater part of the time, except in shops where there are great quantities of welding to be done. For firms which have a moderate amount of work of this character, it is best to send their work to companies making a specialty of the process, rather than to install the necessary machines. Another point that might perhaps be considered as a disadvantage, is the fact that special electrodes or clamping jaws are required for many forms of work, whereas welding in a forge requires only tools of universal application and of the simplest kind. The holding jaws required for electrical welding, however, are very simple, being in their nature something like the special chuck jaws often used for holding work in milling machine vises.

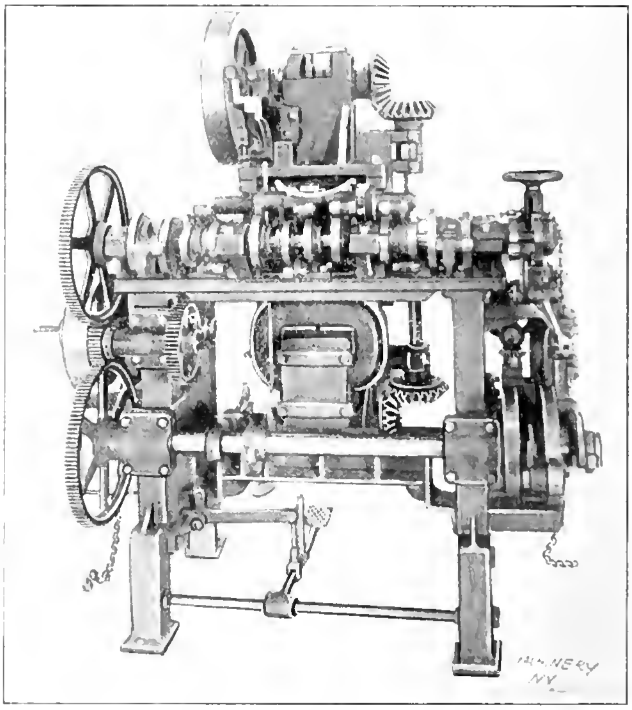

Fig. 5. Rear View of Chain Welding Machine.

Automatic Machinery for Electrical Welding.

One of the noticeable features of this method of welding is its applicability to special work. The Thomson Company builds special machinery, some of it of a high degree of complication, for manufacturing a wide range of metal products. We show two or three examples of such machinery. In Fig. 3 is illustrated a machine intended to be used in such work

as welding belt and harness buckles, rings, etc. It is exactly identical in its operation with the machine shown in Fig. 1, except that the clamping and the pressing together of the ends of the work is effected by cam movements. The throw-out of the current is automatic, as before. The switch is thrown in again by a cam instead of by hand. The clamps are water cooled. In making each weld, 3,000 watts are used for a second. All the boy has to do is to feed in the buckles, which drop out of themselves after being welded.

Figs. 4 and 5 show front and rear views, respectively, of a highly complicated chain welding machine. This machine simply welds the joints, the chain having been formed, assembled and closed by automatic machinery. It is fed through the clamps or dies by the hand of the operator, all of the other movements and the control of the switch being automatic as in the previous case.

Another special application is in the making of wire fencing, and wire mesh for reinforcing concrete. In this case cross wires are automatically laid on strands of continuous wire, spaced suitable distances apart and firmly joined to them by welding at the points of junction. This makes a fence which is in its completed form one solid piece, instead of being held together by twisting the wire or soldering. The operation of "spot" welding is employed in many cases for joining sheet metals to each other, such as for fastening handles, spouts and other attachments to cooking utensils, etc. In this case it takes the place of riveting. The two metals are joined together under the contact points, being fused into homogeneous contact.

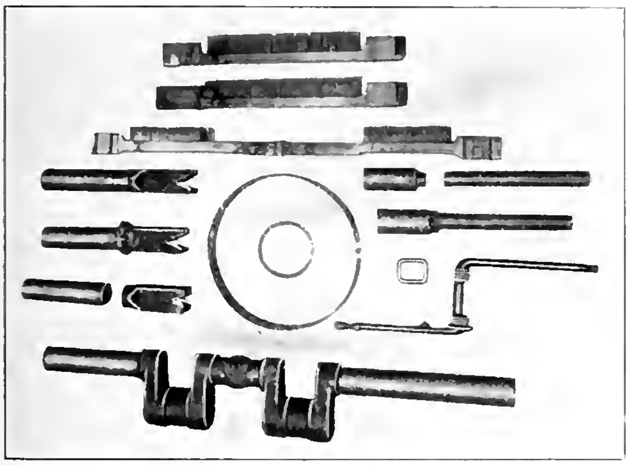

Fig. 6. Examples of Electrical Welding.

Fig. 6 shows a number of examples of the work produced by this process, which will serve to give some idea of its range. The three upper pieces are combs of a kind used in working wool. In the machines in which these are used, the hard service given them crystallizes them and causes them to break. They are easily repaired by adding new ends, or (in the case of the double ones) by rejoining them together at the middle. This can be done by this process and still keep the piece to accurate dimensions. The tools shown at the left are used for stone cutting in pneumatic or steam hammers. The breakage of these pieces is another case of crystallization under continued impact. They can be repaired, as shown, by welding the broken pieces or by putting on a new soft steel shank, at a fraction of the cost of forging and forming a new tool of high carbon steel. The two hoops in the center are similar in character to the work shown in progress in Figs. 1 and 2. The counterbore blanks at the right are similar to the work shown in the article in the October issue. A harness buckle and a welded bicycle crank are also shown. The large two-throw crank was built up from commercial forgings. It is possible to use these in building two, three, four, or other multiple throw cranks, with the throws set at any desired angle with one another, thus making costly special forgings unnecessary.

This process of electrical welding is controlled by the Thomson Electric Welding Co., which is prepared to do jobbing work, to lease standard machinery, or build special machinery, as may be required for doing work of any kind that can be done by this method.

BROACHING A DOVETAIL KEYSEAT IN A TAPER HOLE.

T SQUARE.

It was desired to broach a dovetail keyseat in the crank-shaft hole of a large quantity of bicycle cranks. The cranks were of nickel steel and had a 10-degree taper hole, with a minimum diameter of 17/32 inch, to be broached to receive a flat key, 3/8 inch wide by 1/16 inch thick, dovetailed to a 10-degree included angle. When the keys were driven into place in the cranks, the latter were required to be interchangeable on the crank-shafts, which were slabbed off on one side of the taper end to correspond with the key in the crank, and fitted with an ordinary check-nut to retain the crank.

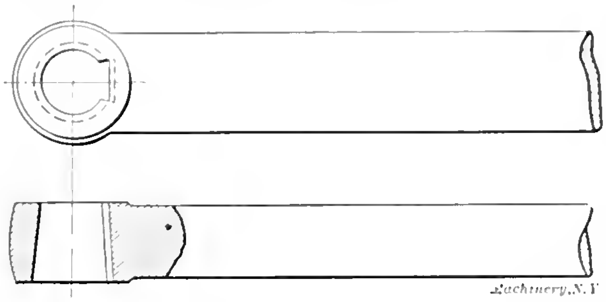

Fig. 1. View of the Broached Work.

To fit a key in this manner and insure interchangeability and a simultaneous fit on both key and crank, requires a nice degree of accuracy; and considering this, and the toughness of the steel, as well as the necessarily limited diameter of the broach, it was expected that the operation would prove expensive. Subsequent experience with the use of the device here illustrated, however, proved otherwise, as thousands of the parts were broached most successfully at a remarkably small cost. Fig. 1 shows the piece to be broached. Fig. 2 shows a machine steel plate, planed on the bottom and sides to fit the die-bed of an ordinary 8-inch stroke drawing press, and planed on the top to an angle of 5 degrees. After the planing operation a hole was bored at right angles with the top surface, to receive a tempered guide bushing *A*, which was pressed into place. The guide hole for the broach was then put through at right angles with the bottom of the plate. Thus it will be seen that when the crank is placed in position over the guide bushing and brought into contact with the stop pin *B*, the surface to be broached will be parallel with the line of travel of the broach.

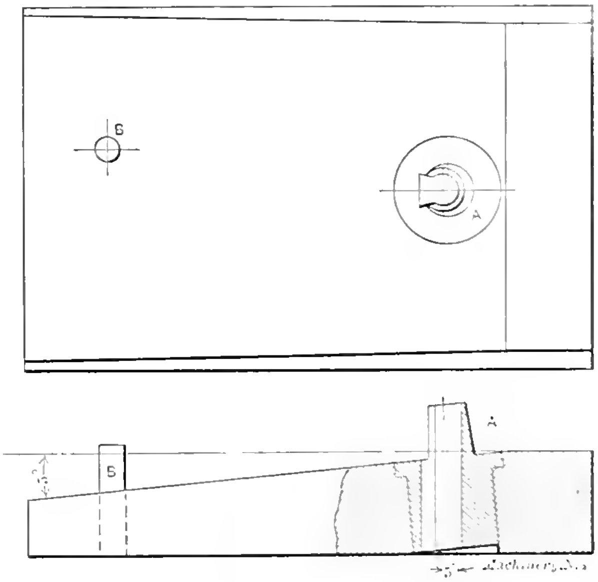

Fig. 2. Fixture for Holding the Work.

Fig. 3 shows one of a series of three broaches which are required to complete the cut. These are made to slide freely through the guide bushing *A* (Fig. 2), and are held in the proper position in the holder *D* by means of a locating piece *C*. As the press reaches the limit of the downward stroke, the broach, which has ceased cutting, simply drops through

the bust [illegible] to the hand of the operator, who then inserts broach number 2 into the holder as the press reaches the upward limit, thus making it unnecessary to stop the machine to insert the tools. Great care should be experienced to keep the teeth of broaches of this kind free from chips, which can easily be accomplished by the operator passing his fingers downward over the face after each removal from the guide bushing, and before depositing in the pan of oil.

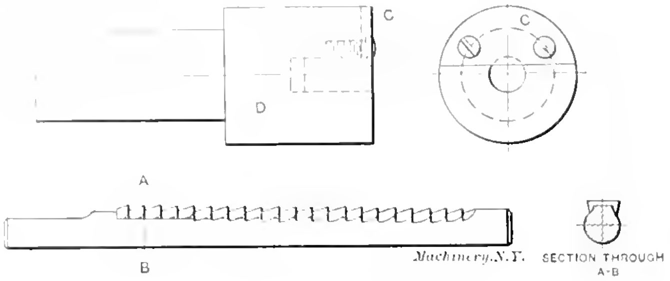

Fig. 3. The Broach and its Holder.

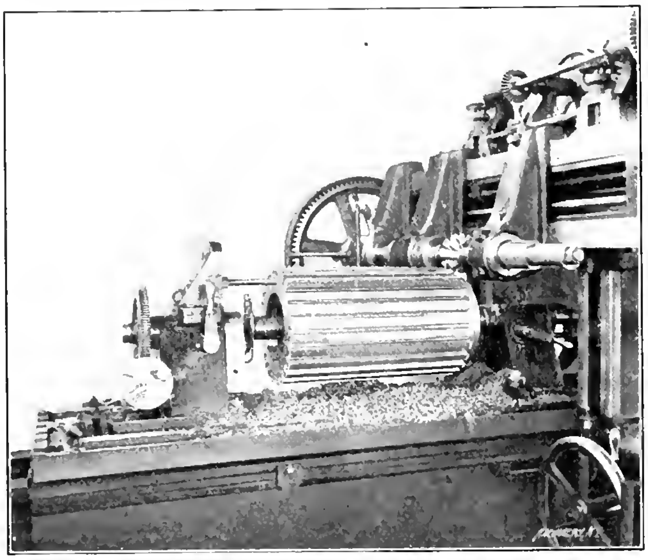
In tempering broaches of the shape used in this operation, the best results can be obtained by slowly heating the piece, face downward, in a charcoal fire. When heated face upward, the piece will invariably bend, making the face concave, and as they require to be reasonably hard, it is a difficult matter to straighten them.

* * *

CUTTING A LARGE SILENT CHAIN PINION.

C. M HAMERSLY.*

At the Link-Belt Co.'s Philadelphia plant the problem of cutting 26 teeth of 2-inch pitch in three forged steel blanks each $16\frac{1}{2}$ inches diameter, 27 inches face, with a hub on one end $14\frac{3}{4}$ inches diameter by 2 inches wide, making a total width over all of 29 inches, proved too much for the automatic gear machines, owing to the exceptionally long face.



Cutting Long Face Pinion for Renold Chain on Slab Milling Machine.

The difficulty was finally solved by performing the operation on a Bement, Miles & Co.'s 24-inch horizontal slab milling machine, using a pair of heavy index centers constructed by the company, especially for this class of work. The illustration shows the blank after it had been stocked out, and with the finishing cutter forming two teeth at the same time. In cutting the teeth 350 pounds of metal was removed. The blanks weigh 850 pounds each, and have a 10-inch bore.

These pinions form part of three silent chain drives of 350 H P. each, that are to transmit power for a wire-drawing bench at a plaut of one of the large steel companies, each drive consisting of a wide-face pinion connected to two large gears by two strands of 2-inch pitch Renold silent chain, each strand 12 inches wide.

* * *

The reason why men who mind their own business succeed is because they have so little competition.

INCLINED PLANE SHOP CAR ELEVATOR.

The accompanying half-tones, Figs. 1 and 2, and the line engraving, Fig. 3, illustrate an interesting appliance installed in the shops of the firm of H. Bollinckx, 117 Chaussée de Mons, Brussels, Belgium. There is a difference in the level of two departments in the firm's works, and some difficulty and loss of time was experienced in transporting material from one to the other. Due to the fact that the work was of a varying nature, and some of the pieces to be transported very long, the ordinary elevator did not suit for bringing the material from the lower to the upper level, or *vice versa*. For this reason, an inclined plane car was installed on which the regular shop cars could be placed and raised or lowered to the levels of the different shops, as required. The platform of the inclined plane car is provided with rails for this purpose, as

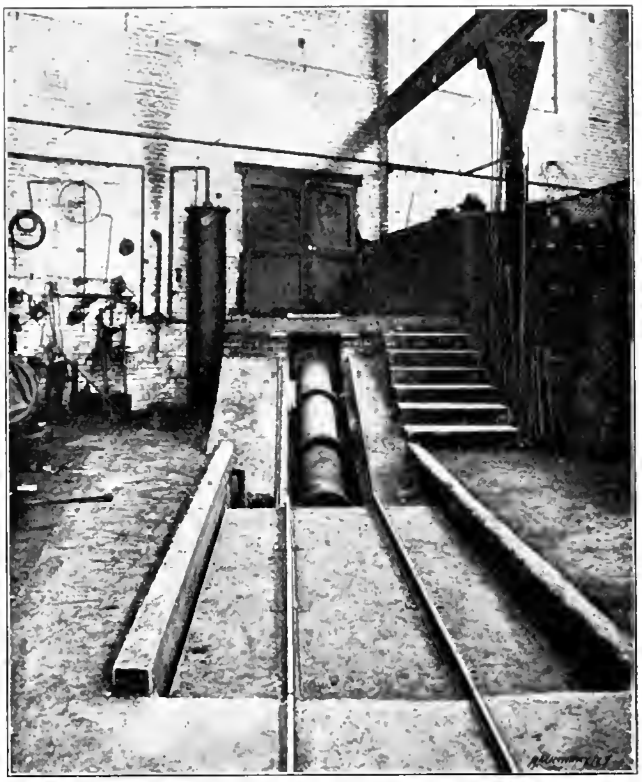

Fig. 1. Shop Car Elevator at Lower Level of Travel.

Fig. 2. Inclined Plane Shop Car Elevator at Upper Level of Travel.

shown in Fig. 1, where the car is located at the lower level of its travel. In Fig. 2 the inclined plane car is shown in its upper position, level with the floor in the other shop, and with a shop truck, loaded with a casting, on it. The platform of the inclined plane car is supported by a framework *D*, mounted on wheels and traveling on an inclined track. The power for the motion of the car is transmitted to it through the cylinder *E* which is filled with water and is connected with the tank *C*, shown at the left-hand side of the upper platform. The tank *C* is connected with the compressed air system of the shop by the piping *F*, thereby obtaining the required pressure on the water. The piping *A* connects the tank *C* and the cylinder *E*, and the valve *B* on the piping *A* is provided so that the inclined car can be made to stay wherever it is stopped. This is very important in order to prevent the car from sliding down again when it has arrived at the top level. When the car is again required to descend, the compressed air is let out at *H*, the valve *B* between the cylinder and the tank is opened, and the car descends in about thirty seconds. The valve *B* is opened by raising the counterweight *G* on the lever of the valve. When the inclined car has reached the lower level, the operator simply drops the counterweight, and the valve is shut automatically. At this time the air valve may be again opened so that the water in the cylinder *C* is under pressure, ready for the next lifting of the car to the upper level. The valve *B* being shut, the pressure cannot be transmitted from the tank *C* to the cylinder *E* before the valve *B* is again opened. The pressure of the air is kept at about seventy to seventy-five pounds per square inch. This gives a total lifting power of 22,000 pounds.

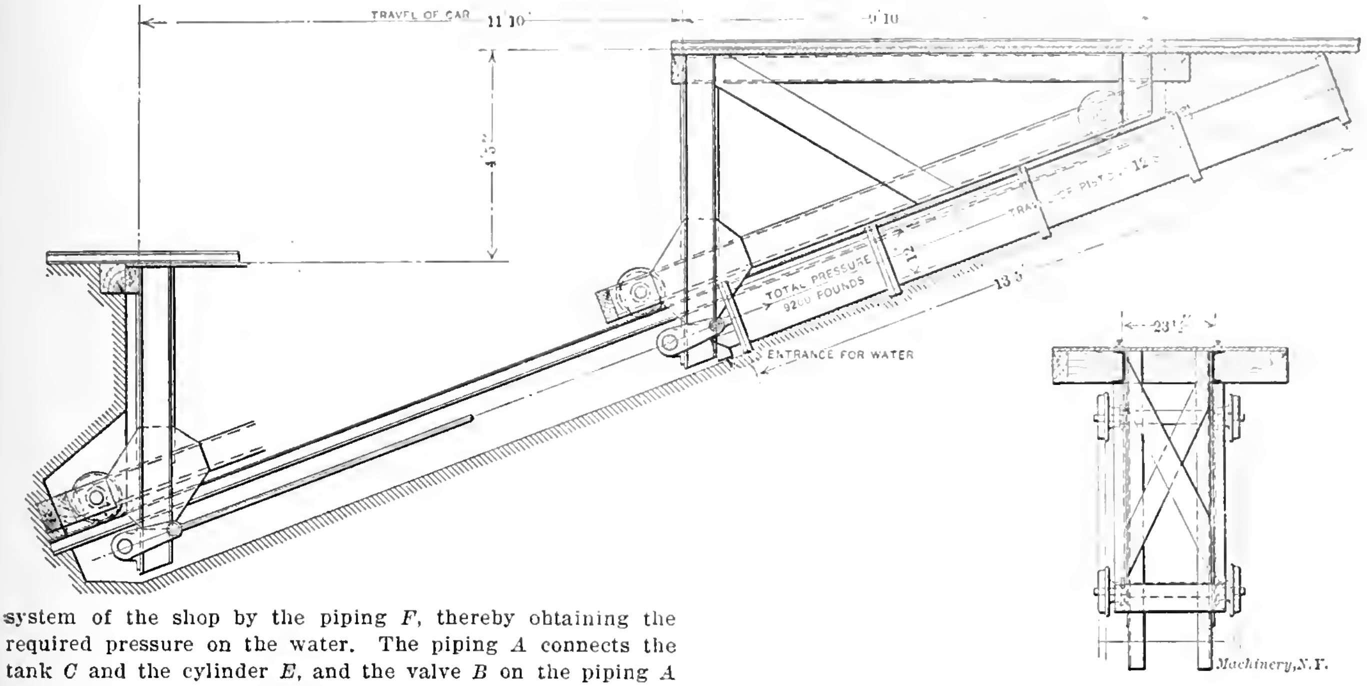

Fig. 3. Elevation and End View of Shop Car Elevator.

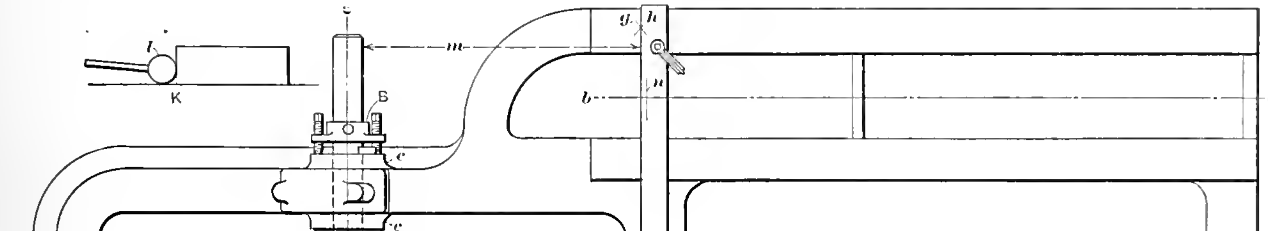
MACHINE SHOP PRACTICE.*

BABBITTING THE PILLOW-BLOCKS OF A DUPLEX BED

Babbitt metal is used very extensively on many kinds of machinery as a lining for the bearings, instead of the more expensive bored box, which requires considerable care in fitting. With this metal it is possible to line bearings quickly, and its extensive use is due to the resulting economy, rather than to the anti-friction qualities which it possesses. The temperature at which it becomes molten is low, and, consequently, it is easily melted over a common forge fire. By the use of a babbitting mandrel, the diameter of which is equal to, or slightly greater than, the journal of the bearing, the operation of boring is eliminated. For bearings which are large and important, however, the mandrel is often made smaller than the finished bearing, and the latter is bored after the metal has been expanded and compressed. It is common practice when babbitting two-part bearings, to expand the metal by beating it with the peen of a hammer, but owing to the lack of room, this method cannot be employed when the bearings are solid, especially if small and of considerable length. The same result is obtained in such cases, by forcing a tapered arbor through the bearing in a broaching press, or by other means, the size of the arbor being such as to leave



Plan of a Duplex Bed, showing Method of setting the Babbitting Mandrel when Lining the Pillow-blocks.

---

* With Shop Operation Sheet Supplement.

sufficient metal for reaming or boring. Still another method which has proved satisfactory in practice, is to bore the bearing to within about 1/32 inch of the finished size, replace the boring tool with a cylindrical piece of steel having polished spherical ends, and feed the latter through the bearing. The length of the tool should be sufficient to compress the hole to within reaming size. As is well known, there are on the market a number of alloys known as babbitt metal, some of which are of inferior quality. If care is taken, however, to obtain a high grade metal, small and medium-sized bearings may be lined with it, and in use will prove satisfactory, without any peening or stretching, as the shrinkage of such metal in cooling is comparatively slight.

Obviously, before the metal is poured into the bearing, the mandrel must be set in correct relation to the other parts of the machine. When there are surfaces which have previously been finished, such, for instance, as the guides for the cross-head, these may be used to advantage in setting the mandrel. If much work of this kind is being done, what are known as babbitting jigs should be made. These are simply fixtures which bear against or fit into any finished surface or hole with which the mandrel must be aligned, and which hold the latter in the correct position while the babbitt is being poured. In the present article, the method of setting the mandrel, and babbitting the pillow-blocks of a small duplex vacuum pump bed, will be presented. This pump is of the type having forked connecting-rods which straddle the steam cylinders. The cross-heads are located between the steam and air cylinders, and are supported entirely by the piston-rods, instead of by guides; therefore the top of the bed and the sides of the pillow-blocks are the only finished surfaces available in this case.

Before the bearings are babbitted, the machine work on the pillow-blocks and caps should be completed, and, as both parts of the bearing, in this case, are to be lined at one time, the caps should be fitted and bolted into place. Steel liners about 1/16 inch thick should be inserted beneath them at points *d*, so that when the bearings have become worn, the play may be taken up by lowering the cap *A*, which is easily done, simply by inserting thinner liners. The anchorages for retaining the metal in the bearings, if they are not cored into the casting, should also be cut or drilled in. The babbitting mandrel is then set in place in the bearing, in the position which is subsequently to be occupied by the shaft. This mandrel is the exact size of the shaft, and the type here shown is provided with a clamping collar *B* which holds it in position, and two adjustable collars *C* and *D* which retain the molten metal.

In setting the mandrel, there are three requirements which must be considered: the center line *c—c* of the crank-shaft must be at right angles with the center line *a—a* of bed, and parallel with, and, approximately, at least, the required distance above the top surface of the latter. It is desirable that the shaft, when in place, be concentric with the bosses *e*, and, therefore, we shall assume that sufficient metal was removed from the top surface of the bed to make the distance *h* approximately the drawing dimension. This being the case, we have only, when setting the mandrel for height, to adjust it until the collars *C* and *D* are concentric with the bosses. The next step is to set the mandrel parallel with the finished surface of the bed. Locating points for accomplishing this quickly and accurately, may be provided by finishing small spots *f* beneath the bosses at the time the casting is planed; each spot, of course, being machined at the same setting of the tool. The mandrel is then set by calipering from these spots to the flanges of the collars *C* and *D*, which should be of the same diameter. If, however, such spots have not been provided, the same result may be obtained by holding a straight-edge, long enough to reach out to the mandrel, on the surface of the bed, first on one side and then on the other, and calipering the distance between the mandrel and the straight-edge.

If the bed was properly set when planed, the sides of the pillow-blocks will be parallel with the center line *a—a*, but as these surfaces are small, they cannot well be used for squaring the mandrel with this line. A line at right angles with the line *a—a*, however, can easily be scribed while the bed is on the planer, by placing a pointed tool in the tool-post, lowering it just enough to graze the finished surface of the bed, and feeding it across. The mandrel may then be set parallel with this line by the use of an inside micrometer gage having a bent point, as shown at *E*. This is a convenient and accurate method, but if no such line has been made, a long straight-edge *F* may be set at right angles with the line *a—a*, and used instead. To accomplish this, a wooden centering piece is inserted between the pillow-blocks, and a point *G* located midway between their inner surfaces. A point *H* is also located midway between the center lines *b—b*, if the central point used in setting the bed on the planer is not visible. Then, with a pair of long trammels, arcs *g* and *h* are scribed from the centers *G* and *H* respectively, and the edge of straight-edge *F* is set to coincide with the intersection of these arcs. The mandrel may then be set parallel with the straight-edge. As the former is above the latter, a gage equipped with a special leg, as shown at *K* in the engraving, will be found convenient for accurately measuring the distance between the two. This leg simply consists of a short cylindrical piece *l* (drilled to receive the gage wire) which bears against the surface of the bed and straight-edge, and insures the same vertical contact against the latter. As will be seen by referring to the engraving, this gage can only be used, in this case, at points *m* and *m*, where the straight-edge is in contact with the bed. If the mandrel is shorter than the one here shown, lines *n* and *o*, equidistant from the edge *F*, can be scribed with a pair of hermaphrodite calipers, and a gage *E* used to set the mandrel from these lines. Of course, after each horizontal adjustment, the mandrel is tested for parallelism from the spots *f* or with a straight-edge, as explained. The middle collar *C* should not be set against the boss *e* and tightened, until after the necessary adjustments have been made.

Prior to pouring the babbitt into the bearings, the latter should be heated somewhat to prevent the molten metal from being chilled when it comes into contact with the casting, as this would make the metal sluggish and doubtless result in an imperfect lining. It is also the practice to smoke, or cover with paper, those parts of the mandrel which are to come into contact with the metal, when babbitting solid bearings, to facilitate the removal of the mandrel from the bearing when the metal is cooled; but for two-part bearings, such as herein illustrated, this will not be necessary. As before stated, both the pillow-blocks proper and their caps are to be lined at one pouring of the metal. To accomplish this, liners *r* of cardboard, a little longer than the length of the bearings, are inserted between the caps and the pillow-blocks to prevent the metal, when it is poured into each of these parts, from uniting; the bed is then turned on its side, so that the mandrel stands in a vertical position, and the metal is poured from the ends of the bearings. When the bearings are being scraped, as described on the Shop Operation Sheet accompanying this issue, the shaft itself, or a special scraping-in mandrel should be used as the hot metal is apt to spring the one used when babbitting. A portable forge, preferably with a coke fire, is desirable for heating the metal, as it can be brought to the place where the work is being done. When the fire is some distance from the work, the metal is often over-heated, to prevent it from being too cool for pouring, and the effect of high temperatures on metals of low fusibility is always harmful. The method of testing the temperature of the metal (given in the Shop Operation Sheet accompanying this issue) by heating it sufficiently to char a pine stick, is perhaps as reliable and practicable as any—at least it has the merit of simplicity, which should prevail as far as possible in connection with all shop work.

* * *

During the month of October the "surprise tests" on the Pennsylvania Railroad, numbered 22,831, and with the exception of 82 cases, the employes obeyed the rules to the letter. Of these tests, 3,365 were for the observance of block signals set in unexpected ways, and the percentage of those observing these signals was 99.1. To ascertain the thoroughness with which employes observe emergency signals, such as fusees, torpedoes, etc., 3,357 trains were tested, and in 99.6 per cent of the cases the rules were obeyed perfectly.

APPLICATION OF LIFTING DEVICES TO ASSEMBLING WORK.

ALFRED SPANGENBERG.*

In assembling work, the operation of scraping the sliding or revolving machine elements to a fit, necessitates their being lifted and turned over a number of times. When the pieces are too heavy to be lifted by hand, the importance of providing efficient lifting devices is much greater than is usually apparent. Very frequently the time consumed by the scraper hands in trying the pieces together to find the bearing, and in waiting for the crane, exceeds, by quite an appreciable percentage, the actual length of time consumed in the operation of scraping.

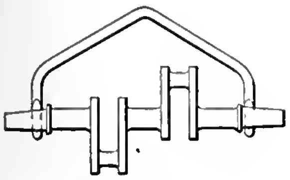


Fig. 1. Machine Steel Sling for Lifting Crank-shafts.

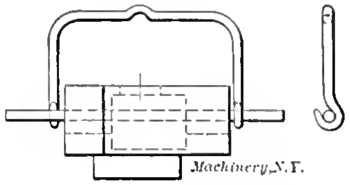

Fig. 2. Device for Lifting Turrets.

In many instances a properly designed lifting device is far superior to a chain or rope for handling the work, and in cases where a device can be designed to eliminate the use of both a chain and crane, a large saving in time can reasonably be expected. The main points to be considered in the design of an efficient lifting device are stated in the following rules:

1. The device must be safe and simple.
2. It must admit of being quickly attached to the piece to be handled.
3. Avoid the necessity of detaching the device when trying the pieces together.
4. In case the work has to be turned over to scrape the surface, balance the piece so that it will swivel easily and yet hang in a position to slide or lower onto the fixed member.
5. Make the device adjustable to allow for the varying center of gravity in similar pieces of work.

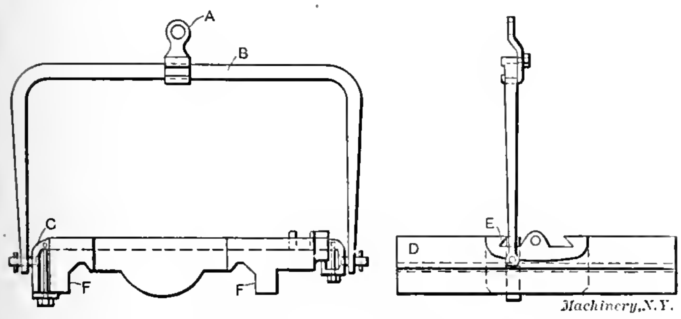

Fig. 3. Sling for Lifting Lathe Carriages, which is equipped with an Adjustable Crane-hook Eye.

6. If possible clamp the device to the work by making use of holes already in the work.
7. Admit of close adjustment for height.
8. Handle the work without the use of a chain or crane.

The accompanying engravings illustrate a number of lifting devices, and suggest their application to a variety of work. The function of the device illustrated in Fig. 1 is clearly indicated by the sketch. The device is made of round machine steel bent to the shape shown. Fig. 2 represents another application of a similar device for lifting turrets. The device is attached to the turret by means of a round bar passing through the holes in the turret. The ends of this bar are left long to serve as handles for revolving the turret on its carriage to find the bearing. A device of this character covers the fundamental principles laid down in rules 1, 2, 3, and 4.

The device shown in Fig. 3 is for handling a lathe carriage, and illustrates an application of rule 5. It will be observed that the eye *A* can be adjusted along the frame *B*. This is to balance the carriage and allow for the varying center of gravity in different carriages. The method of clamping the swivel bar *C* to the carriage is clearly indicated. The carriage is balanced lengthways so that the end *D* will be raised first, the object being to prevent the swivel bar *C* from slipping away from the angle *E* of the carriage. In some designs the sides of the carriage at *F* are a close fit on the lathe bed. In this case the carriage may bind when being lifted off the bed, and if a power crane is used there is danger of springing the carriage. The safety device shown in Fig. 4 overcomes this difficulty, and is so simple that little explanation is needed. The device is suspended from the crane hook by the link *G*. The hook *H* is for attaching the carriage by the device shown in Fig. 3. When lifting the carriage off its bed most of the weight is taken by the crane; the lever *I* is then pulled down until the spring pin enters the hole *J*, when the carriage is clear of the bed. The operation is reversed for lowering. By this method any tendency of the carriage to bind is quickly felt, and the danger above referred to avoided.

Fig. 5 illustrates a method of lifting a swivel by hand. Two round machine steel bars, about 12 inches longer than the swivel, are laid one in each angle and bolted together as indicated. The projecting ends serve as handles to lift the swivel. In case the swivel is lifted by a crane, a sling chain is passed around the handles to lift the swivel from its shoe; it is easily turned over by making a hitch to one of the bars.

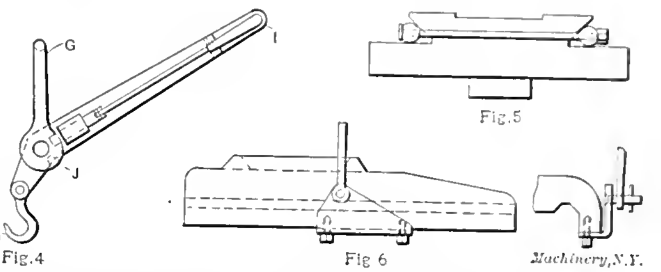

Fig. 4. Crane Attachment, for ascertaining whether a Piece being lifted from its Seat binds. Fig. 5. Device for lifting a Swivel by Hand. Fig. 6. Method of attaching a Lifting Device to a Turret Carriage.

The method of attaching a lifting device to a turret carriage is clearly indicated in Fig. 6. The point mentioned in rule 6 is observed in its design, and the holes already drilled in the turret carriage for the gibs are made use of for clamping the swivel plates.

The gravity tongs shown in Fig. 7 are very efficient for handling work of the character represented. They are so simple that no description is necessary.

For lifting a lathe face-plate for the purpose of screwing it onto the spindle, the method shown in Fig. 8 is very convenient and enables the work to be done quickly. The face-plate is lifted by the gravity tongs. The taper shank of the pin *A* fits into the spindle *B*, and the straight end is an easy fit in the hole of the face-plate. When the pin is lightly driven into the spindle hole, it supports the face-plate after it is released by the tongs. Being thus centered and free to revolve, the face-plate is easily screwed onto the spindle.

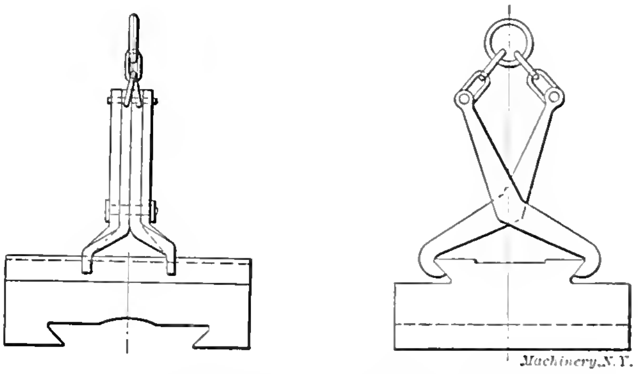

Fig. 7. Gravity Tongs for Handling Work such as illustrated.

Especially where head-stocks are built in lots, this method of screwing on the face-plates will save considerable time.

The function of the device shown in Fig. 9 is clearly indicated by the drawing. The device is an application of rule 7, and is for lifting turret lathe chucks when attaching them to the chuck gear. The T-slot in the chuck is made use of to clamp the device. The turnbuckle, with its right- and left-

---

* Address: 951 W. 5th St., Plainfield, N. J.

hand threads, provides an easy adjustment for height so as to center the chuck with the gear.

In shops where the crane facilities are limited, the jib crane shown in Fig. 10, which is used in connection with an air hoist or chain fall, will be found very useful. With this outfit there is no excuse for not being "on the job." The ball thrust bearing A allows the arm to be swung easily when under load. The base can be clamped to a lathe bed, cross-rail, or any solid foundation, and the device used in connection with the lifting devices previously referred to.

Fig. 11 shows two views of a device designed by the writer, for fitting a saddle onto a boring mill or planer cross-rail. Rule 8 is observed. The object of the device is to provide a means for holding the saddle in a position to scrape, turn it over, and slide it onto or off of the cross-rail, without the use of a crane. Referring to the illustration, the frame *A* has four legs *B*, and is fastened to the cross-rail by the braces *C*. This frame serves the purpose of a track to guide and support the saddle *D* when it is off the cross-rail *E*. The saddle is carried by the strap *F* and rollers *G*, and when in position to be scraped, is held by the clamp *H*. By referring to the elevation shown in Fig. 12, of a similar device, it will be observed that the frame at *I* is cam-shaped. The object of this curve in the track is to keep the saddle from touching the end of the cross-rail while being slid on or off, making the operation easy and preventing a false bearing being made on the saddle, as would be the case if the saddle had to drag over the end of the cross-rail. Fig. 12 represents the end of a boring mill cross-rail lying on horses, in position to have the saddle fitted. In practice the edge *J* of the cross-rail would be elevated slightly so as to easily keep the saddle in contact with this edge when it is being slid along.

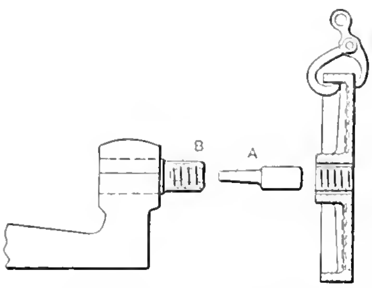

Fig. 8. Appliances which Facilitate placing the Face-plate on the Lathe Spindle.

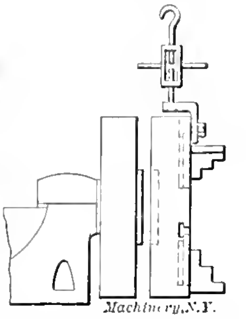

Fig. 9. Crane Attachment for Lifting Turret Lathe Chucks.

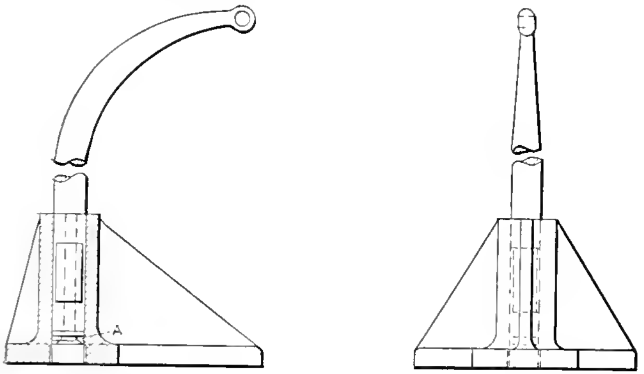

Fig. 10. Small Individual Crane provided with Ball Thrust Bearing.

When using a power crane, and lifter similar to the one shown in Fig. 3, for doing the work just described, trouble was experienced in obtaining the proper adjustment for height so that the saddle would slide easily onto or off of the cross-rail. This was to be expected, as the variation in height had to be within a limit of say ¼ inch, an adjustment not easily obtained with a power crane. The main advantage to be gained, however, by using the device illustrated in Fig. 11 was in not having to wait for the crane.' A similar device could easily be made for handling lathe carraiges when fitting them to the bed.

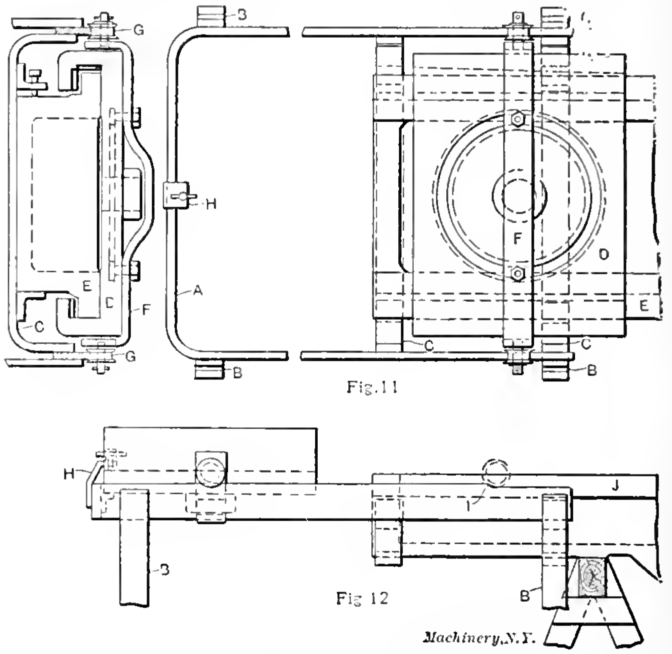
* * *

The United States exported $267,524 worth of aluminum in eight months during 1908.

CARNEGIE'S PROFIT-SHARING PLAN.

An equitable reward for labor—that is, a just share in the profits as well as the losses of an enterprise—may be impossible under present economic conditions, but there are many able thinkers who believe that it can be more nearly realized than is possible with any of the existing schemes of stimulating production, *i. e.*, piece-work, bonus, premium, "individualized efficiency," etc. The result of all the existing plans has been, sooner or later, to *fine* the worker for greater production by reducing wages. The consequence is that workmen have virtually set a limit of daily production in almost every industry beyond which they will not go.

Andrew Carnegie, in his new book, "Problems of To-day," makes the prediction that the wage system as it is at present maintained is doomed to extinction. He sees ahead to the time when the wage worker of to-day will be the partner in a profit-sharing system which will do away with all the recognized methods of rewarding labor. Mr. Carnegie's idea is that the profit-sharing system will extend so far that all branches of industry will adopt it. He advocates the guaranteeing to the workingman, of the minimum wage, solely to keep his mind easy and free for his work, but the wage should only be a part of the pay of the worker. He should have an interest in the business—a partner's interest—with the status of a share-owning official and a voice in the management. The workingman and the capitalist, under the universal profit-sharing system, will become one. He holds that the universal profit division system will not only benefit the workingman, but will be a great help to business and industry generally. With every employe a shareholder in the particular shop or establishment that claims his labor, most of the disputes between capital and labor would be prevented. There would be a feeling of mutual regard, which is now sadly lacking.



Figs. 11 and 12. Device used when fitting a Saddle to a Cross-rail, which enables the Former to be removed from the Latter and scraped, without the Use of a Crane.

"Thus we see that the world moves on, step by step, toward better conditions. Just as the mechanical world has changed and improved, so the world of labor has advanced from the slavery of the laborer to the day of his absolute independence, and now to this day, when he begins to take his proper place as the capital-partner of his employer. We may look forward with hope to the day when it shall be the rule for the workman to be partner with capital, the man of affairs giving his business experience, the workingman in the mill his mechanical skill, to the company, both owners of the shares, and so far equally interested in the success of their joint efforts, each indispensable, so that without their cooperation success would be impossible. I am convinced that the huge combination, and even the moderate corporation, has no chance in competition with the partnership which embraces the principal officials and has adopted the system of payment by bonus or reward throughout its work. The latter may be relied upon, as a rule, to earn handsome dividends in times of depression, during which the former, conducted upon the old plan, will incur actual loss, and perhaps land in financial embarrassment."

LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

ACCURATE METHOD OF SETTING MILLING CUTTERS.

In a certain shop where gears are required to be cut within a limit of 0.00025 inch, the cutters are set in the following manner:

1. The cutter is centered over the arbor as nearly as possible, with a gage.
2. The blank is clamped to the arbor and a cut is taken through.
3. The blank is taken off the arbor and the cut is colored with copper sulphate.
4. The blank is *reversed* on the arbor and *not fastened.*
5. The cutter is run through the cut again and the points where the cutter touches noted.
6. The table is re-adjusted and the operations repeated until the cutter touches evenly on both sides.

The blank floats on the arbor when reversed and not clamped, and if the cut is not exactly central, the cutter will rub off the copper on one side of the cut at the bottom and on the other side at the top.

H. G. H.

CHANGING OLD LATHE TO INCREASE CUTTING VALUE.

We were blessed with a supply of old lathes that had small cutting power and light feed, and while they were probably good for certain work, they were not suitable for all our work, particularly for shaft turning, as frequently we had more than the customary amount to turn off on the ends; consequently it was decided to try to change one of our most promising looking lathes into one with some modern qualities. We wanted to make it as powerful as was possible under the existing circumstances, and this was accomplished as explained in the following:

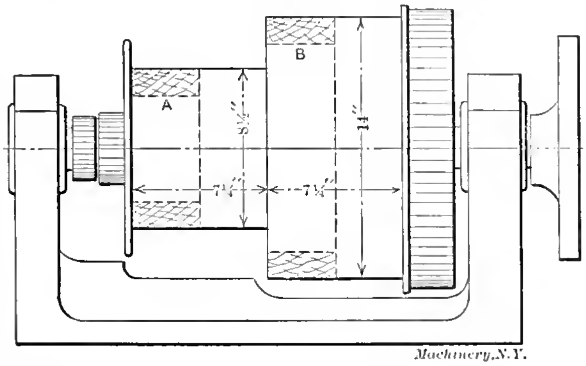


Fig. 1. Change in Cone Pulley to Provide for Wider Belt.

The lathe chosen for this change had the customary four-step cone pulley, driven by a 3-inch single belt, and the ordinary carriage feed. In order to get more pulling power, the width of the belt had to be increased, which was done by changing the cone pulley from a four-step to a two-step cone. This change was accomplished by rough turning the steps at *A* and *B*, Fig. 1, and forcing a solid wooden ring on at *B* and putting one on in halves at *A*. In order to get good holding power of the wood on the iron, three coats of shellac were applied, each one being allowed to dry before applying the other. The last coat was allowed to dry until it was in a sticky condition, then the wood was pressed on the pulley and further secured from turning by screws. The wood and iron surfaces were then thoroughly covered with thick paper. The counter-shaft cone pulley was changed in the same manner. This allowed us to get a 6-inch double belt on the cone pulley. A corresponding increase of power was made in the drive from the line to the counter-shaft. Fig. 1 shows the arrangement of the cone pulley after the change had been made, the dotted lines showing the original contour.

The tool-post had to be made stronger (for the present one would not take the cut that the 6-inch belt could pull) and Fig. 2 shows how this was easily and cheaply accomplished. All parts, except the screws, are cast iron, and did not cost very much to make. The holder has two tool slots which allow a wide range for the tool without the necessity of changing the position of the post. The tool-post can be raised or lowered easily by the ¾-inch adjusting screw *A*, and the slot cut in the lower flange allows the post to be clamped by the set-screw *B* and securely held in any position desired by the operator.

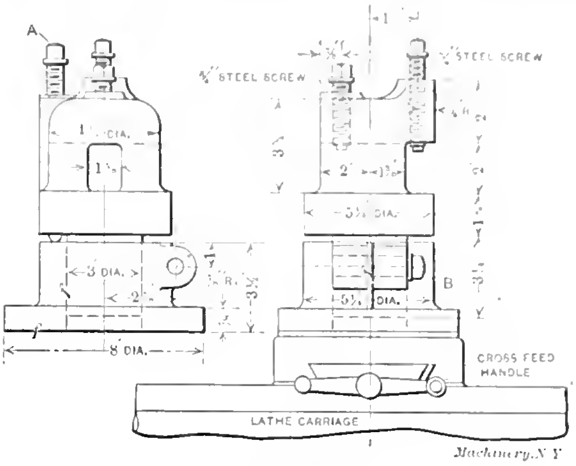

Fig. 2. The New Design of Tool-post.

The change was made for a comparatively small cost, and it increased the cutting value over 100 per cent, and paid for itself in a short time.

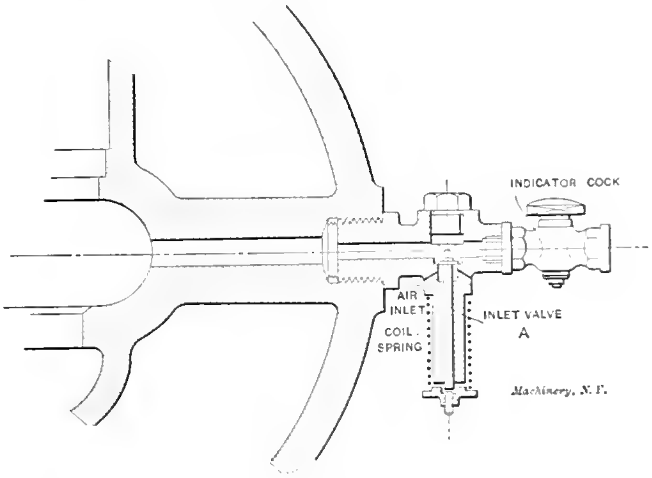
Providence, R. I.

AIR INLET VALVE FOR INDICATOR PIPES OF INTERNAL COMBUSTION ENGINES.

The difficulties met with in taking indicator diagrams of internal combustion engines operating on low grade gases, due to ignition taking place during compression, have often been discussed in the technical papers. The journal *Haeders Zeitschrift* which is devoted to accidents, lately cited several cases where it was impossible to take diagrams because the pipe or passage which leads to the indicator, acted in the same way as an ignition tube. So far as the motors themselves are concerned, it is necessary to stop up this passage in order to permit the machine to operate normally.



Gas Engine Indicator Pipe with Air Inlet which prevents it from becoming Heated.

These inconveniences we have likewise experienced, but we have completely overcome them, thanks to our valve for admitting air, which is illustrated in the diagram shown herewith. During the suction of the mixture, valve *A* permits the outside air to enter and clear the indicator passage of all burned gases. As the tubes are full of pure air during the compression stroke, the mixture is prevented from entering, and, furthermore, the air cools the passage to the indicator

very effectually. This valve can be employed with very good effect also for cooling any closed cylinder space which heats too rapidly, or a corner where the hot gases have a chance to remain confined and thus produce premature ignition. The device can also serve to cool the valves without water, introducing the air through the stem.

Huyssinghen, Belgium.

WINDING SPRINGS WITH INITIAL TENSION.

There are many spring winding devices, but it is seldom one sees anything for winding springs with initial tension, and, in fact, many mechanics would be "up against it" if given a job of this kind. One of the simplest and most effective devices that I have seen for this work, was made by W. A. Bright, foreman of the Decatur Novelty Works.

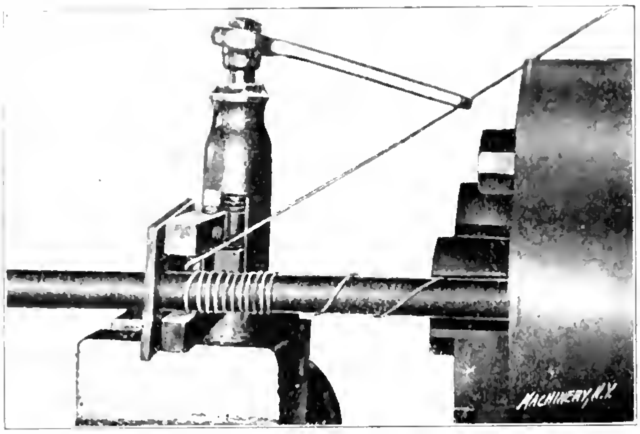

Fig. 1. Method of Winding Spring with Lathe running Forward.

For the sake of clearness, and to show the way the wire runs when winding, I have used a piece of coarse string and have wound it on the mandrel with the coils apart to show the direction of the spiral. Fig. 1 shows how a spring is wound with the lathe running forward, the wire being fed from the operator's left as he stands in front of the lathe. Note the way the cord is run half around the guide pin, and how it is shoved over against the last coil by the pin as it comes around the mandrel on the first turn. Fig. 2 shows the way wire is fed from the back, which Mr. Bright considers the handiest. When winding in this way the lathe is reversed, and the wire is given about a three-quarter turn around the guide pin as it feeds on the mandrel. In winding a spring in this way, the lathe carriage must be fed along so as to give it a lead of a few thousandths inch over the winding of the wire, in order to prevent the wire from climbing upon the coil.

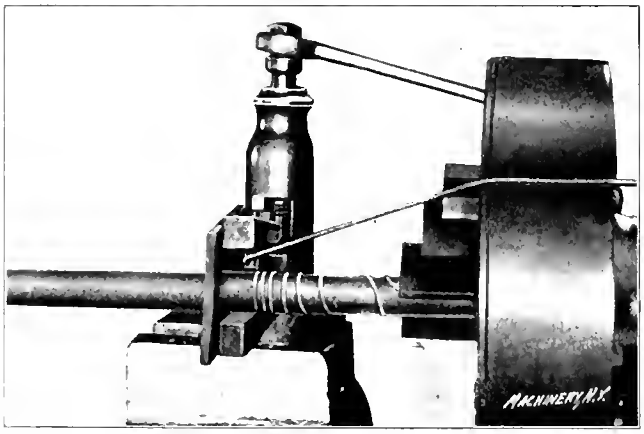

Fig. 2. Winding Spring with Lathe running Backward Note that Wire makes Return Bend around Guide Pin.

Two of the springs wound in this way are shown at *A* and *B*, Fig. 3, and the amount of initial tension is shown by the spring at *C*. This spring is of 14 gage wire, 3/8 inch in diameter, and 3 inches long. The scale registers 24 pounds and the coils have separated so little that it is impossible to insert a common business card. The large spring *E* registered 50 pounds on another scale, with no sign of separation. The device shown at *D* is the same as shown in the lathe in Figs. 1 and 2. The spring *E* is inserted in an exceedingly handy jig for forming the loop on the end. The construction of this jig is too clearly shown to need explanation.

Decatur, Ill. Ethan Viall.

ECONOMICAL DESIGN.

The work of the draftsman, though primarily concerned with the correct layout of mechanisms for performing certain predetermined operations, does not end, by any means, when this layout has been brought within the limits of machine construction, or rather within the realm of mechanical feasibility. When the arrangement has reached this stage, it is absolutely necessary that every detail of the mechanism be carefully considered with reference to its manufacture. Slight modifications in the design of the details often make a big difference in the cost of manufacture, and modern conditions demand that this phase of machine design be very carefully considered.

The engraving shows a sectional plan of a lathe apron, designed by the writer, which will perhaps more fully illustrate what is meant by the title of this article. *A* is a straight-face worm gear driven by the worm on the splined lead-screw. *B* is a friction gear which, by means of a tumbler gear (not shown), may be connected at will either to the gear *C* or the cross-feed-screw pinion (not shown). The gear *C* is keyed to the mild steel rack pinion *D*. *E* is the hand feed-shaft pinion; *M*, the apron; *H*, the apron cover bolted to the front of the apron; *F*, the lead-screw half-nut; *L* the cam for engaging the lead-screw nut, and *G*, the lever for operating the cam. All the bosses *K*, on the apron cover, are the same height so that they may be machined on the planer in quantities. A measuring block is used to set the tool to the proper height. One setting of the tool sizes the whole lot, whereas, if these bosses were faced on the drill press, there would have to be twelve measurements made (including those for the two shafts not shown) to insure an accurate job. Similarly, all the faces *J* on the inner side of the apron *M* are in the same plane. These faces also are machined on the planer and the dimension *N*, that is, the distance from the face *J* to the apron cover seat, obtained from a suitable measuring block.

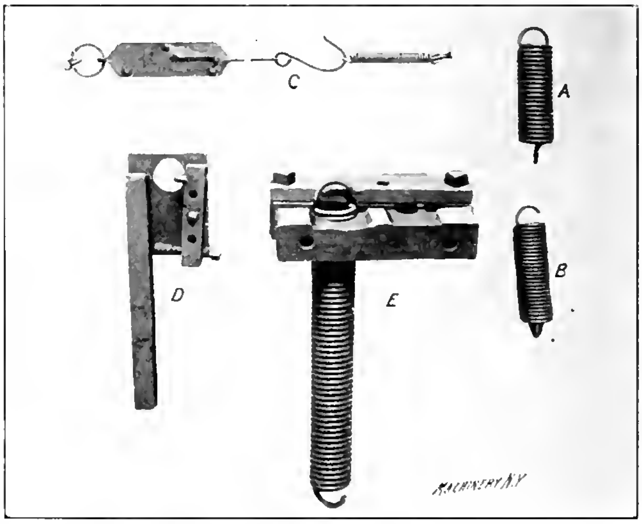

Fig. 3. Sample Springs and Device for Guiding the Wire as it is wound on the Mandrel.

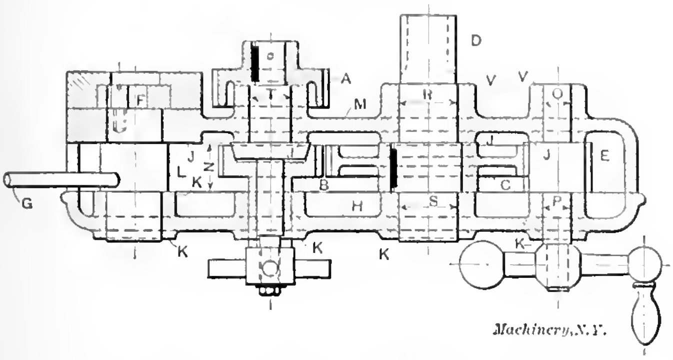
It will be seen that practically all facing on the drill press is done away with; in fact, there is only one boss on the whole carriage that is faced on this machine and that is the one for the worm gear *A*. With the exception of the faces *V*, which are not machined at all, all faces are machined on the planer.

Another operation which is perhaps even more important, is the drilling of the holes for the various shafts. There are twelve bearings in the carriage, altogether—six in the apron and six in the cover, that is, six shafts each with two bearings. Before any of the bearings are drilled, the cover is bolted to the apron, after which the whole carriage (the apron and carrriage are cast together) is mounted in a jig

on the drill press. The special feature which I want to point out is that both bearings of each of the six shafts are equal in diameter; thus *O* is the same size as *P*, *R* the same as *S*, and so on. This is of great importance when drilling the bearings, as the drill may be fed straight through both apron and cover in every case. This is a great convenience and saves considerable changing of drills and jig bushings, which would be inevitable if the two bearings of each shaft were not equal in diameter. Another advantage is that ordinary reamers may be used to ream the bearings, where otherwise special double ones would be necessary to insure correct alignment of each pair of bearings.



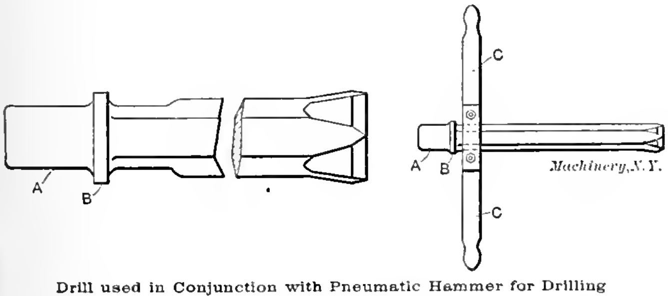
Example of Design in which the Method of Manufacture was considered.

There is still another advantage with this design in that none of the shafts, with the exception of *T*, require fastening endways, the apron cover attending to this. Suppose that the pinion *E* were made separate from its shaft and keyed on; if the shaft were put in from the front, the bearing *P* would require to be larger than *O* to allow the key to be passed through, and if the friction of the keyed joint was not depended on, a collar or some other fastening would be required to hold the shaft endways. With the arrangement shown, however, each of the shafts is largest in diameter between the two bearings, so that the shoulders thus formed do away with all end movement. Of course, this is an incidental feature of the design, but, nevertheless, it is a useful one.

Keighley, Yorkshire, England. ALBERT CLEGG.

INTERESTING USES OF THE PNEUMATIC RIVETING HAMMER.

The writer had occasion to set a bed-plate on an old concrete foundation and the thought of drilling eight $2\frac{1}{2}$-inch anchor bolt holes about 3 feet deep, by the old-fashioned method of sledge-hammer and stone drill, set his mind to work. The outcome was the making of a stone drill such as shown in the accompanying engraving. The shank *A* was turned to suit a pneumatic riveting hammer, and hardened. Two handles *C* were also provided and bolted under the collar *B*, as shown. It required two men to operate the drill, one to run the hammer while the other turned the drill back and forth about a quarter of a turn. The result was that the holes were drilled in less than three hours, which is only a fraction of the time usually required for the same work by the old method.



Drill used in Conjunction with Pneumatic Hammer for Drilling Anchor Bolt Holes.

Another interesting use of the pneumatic riveting hammer, is to drive out fitted bolts that have become tight by rust or other causes. The instance in this line to which the writer refers was the removal of connecting-rod strap bolts on a small locomotive. These bolts were driven in from the top, and when it was necessary to take them out it was impossible to move them, and as a fair blow could not be given with a sledge, this method was abandoned. A 10-ton hydraulic jack was then tried, and while it would lift one side of the engine, the bolts would not stir. The pneumatic hammer with the ordinary button-set in it was next applied, and the result was that the bolts were removed in less than a minute each.

R. S. F.

IMPROVEMENT IN FEMALE CENTERS FOR FLUTING SMALL TAPS.

The improvement in female centers shown in the accompanying illustration is intended to be used when fluting taps 3/16 inch in diameter or smaller, provided with male centers. In Fig. 1 is shown the ordinary half center, as usually employed, which is expensive to make, and which is not very satisfactory, as it does not hold the tap as securely as a solid center. Besides, these centers wear out quickly, and the cost of maintenance therefore becomes considerable. In Fig. 2 is shown an improvement which possesses several advantages. The centers themselves are located in a circular washer or disk, having a projection on one side, which fits into a recess in a shank, which in turn fits into the tailstock. These round disks are made from tool steel but are not hardened, while the shank is made from machine steel. The object of not hardening the disks is to avoid the risk of breaking the fluting cutter if it should happen to run into the disk when fluting very small taps. The disks are provided with six holes, and as soon as one wears out, the disk is simply turned around to the next hole until all six are worn out. The disks are held to the holder by an ordinary fillister-head screw. In order to bring the hole used as a center in line with the spindle, the bottom hole is provided with a small pin which fits into a corresponding hole in the holder. One of these center disks will last five times as long as the center shown in Fig. 1, and as it costs no more to make, the advantage gained is obvious. CHARLES E. SMART.

Greenfield, Mass.

Figs. 1 and 2. Ordinary and Improved Forms of Centers for Holding Small Taps when fluting them

INDEXING IN DEGREES AND MINUTES.

Here is a kink that may be of interest to some brother tool-makers or machinists. Some time ago I had a job that required to be indexed in degrees and minutes, and this is the way it was done: Taking a B. & S. indexing head, I used the 54-hole division on the plate, which gave me 1 degree every 6 holes, or 10 minutes to one hole. I then made a plate, as shown in the engraving, where *A* is a stud that fits any of the 54 holes and serves as a pivot for the plate. The 9 holes are located so as to divide the space between two holes, of the 54-hole circle, into 10 equal parts, each part being equivalent to 1 minute on the work. With this arrangement, I was able to index any number of minutes.

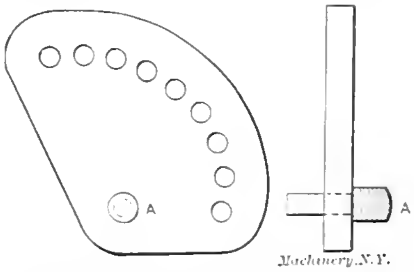

Plate for Dividing the Space between Two Holes on the Index Plate so as to obtain Minute Divisions.

New Britain, Conn. J. MATHIEU.

[An index plate having a 54-hole circle is special on Brown & Sharpe machines, but a regular 27-hole circle could also be

used for indexing 10 minutes. Obviously, the number of holes for indexing one degree would be one-half that of the former case or 3 degrees; therefore it would be necessary to double the number of holes in the dividing plate to obtain one-minute divisions.—EDITOR.]

UNIQUE METHOD OF FINISHING CYLINDERS.

The cylinder and piston shown in Fig. 2 are used on a gas machine for automatic block signals. They are made of bell metal, and the piston was required to so fit the bore of the cylinder that sufficient gas, under 40 pounds pressure, would leak past it to bring the pressure in a receiver of given size, up to 30 pounds, in 10 minutes. This job was a very expensive one, as a variation of a thousandth of an inch one way or the other would mean that the requirements would not be fulfilled. Originally these cylinders were bored and then lapped to size with vaseline and powdered glass. By this method about three out of every ten stood the test. I was given this job to perfect, and as it was the first work that I had done in this particular shop, I felt somewhat uneasy, but went ahead with it nevertheless. Twenty-five cylinders were first bored on the lathe with a boring-bar, to within from five to ten thousandths of an inch of the finish size, which is 2½ inches. The cylinders were then pressed on mandrels and turned on the outside. While doing this I thought of a scheme for finishing the bore which would not only make it possible to do the work quickly and accurately, but which would produce a smooth surface as well. The plan was to enlarge the cylinders to the finish size by forcing hardened tool steel plugs through them, each plug being slightly larger than its predecessor. Four tool steel plungers, 12 inches in length and varying in size from 2.441 to 2.500 inch, were turned, hardened, and ground and the ends rounded to prevent the cylinders from being roughed. A press, as shown in Fig. 1, was then made for forcing the plungers through the cylinders. Its construction is so simple that little explanation is necessary. The cylinder *A* was clamped between two plates *B* having annular recesses into which the cylinder flanges fit. The four steel plungers *C*, beginning with the smallest, were then forced through the cylinder by a 10-ton hydraulic jack. The bores of the cylinders, when finished by this method, were as smooth as a gun barrel and the required size.

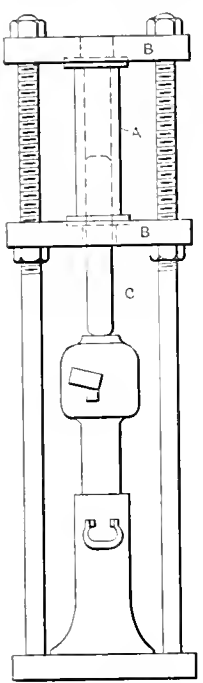

Fig. 1. The Press equipped with a 10-ton Hydraulic Jack.

The next thing was to determine how much to grind the pistons under size to give the amount of leakage required. By experimenting, this was found to be three-fourths of a thousandth. All of the pistons were then ground to the same size by the aid of a micrometer. This method of doing the work was so successful that twenty-four out of twenty-five of the pistons and cylinders stood the test. Before testing, part of the hole through the piston, which was drilled in for the arbor, was plugged with babbitt. The piston was then placed in the cylinder and the ends of the latter tightly closed. The gas, under 40 pounds pressure, was then admitted to one side of the piston and the time noted. If, after a lapse of 10 minutes, the gage connected to the opposite side of the piston by a short length of pipe, indicated 30 pounds, the relative sizes of piston and cylinder were correct.

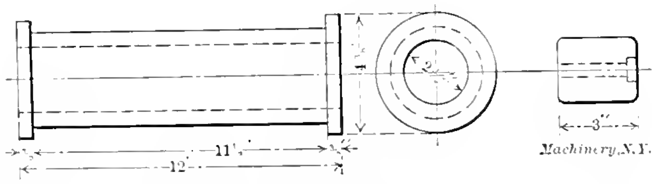

Fig. 2. The Cylinder, the Bore of which was finished by forcing Hardened Steel Plugs through, as illustrated in Fig. 1.

Plainfield, N. J. JOSEPH R. WEANER.

POWER TAPPING.

In ordinary shop practice hand tapping has been most commonly used, but in recent years, with the improved tapping machines, tapping attachments, and collapsible taps, power tapping has in many instances taken the place of the hand tapping method. Of course, in some cases it is impossible to do anything else but tap a hole by hand.

The great disadvantage of tapping by hand is the time consumed. While cutting a thread with a tap is not a difficult job, it requires care in the manipulation. To tap a hole by hand requires two or three taps. The first tap is the taper tap. This starts the thread and care must be taken when starting this tap to keep it parallel with the hole to be tapped. Then the plug tap is used which completes the thread. If the threads go to the very bottom of a "blind" hole, the third tap is used, which is called the bottoming tap.

SPEED OF STANDARD TAPS.

Diameter of Tap.	Cast Iron.	Wrought Iron.	Diameter of Tap.	Cast Iron.	Wrought Iron.
3/16	340	265	1	72	57
1/4	295	230	1⅛	63	50
5/16	240	190	1¼	57	45
3/8	197	152	1⅜	51	41
7/16	170	122	1½	46	38
1/2	145	114	2	34	28
5/8	117	91	2¼	30	26
3/4	96	76	2½	26	23
7/8	84	65	..	..	..

When tapping by power one tap is all that is necessary. The tap is securely held in a chuck which guides it straight. In machine tapping it is found advisable to drive the tap by means of a friction tap holder or some other friction drive. The friction must be adjustable, so that enough tension can be secured to drive the size tap being used. If the tap should strike bottom or a hard spot in the casting it will slip.

To secure good results in machine tapping it is necessary to run the tap at the proper speed. Of course, speed depends a great deal on the metal being tapped and the condition of the tap. Under ordinary conditions, with the tap in good shape, speeds of 15 to 20 feet per minute have been found satisfactory. The following table gives the proper range of speeds for taps most commonly used.

Cincinnati, Ohio. A. C. PLETZ.

CRITICAL SPEED CALCULATION.

If the deflection of a revolving part is due only to the weight, the critical speed is always a function of the square root of the shaft deflection. Below are given formulas for calculating the critical speed for four different cases. In the formulas:

W_1 = weight of wheel in pounds,
W_2 = weight of shaft in pounds,
D = diameter of shaft in inches,
l = one-half the distance between bearings in inches,
$L = 2l$,
N = critical speed in R.P.M.

Case 1.—*Unloaded Shaft.*

$$N = c\frac{D^2}{\sqrt{W_2 l^3}}$$

Kind of Bearings.	Value of *c*.
Two flexible bearings	794,000
Two fixed bearings	1,775,000
One flexible, one fixed bearing	1,285,000

Case 2.—*Single load at center between bearings.*

$$N = c\frac{D^2}{\sqrt{W_1 l^3}}$$

Kind of Bearings.	Value of *c*.
Two flexible bearings	558,000
Two fixed bearings	1,116,000
One flexible, one fixed bearing	837,000

Case 3.—*Single load; load not at center.*

$$N = c\frac{D^2}{\sqrt{KW_1L^3}}$$

in which formula

$$K = \frac{a(L-a)\ (2L-a)\ \sqrt{2La-a^2}}{L^4},$$

if a = distance from load center to center line of farther bearing.

Kind of Bearings.	Value of c
Two flexible bearings	900,000
Two fixed bearings	1,800,000
One flexible, one fixed bearing..........	1,350,000

Case 4.—*Multiple Loaded Shaft.*

$$N = \frac{N_1\ N_2\ N_3}{\sqrt{N_2^2\ N_3^2 + N_3^2\ N_1^2 + N_1^2\ N_2^2}}$$

In which formula

N = critical speed of system,

N_1 = critical speed of unloaded shaft,

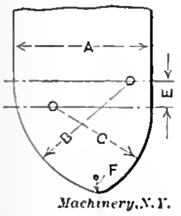
N_2, N_3 = critical speed of each load separate.

These formulas apply to steel shafts having a modulus of elasticity $E = 30{,}000{,}000$. E. A. LÖF.

Chicago, Ill.

STANDARD DRILL AND REAMER TABLES.

The accompanying tables give all the necessary data for laying out correct drill and reamer fluting cutters. The drill table stops at the 1¼-inch size. Larger drill cutters are laid out in the same ratio, approximately; *E* loses about 0.04 inch for every half inch in diameter that the drill increases until the dimension disappears; *C* also decreases as shown until it equals one-half of *B*. In making the formed tool, the outline of the cutter is laid out on zinc and a fly tool made, after which the formed tool is planed and finished.



DIMENSIONS OF DRILL FLUTING CUTTERS.

Diameter of drill = D.

Size of Drills, D	A	B	C	E	F

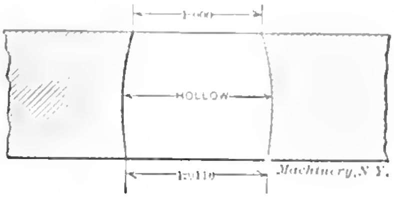
NOSMOT.

ECONOMICAL METHOD OF MAKING BLANKING DIES.

Die-makers are familiar with the fact that dies when hardened will swell in such a manner that the central portion of the metal in a hole will bulge out towards the center. In order to give sufficient clearance to a die in spite of this tendency, it is necessary to provide for a rather large clearance angle. This being done, it is evident that when the die has been ground down to a certain depth, the hole is very much larger than it was originally, and for many purposes the die must be discarded before it has been used up. The following method of making dies permits them to be ground down until but a small thickness of the steel is left, and as the writer has used the method successfully for the past four years, it may be of interest to others.

Take a die blank one inch thick and lay out the correct form on the blank, drill to the scribed lines, remove the core, and then finish the die with a clearance of about one third of one degree, or twenty minutes, which will give a clearance of about 0.0058 inch on each side at the bottom of the die. Now, scrape or file the center of the die hollow, as shown in the illustration. The amount removed at the center should be about 0.003 inch. Then harden as follows: Place a piece of cast iron or machine steel larger than the surface of the die on the top of a coke fire, and heat it to a cherry red. Then place the die with the face down on this cast iron or machine steel piece and heat until it is cherry red; then plunge the die in slightly warmed clear water, and keep it in the water until it becomes of the same temperature. Then remove it from the water and quickly place it on the fire again, and heat it until it is warm enough to melt soft string solder. Then dip it again, thereby finishing the hardening and tempering process. When the die is so hardened it will swell about 0.003 or 0.004 inch in the center so that the opening will not be any larger in the center than it is at the bottom, and the die may be ground and sharpened all the way down and used until too thin for service. Dies made in this manner will give better satisfaction and perform about three times as much work, or, in other words, last three times as long, as dies made with the ordinary 1 or 1½ degree clearance. The same hardening process should be followed in hardening punches.

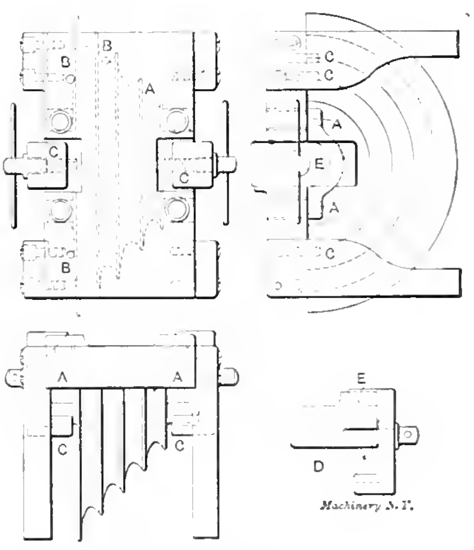


Method of making Blanking Dies which permits them to be ground off on the Face, thus insuring Long Life.

St. Louis, Mo. JAMES S. GLEW.

JIG CLAMPING DEVICE.

We had a number of cast-iron pulleys that were to be used in connection with special lacing machines, and these were cast in halves to make it convenient to fasten them on shafts that were located beneath the benches, in the factories where the machines were to be used.



Plan and Elevations of Jig with Work in Place.

A jig was made for drilling the four holes *A*. There is nothing remarkable about its general design, yet it possesses a neat clamping feature which is so superior to the usual method employed, that I considered it worthy of note. To set the casting preparatory to drilling it is placed against

the [illegible] pins *B*, one of them engaging a groove in the casting, which sets it in the proper relation with the holes in the jig. The clamps *C* are then tightened, the right side of the casting being clamped first to prevent it from shifting.

The working principle of the clamp is clearly shown in the detail *D*. As the clamp is drawn in it ascends the incline *E*, thus moving in the direction of the arrow and tightening against the hub of the casting. The clamps are made with a V which insures a firm hold. PEDRO.

HOLDER FOR DRAWINGS IN MACHINE SHOP INSTRUCTION.

The accompanying half-tone, Fig. 1, and the reproduction of an instruction sheet, Fig. 2, show a method which has proved successful in the instruction in machine tool work at the Saginaw High-school, Saginaw, Michigan. The instruction sheet in Fig. 2 gives all the most needed information regarding the machine on which the pupil is put at work, and is mounted directly on the end of the lathe bed, as shown in the half-tone. This arrangement has proved a [illegible] convenience, and a most effective means of keeping the needed information constantly before the student. Of course, the cutting speeds are only approximate, and are solely given as a basis of calculation. They are given in such a series as can be most easily remembered by the student. The drawing from which the student is to work is also mounted in the same way, above the instruction sheet, as indicated. The lower part of the board may be used as a desk where the student can carry out simple figuring relating to his work, and make notes and sketches if necessary. It might be added that this idea may be suggestive even for the ordinary machine shops. L. N. BRYANT.

ADJUSTABLE EXTENSION TOOL-HOLDER FOR PLANER AND SHAPER.

The accompanying line engraving, Fig. 1, and half-tone, Fig. 2, show the construction and use of an adjustable extension tool-holder which was made to meet the requirements of the operation shown in the half-tone; that is, the cutting of a ⅝-inch rack seat in the sliding head of a sensitive drill press. The construction of the tool is clearly indicated in Fig. 1, and the adaptability of this simple holder is easily seen, the machinist no doubt finding ample opportunity for using this tool for many purposes on planer and shaper work. The steel used for the tool itself is Novo high-speed steel. It will be noted that the clearance angle at the bottom of the tool is obtained by the angle at which the tool slot is cut in the holder. The tool-holder shown has given excellent results for heavy work, is exceptionally rigid, and, being provided with facilities for the adjustment of the tool, avoids unnecessary over-reaching. Tools of different widths and thicknesses may be applied to it. DIETZ.

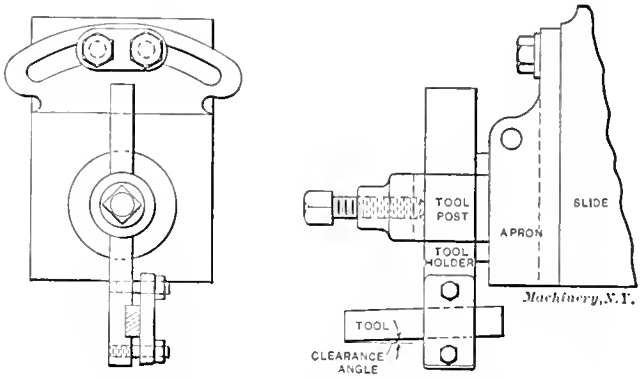

Fig. 1. Adjustable Extension Tool-holder with Tool.

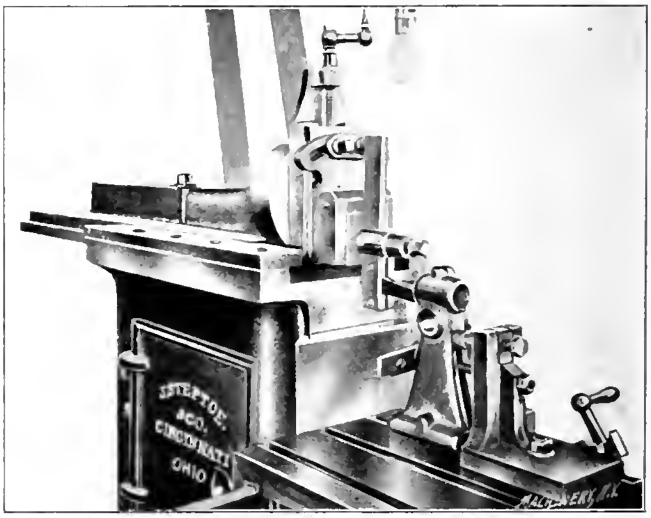

Fig 2. Class of Work to which the Holder is adapted.

TURNING SOFT RUBBER.

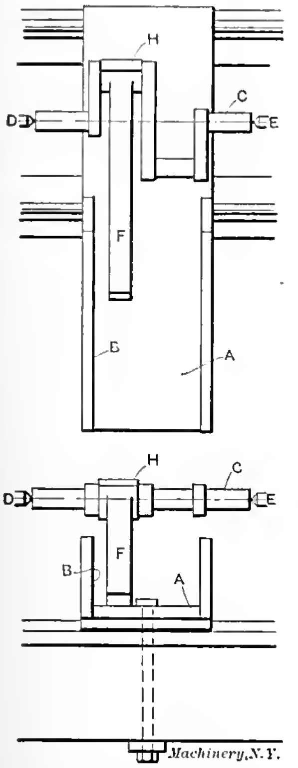
Replying to the question of "L. M." in the December issue of MACHINERY, relating to turning soft rubber, I would say that whenever the shape will permit, soft rubber can best be turned upon a wooden arbor, there being a tendency towards slipping when an ordinary steel arbor is used. A simple though excellent method of getting the hole for the arbor or of putting

holes in soft rubber for any purpose, is to notch the end of a piece of brass tubing whose outside diameter is the size of the hole desired. This piece of tubing is then used as a drill, and it will cut a clean hole slightly under the size of the tubing. When notched right, the end of the tubing should appear like the edge of a saw, although no clearance or setting is necessary. For a cutting tool, use an ordinary side tool ground with lots of clearance and to a *knife edge*, and this should be set the same as any side tool, but fed like a diamond point tool on a straight cut. After turning, the rubber may be smoothed by the use of sand paper or emery cloth. As regards lubrication, water may be used to good advantage, but the rubber should cut very good without any lubricant.

Lynn, Mass. Chester L. Lucas.

FIXTURE FOR TESTING PARALLELISM OF CRANK-PINS.

The accompanying sketch represents a fixture for testing the parallelism of crank-pins on the crank-shafts of air drills and small, high-speed gasoline engines. It consists of an angle-plate *A* that has grooves that match the ways of a lathe. This angle-plate is clamped to the bed of the lathe, and, by means of the lathe bed, the plane of face *B* of the angle-plate is held at right angles to the axis of the lathe. The crank *C* whose crank-pins are to be tested is placed between the lathe centers *D* and *E*, as shown, and the arm *F* is fastened to one of the pins. The opposite sides of *F* are parallel and perpendicular to the adjacent sides, and the end *H* is similar to the end of a connecting-rod. To test a crank-pin for parallelism, the crank-shaft is moved through different angles, and if the pin is parallel with the crank-shaft axis, arm *F* will be parallel with the face *B* of the angle-plate. If the pin is not parallel, the amount it is out can be detected with a pair of inside calipers.



Plan and Elevation of the Fixture for Testing Crank-pins.

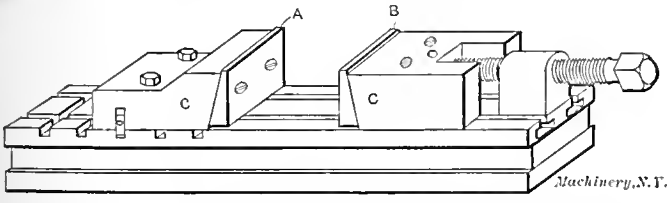
Aurora, Ill.

A DRILL PRESS VISE.

The drill press vise shown in the illustration is "homemade," and one that I used for a number of years. The construction of the vise is simple, and it is almost indispensable for holding small work in the drill press. By referring to the illustration it will be seen that the jaws *A* and *B* are tapering on the back, and also that there is a slight space between them and the vise bed. The jaws are held up by springs, located within the blocks *C*, which bear against nuts attached to the jaws. These nuts fit into T-slots in the blocks *C* and keep the jaws in place. When a piece of work to be drilled is placed in the vise and the jaws are brought to bear on it, the pressure causes them to move downward, thus bringing the work down solid on the parallels with a positive downward pressure, whereas the ordinary vise jaws tend to spring or draw the work away from the parallels, even when it is rapped with the hammer. The jaws and their holders are square with the bed of the vise, and, as the vise is finished square all over, it can be used on the edge, end, or in the usual position.



A Drill Press Vise with Jaws that move Downward when Work is clamped between them.

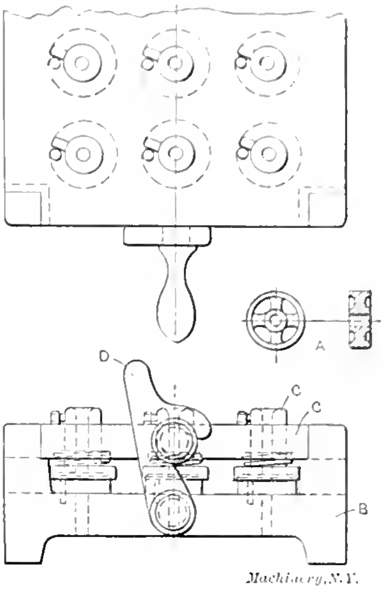
Elgin, Ill.

MULTIPLE JIG FOR SMALL PULLEYS.

We have large quantities of the rough gray iron pulleys, shown at *A* in the engraving, to drill, and so made the jig, a half plan and end elevation of which is shown. This jig is used on a twelve-spindle multiple drill, and in the end view the work can be seen in position. The jig consists of the gray iron base *B* into which is fitted the gray iron cover *C*. The cover *C* holds twelve steel bushings with their ends cupped to center the work. A coiled spring is placed between the cover and bushing to take up any variation in the work. The cover is not hinged to the base as is common with jigs of this style, but is held by latches *D*. By swinging the latches off the handles of *C*, the cover may lifted off out of the way and the base emptied of the chips and work at one time. We found this jig very handy and accurate.

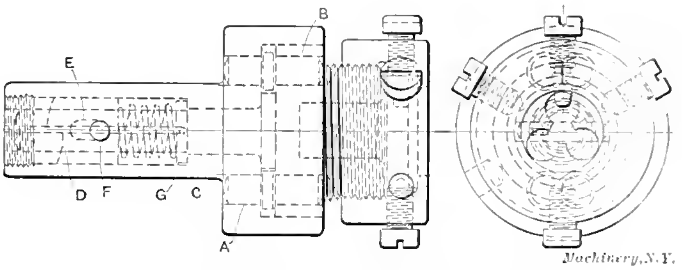


Jig for Drilling Small Pulleys in a Multiple Drill.

P. F. Setag.

RELEASING BUTTON-DIE HOLDER.

The accompanying illustration shows a button-die holder of the releasing kind designed to work on the Brown & Sharpe automatic screw machines. It gives especially good results where the spindle cannot be made to reverse accurately, or where the die is working up to a shoulder.



Improved Design of Releasing Die-holder.

At *A* and *B* are shown the releasing pins which hold the die rigid while the work is being threaded. The spindle reverses when the die is at a certain fixed distance from the shoulder, but before the spindle can complete its reversal, the holder threads right up to the shoulder. The pins *A* and *B* are then disconnected, allowing the spindle *C* to rotate freely.

The spindle is now rotating in the reverse direction when after one-half revolution of die holder the clutch teeth at *D* engage and allow the die to be drawn off the work. The slot shown at *E* is cut in one of the engaging clutches, and the pin *F* is a drive fit in spindle *C*. The diameter of the wire in spring *G* should be from 0.023 inch to 0.032 inch, depending on the pitch of the die used; a die with a fine pitch would not work well with a stiff spring. By the insertion of the washer *G* it will be noted that the spring rotates freely with the spindle and is not subjected to any twisting moment, as it would be if it were in contact with the shoulder in the stationary part of the tool.

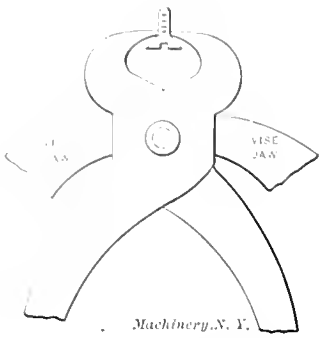
SHOP KINKS.

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

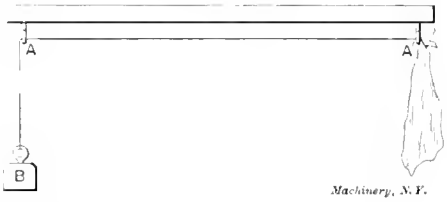
HOLDING SMALL SCREWS WHILE FILING OFF THE POINT.



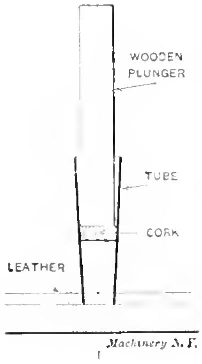
The kink indicated by the accompanying line engraving may be of interest and service to some of the readers of MACHINERY. Some short screws, with bevel heads, were a trifle too long, and were to be shortened by filing off the point. The engraving shows plainly the method of holding the screws while filing. Holding them in this way neither injured the heads of the screws nor the thread. C. F. EMERSON.

ATTACHING INK RAG TO DRAWING BOARD.

Although the ink rag may be one of the minor details in a drawing room, it is nevertheless universally used. The method of fastening it to the drawing board as shown in the engraving, is much better than the usual permanent fastening. A string passes through two screw-eyes *A*, one at the front, the other at the back of the drawing board. The ink rag is tied at the front end of this string, while at the other end is a small weight *B* which returns the rag, after being used, to its proper place at the left of the board. If the draftsman is at the right end of the board, he needs but to reach for the rag, use it and let go, which is ofttimes very convenient. WINAMAC.



METHOD OF INSERTING CORKS IN FRICTIONS.



The accompanying engraving illustrates a method of inserting corks in frictions. The friction in question was lined with leather, ⅜ inch thick, and corks ⅞ inch in diameter were pressed into holes ⅝ inch in diameter. The taper tube shown was four inches long, about one inch in diameter at the large end, and the small end just small enough to fit in the hole punched in the leather. The corks were first soaked in some fairly warm water, after which they were pressed into place with the wooden plunger indicated.

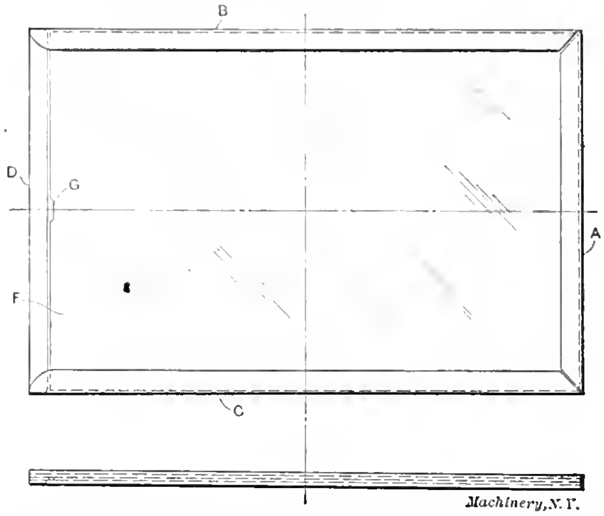
Aurora, Ill. JOHN B. SPERRY.

BLUE-PRINT PROTECTOR

A simple way of protecting blue-prints from being destroyed when sent out in the shop, or when otherwise handled to a great extent, is shown in the accompanying illustration. The protector consists of a sheet iron frame with the edges *A*, *B*, and *C* bent over as shown. The side *D* is left open for the insertion of the print. This side, however, is turned over and hammered down, forming a stop or holder for the print, preventing it from slipping out. On top of the print is placed a sheet of transparent celluloid *F*. A little notch is made in the celluloid at *G*, permitting of getting hold of the blue-print under the sheet for pulling it out. By using this protector many blue-prints will be saved from premature destruction. L. H. GEORGER.

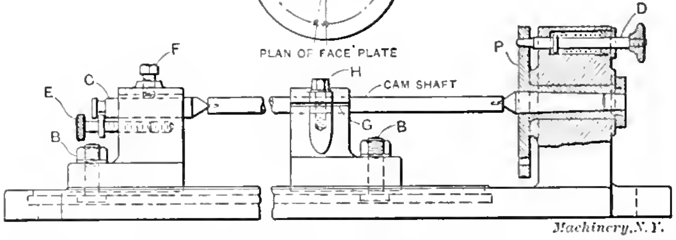
Buffalo, N. Y.

[The method proposed by our correspondent for protecting blue-prints may undoubtedly be of value in some cases, but for ordinary shop use it would be rather expensive, because large celluloid sheets are rather high priced. The cheapest and simplest way of protecting blue-prints is to mount them on bristol board, and varnish them with some kind of high grade varnish. There is one objection to this manner of protecting the prints and that is that if the varnish becomes scratched, it is then sometimes difficult to discern the figures and lines under the scratched portion. The same, however, holds true of celluloid covering as well. This covering will easily become scratched in the shop, and when celluloid is badly scratched it is equally difficult to see the object under it plainly, and at the same time it is impossible to restore it to its original condition.—EDITOR.]



GAS-ENGINE CAM-SHAFT KEY-SEATING FIXTURE.

This fixture is used for milling key-seats in the cam-shaft of a four-cycle, four-cylinder gas engine, with both exhaust and inlet valves on the same side, and actuated from one cam-shaft. The fixture consists of a cast iron base and head-stock, a movable tail-stock, and a steady-rest, which clamps the cam-shaft and holds it firmly in position while the cutter is milling the key-seat. A plan of the face-plate *P* is shown in the illustration. The slot *S* receives the tail of a dog, which is fixed to the cam-shaft. The indexing holes are laid out the required number of degrees apart, depending upon the angle of action of the cams. The angle a should be one-half the angle of action of the exhaust cam, plus one-half the angle of action of the inlet cam, plus one degree. This allows two degrees travel of the crank-shaft from the time the exhaust closes until the inlet opens. The face-plate is locked in position by the spring-plunger *D*, the end of which fits into tapered holes to insure a perfect fit. The center *C*, in the tail-stock, is operated by the screw *E*, and is flatted on top for the set-screw *F* which locks it. Both the tail-stock and steady-rest are held in place by the bolts *B* and *B*, which slide through the T-slot in the base. The bearing in the steady-rest, that the cam-shaft slides through, is slotted at *G*, thus allowing the bolt *H* to clamp the shaft. An ear is cast on each end of the base, and is slotted to receive the holding-down bolts; two are sufficient as the cut is light. W. A. SAWYER.



NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

IMPROVEMENTS IN THE NO. 2½ BATH UNIVERSAL GRINDING MACHINE.

A Bath universal grinding machine of an older type was described in the March, 1905, issue of MACHINERY. The improved design which we herewith illustrate has the same general construction. The table is mounted on a bed which is adjustable to any required angle about a bearing on the top of the base; the wheel spindle is mounted in a head vertically adjustable on a column at the back of the machine; the spindle is driven by a counter-shaft idler which adapts itself to the change in the position of the spindle pulley due to the vertical adjustment; and a very complete set of attachments is provided adapting the tool to grinding of any kind, from the sharpening of the cutters, reamers, etc., to cylindrical grinding, both external and internal, and surface grinding. The most noticeable improvements are the provision of improved automatic feeding apparatus for cylindrical and surface grinding, the new design of the wheel spindle-head, and the provision of the new attachments for doing certain classes of work more conveniently and expeditiously.

Fig. 1 shows the machine as a whole, its general arrangement being as just described. Fig. 2 shows the apron which is provided with two separate power cross-feeds, in addition to the original automatic reversing longitudinal feed. One of these cross-feeds, acting on the ratchet dial on the left, gives minute movements, and is used for cylindrical grinding; it is provided with an automatic stop for sizing the work. This dial is geared with the cross-feed screw to give the required sensitiveness of movement. The link motion operating the double ratchet and pawl movement on the cross-feed screw at the right, gives the coarser feed required for surface grinding. This feed operates at each end of the traverse, is reversible and may be effected at one or both ends of the stroke as required. The cylindrical cross-feed may be made as fine as 0.0002 inch per stroke, while that of surface grinding from 1/64 to 3/32 for each stroke of the table. The reversing mechanism is positive so that work may be ground close to a shoulder. The table slide is controlled by a single lever which reverses the feed in either direction, and starts or stops the traverse movement. By turning the handle at any point of the movement, the table will be stopped at the end of the stroke. The cylindrical grinding feed acts at each end of the table stroke, and the power for operating it is taken from the mechanism that reverses the table slide, through the compression swivel plunger shown below the large knurled knob in the center of Fig. 2.

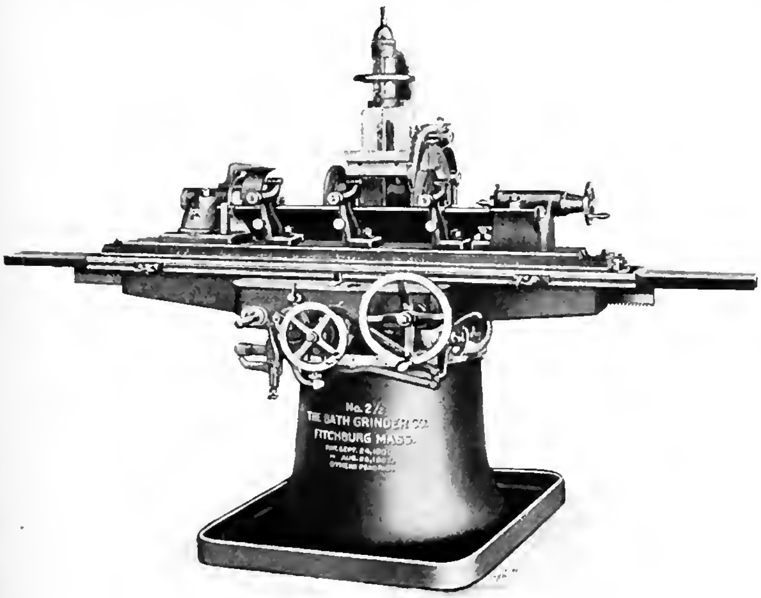


Fig. 1. The Improved No. 2 1-2 Bath Universal Grinder.

Fig. 4 shows the improved spindle-head, rigged up with the various attachments furnished for it. At *A* is seen the plain head. The finished bright surface at the end of the spindle bearing is for convenience in using a square or bevel protractor in setting work or attachments on the machine. Clearances in cutter and reamer grinding, and the setting of the wheel with relation to the work, are measured by the combined elevating screw and sliding graduated rod, together with the revolving dial on top of the machine. These give the micrometer readings. At *B* an extension arbor support for the wheel is shown attached to the head. This is used in surface grinding, sharpening form-cutters, finishing snap gages, and on similar work where a large overhanging of the wheel is desirable. At *D* is shown the method employed for clamping the various forms of tooth rests to the spindle head. The same screws are used as in clamping the overhanging arm in *B*. It should be noticed that the rests can be brought to the cup or disk wheel either from above or from below. At *E* is shown the head as arranged for plain cylindrical grinding, with a wheel hood and the makers' "Wizard" water spout. This water spout is of a peculiar design, which will furnish water a drop at a time or in full stream, without any spattering caused by the air blast from the wheel.

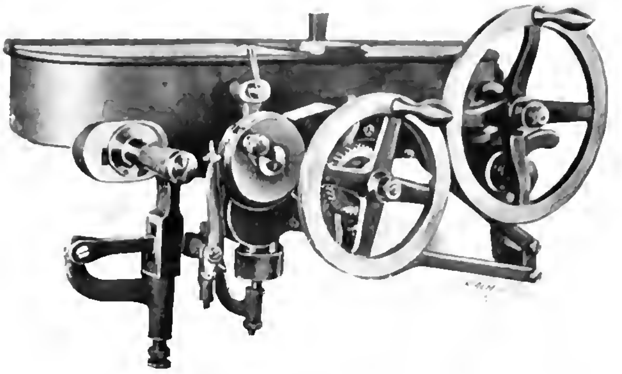

Fig. 2. Apron of the Grinder Provided with Two Cross Feeds, One for Cylindrical and the Other for Surface Grinding.

At *C* is shown a head as arranged for internal grinding. The arm which supports the internal spindle is mounted in a suitable seat at the base of the spindle column. The belt may be tightened while the machine is in motion by a vertical adjustment of the regular spindle head. In Fig. 3 are shown various internal grinding spindles, made with detachable flanged bearings. These spindles are made in different lengths and diameters to suit the character of the work being ground. That at the left is used for internal grinding of the heaviest character.

In Fig. 5 is seen another of the new attachments. This is a universal holder mounted in the tail-stock. It is shown grinding the side teeth of a side milling cutter, using an 8-inch cup wheel. The hinged plunger tooth rest should be noticed. In changing the angle, the cutter and tooth rest are adjusted at the same time, both being mounted on the same support. In sharpening this cutter, the tooth is reciprocated by the handle shown, it being un-

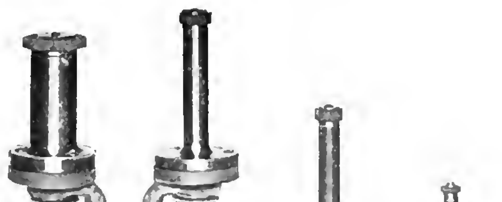

Fig. 3. Type of Internal Grinding Spindles used, carried in Detachable Flanged Bearings.

necessary to operate the table. In Fig. 6 is shown the same attachment engaged in grinding a large gear cutter. The machine is rigged for supplying water to the wheel during this operation. The use of the "Wizard" nozzle makes unnecessary the provision of water shields to keep the machine dry. The same tooth rest is being used as before. The other attachments for this machine, such as the universal holder, horizontal vise, flanged plate, etc., are the same as described in the article previously referred to.

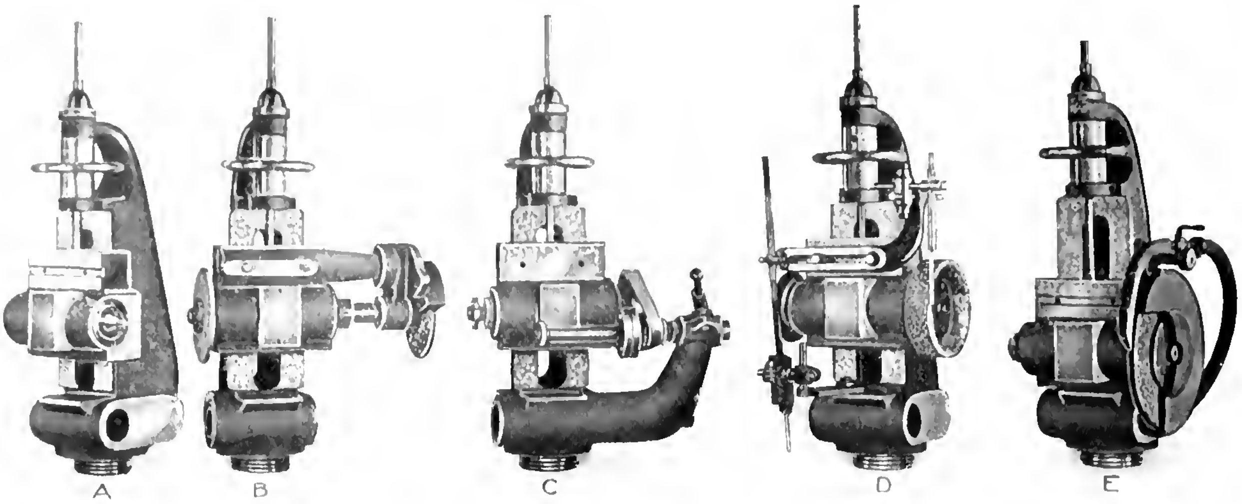

Fig. 4. Spindle Head of the Bath Grinder, Rigged for Various Operations, such as Cylindrical, Internal, Surface and Cutter Grinding, etc.

For external and internal cylindrical grinding, the machine is provided with a suitable head-stock and tail-stock, and with water guards, so as to make it an efficient tool for this work, free from the makeshift attachments often found on a universal tool-room machine. The head-stock swivel is graduated, and the swivel bearing is dust-proof. A dowel pin is provided for setting the swivel adjustment in a central position. The clamp nut and the swivel binding nut are both in the center of the head-stock and are independent of each other. The dead center pulley revolves on a conical bearing at the end of the quill, and is held in place by a detachable flange. The quill is so constructed that it can be used for either revolving or dead center grinding. The foot-stock has a spring center. It carries on the front end a flat projection for clamping a diamond holder for truing a wheel, or for clamping tooth rest stands for cutter grinding. Spring rests are used for absorbing vibration and supporting the work in shaft grinding. The supporting pressure on the shaft is relieved when the required diameter is attained. A hand tension screw is also furnished which keeps the supports up beneath the work and assures a rigid bearing. Suitable water shields for wet grinding are provided.

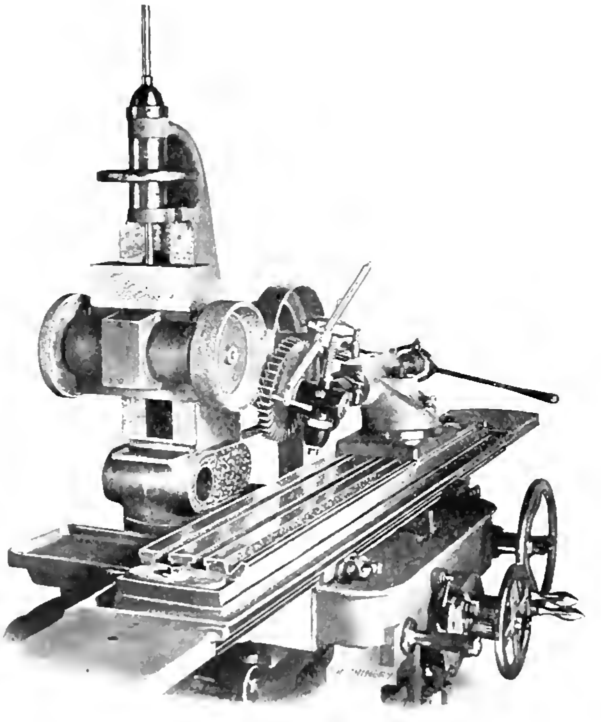

Fig. 5. Grinding Side Teeth of a Milling Cutter with a Universal Holder Mounted in the Tail-stock.

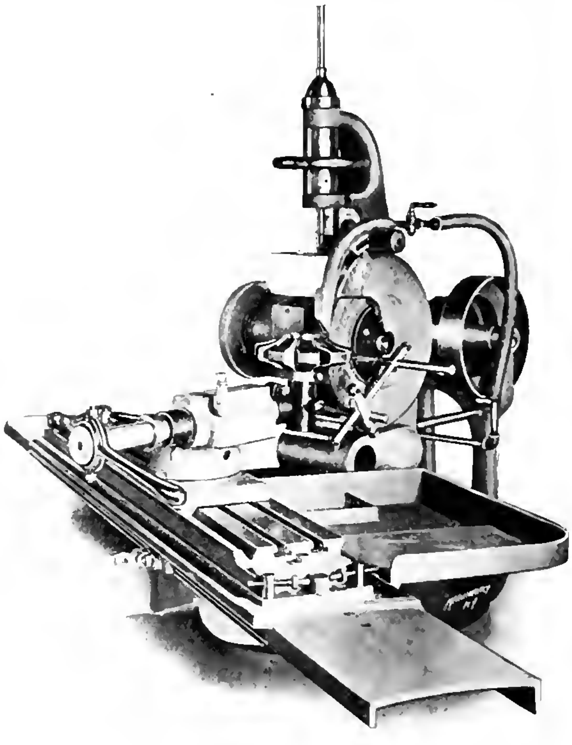

Fig. 6. Universal Holder Engaged in Grinding a Large Gear Cutter.

This grinder can be furnished by its maker, the Bath Grinder Co., Fitchburg, Mass., in any one of a number of styles for different classes of work, depending on the equipment sent with it. For instance, it may be furnished for plain, surface, internal, disk, and cutter grinding of all descriptions, or for any combination of these various purposes.

OESTERLEIN NO. 3 UNIVERSAL AND TOOL GRINDER.

This machine, like previous machines built by the same maker (the Oesterlein Mch. Co., 2850 Spring Grove Ave., Cincinnati, Ohio), is similar in its structural design to the column type of milling machine—that is to say, the work table is fed longitudinally on a saddle, which in turn has a cross adjustment on a knee; this knee is vertically adjustable on ways on the face of the column. This new design, however, bears little resemblance to its predecessors. While intended for the regular work of the cutter and reamer grinder, it is arranged as well to do cylindrical and surface grinding in a rapid and satisfactory manner, being provided with a full equipment of automatic feeds, work revolving connections, water guards, etc. The principal improvements so far as structural features are concerned relate principally to the provisions for wet grinding,

the elaborate safe-guarding of the sliding surfaces from emery dust, and the general strength and rigidity of the whole machine.

The spindle head is mounted on the top of the column, and may be swiveled in position about a vertical axis. This swiveling adjustment is read from graduations. This head is provided with a self-contained splasher and drip trough, as best seen in Fig. 1, which catches water thrown from the revolving work and leads it back into the channels provided for returning it to the reservoir. The spindle is driven by a two-step pulley, giving two speeds for the wheel.

The table bears on the saddle or cross slide for its entire length. The upper member of the table can be swiveled to any angle throughout the full circle, and clamped in any position when so swiveled. For grinding comparatively small tapers, a scale is provided reading in inches per foot. Fine adjustments for such tapers are obtained by a worm meshing with worm-wheel teeth cut in the right hand end of the table in Fig. 1. The slide has V and flat bearings on the saddle, and the saddle has similar bearings on the knee, thus insuring accurate alignment at all times, preserving the longitudinal and cross movement exactly at right angles to each other. The table comes down over its bearing on the saddle on all sides, thus protecting these parts. The bearing of the saddle on the knee is protected, as shown in the front view, by a guard which is supported in the rear, and passing entirely through an opening provided for it in the saddle, covering the ways under all conditions.

The head-stock is provided with swiveling adjustments to any angle in the vertical or horizontal plane. The tail-stock has a spring center, and is actuated by a lever when placing or releasing the work. The vise furnished for surface grinding may be mounted on the head-stock angle support, in which case it can be set to any angle in two planes. This vise may be used for holding round work, as a V-block is provided for its lower jaw. The upper jaw swivels to accomodate any taper; the vise has a back-stop as well, making it convenient for holding straight and taper shank mills for grinding, when they cannot be conveniently held on centers or in collets. The tooth rest provided is universal, and has a micrometer adjusting nut for accurate setting in any position. Back rest and splash guards are provided for cylindrical grinding. One of the latter is shown in place in Fig. 2.

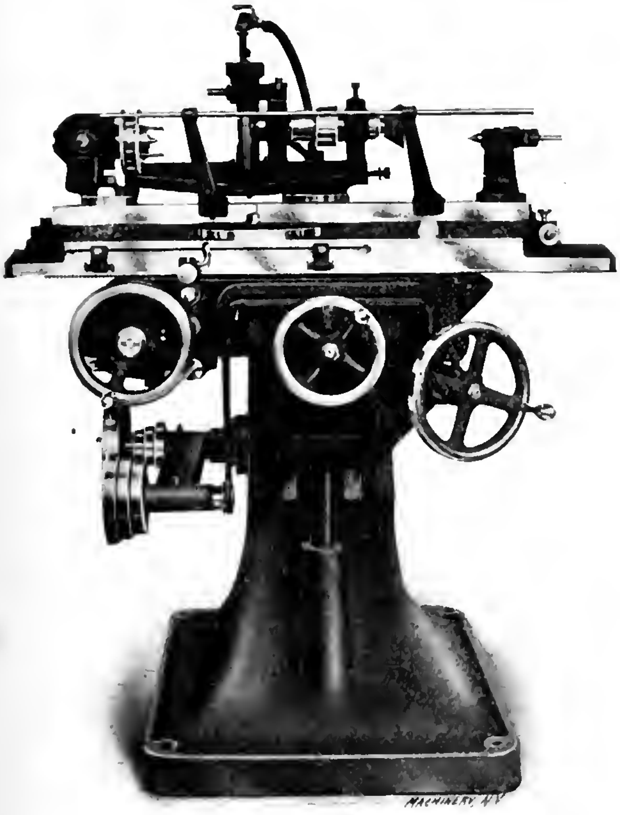

Fig. 1. Front View of the Oesterlein Universal Grinding Machine, showing Protection of Sliding Bearings from Emery Dust.

Besides main counter-shaft for driving the spindle, pump, and feed, there is a supplementary drum counter-shaft for revolving the work in cylindrical grinding. But one belt shifter is needed, as provision is made for starting and stopping the drum counter-shaft by tightening or loosening the belt which connects it with the main counter-shaft. This movement, as may be seen in Fig. 3, is effected by mounting the hangers on pivots and swiveling them by the worm shown, connected to a rod extending downward within reach of the operator. The loose pulley used on the main counter-shaft is shown in Fig. 4. It has a cored chamber, which, when filled with wicking, will retain sufficient oil for a long run. Mounting the pulley on a bushing protects the shaft from cutting or wearing.

Fig. 2. Side View of Oesterlein Grinder showing Provision for Wet Grinding.

The equipment of this machine includes a 4-inch chuck, a vise, head-and tail-stocks, tooth rest, centering gage, extension spindle, raising blocks, internal grinding attachment, seven steel bushed emery wheels of various shapes, the necessary wrenches, the main and drum counter-shafts, a set of dogs in a tray, and a steady rest. The automatic table feed is 16 inches in length, the transverse movement is 8 inches, and the vertical adjustment is 7½ inches. The swing between centers is 9 inches. When raising blocks are used, this is increased to 12 inches. The 6 rates of table feed provided range from eight to fifty revolutions per inch. The net weight of the complete machine is 1,400 pounds.

NEWTON DUPLEX FACE MILLING MACHINE.

A duplex milling machine designed for heavy face milling, or rotary planing of parallel perpendicular surfaces, is shown herewith. This machine is built by the Newton Machine Tool Works, Inc., Philadelphia, Pa. It is noticeable for its rugged design, and the very convenient arrangement of operating the handles and other controlling devices.

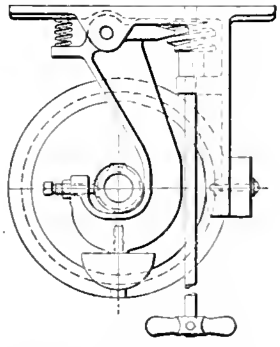

Fig. 3 Belt-tightening Hanger for Drum Counter-shaft, which avoids the use of a Belt Shifter.

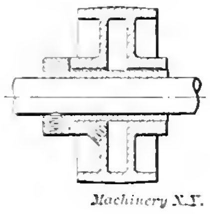

Fig. 4. Loose Pulley used on Main Countershaft; the Core is filled with Wicking.

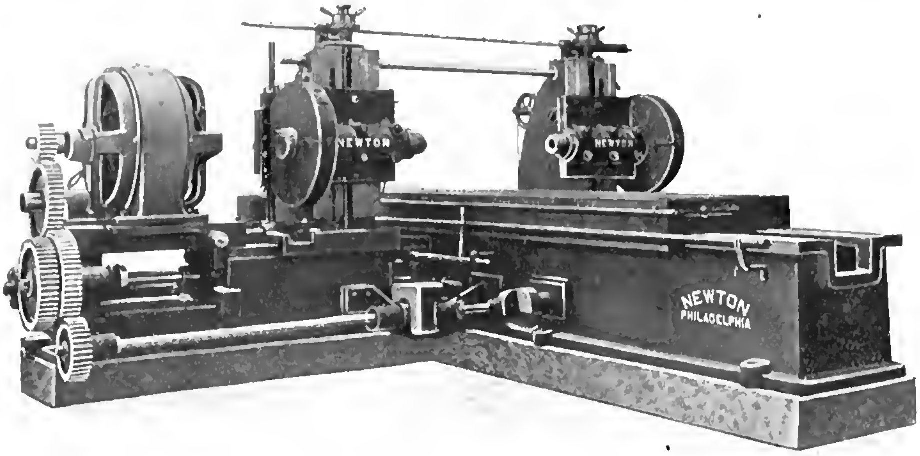
The machine consists essentially of a long bed on which slides the work table, and is provided with two wings on which columns

are adjustably mounted, carrying vertical, adjustable spindle heads. These spindle heads may be adjusted either separately or together, the latter provision being useful if the machine is to be used for slab milling.

A 35 H. P. motor furnishes the driving power. From the armature shaft, the motion is transmitted through a train of gears, to the horizontal driving and feed shafts. On the latter is mounted a double train of miter gears, running loosely on the shaft, to which either may be connected by a double throw Carlyle-Johnson friction clutch. This is seen in the angle of bed in the illustration. This movement is further transmitted through miter gears to a feed box on the other side of the machine, where nine rates of feed are obtained. These feeds range from 0.789 to 8.15 inches per minute at the high speed of the motor, and from 0.394 to 4.08 inches per minute for the slow speed of the motor. Motion is taken from this feed box shaft of the machine, which is connected at the rear through worm gearing with the feed pinion of the table. This horizontal shaft may also be driven through quick acting spiral gears on the horizontal drive shaft by means of the positive clutch shown, which thus serves to connect either the slow feed or the fast traverse.



Double Horizontal Face Milling Machine for Heavy Work.

In the rear of the right hand ring a connection is made from the horizontal feed shaft for slow feed or quick adjustment for the spindle heads. Independent simultaneous movement for these is obtained by adjusting the friction clutches shown at the top of the up-rights. The shaft connecting these may be operated by hand for minute hand adjustment. The table may be clamped in position so as to use the verical feed in a face milling operation.

All the operations of this machine with the exception of the change in the rate of speed can be controlled from either side. This applies to the change from feed to fast traverse or vice versa, and to the reversing of the feed. The vertical and horizontal feed throw-outs are likewise provided with handles on either side.

The panels on which the uprights are mounted are of very solid construction, and are provided with key slots cut from the solid, which permits clamping the uprights securely in position with four bolts each. With this provision the adjusting gibs can always be kept loose for a free running fit. Additional spindle speed changes beyond those given by the two to one variation in the motor are provided for by change gears in the train connecting the armature shaft with the spindle driving gears.

The spindles of this machine are 6 inches in diameter, and are driven by steep lead bronze worm-wheels 33 inches in diameter and hardened steel worms running under continuous lubrication. The spindle heads are counter-weighted, and may be adjusted from 5 to 26½ inches above the table. The uprights have an in and out hand adjustment from a minimum of 30 inches to a maximum of 60 inches between the ends of the spindles. The heavy work table is 42 inches wide, and 15 feet 6 inches long, with a capacity to mill 14 feet in length. It is entirely surrounded by an oil pan fitted with a lubrication system, arranged to drain into a storage tank in the rear of the machine. The oil or water is returned to the cutters by a pump located at the back of the left hand wing. The table is driven by a steel rack and bronze spiral gear.

CINCINNATI PLANER ARRANGED FOR USING EXTENDED TOOLS.

The accompanying illustrations show a planer built by the Cincinnati Planer Co., Cincinnati, Ohio, provided with specially designed tool supports, which allow a great overhang of the tool without loss of stiffness or cutting power. While the planer was originally intended for the particular work of machining locomotive cylinders, the construction is one which can readily be adapted to any work in which a great overhang of the tools is required.

Fig. 1 shows the supports as arranged on the planer. Fig. 2 shows the detailed construction of the added parts. The machine itself, with the exception of the side heads, is the regular planer as arranged for parallel drive. The housings *A* have ways planed on them on the inside, each provided with a dove-tail front surface, and a square surface in the back. In these ways fit brackets *B*, which are counter-balanced with a weight and chain. The use of the chain allows them to be raised and lowered by a crank applied to the sprocket wheel. The brackets are secured to the housing by tightening the taper gib on the straight side. This forces the bracket against the dove-tail, and draws it in against the bearing.

The front end of *B* has a rectangular section, which is machined and scraped parallel with the front face of the housing. On this is fitted a shoe *C*, having a dove-tail on the opposite side, which fits the cross-slide of the special side heads *D*. After the slide is run onto this shoe, the latter is adjusted to the bracket by the two taper bearings, seen best in Fig. 1. When this has been done, the shoe is a part of the side head, and the two move up and down together, the shoe sliding on the bracket. When it is necessary to reach out 21 inches from the housing with the tool, the latter is supported by the bracket, which extends out about 18 inches, as rigidly as if it were mounted close to the housing.

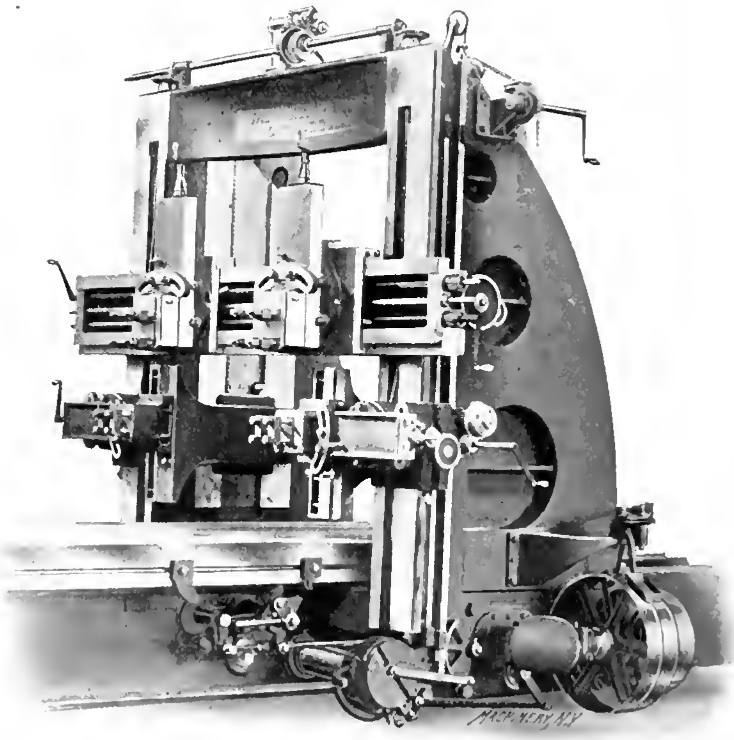


Fig. 1. Cincinnati Planer, with Bracket Supports for Extended Side Heads.

The bracket *B* is made of such a length as to clear the projections

on all sizes and makes of locomotive cylinders and yet have enough bearing so that shoe *C* would never extend over the bearing on the bracket. Fig. 2 shows, in dotted outline, one of the most difficult of the cylinders the planer is intended to handle. This diagram illustrates very plainly the advantage of supporting the tool, when it is necessary to reach out so far to get at the work as is required in piston valve cylinders of this design. When the planer is to be used for other purposes than this special work, the slide can be run back on the side head, as usual, and the brackets raised up out of the way. The machine then becomes an ordinary 72-inch x 72-inch x 18-foot planer, with its full capacity available.

BECHE PNEUMATIC POWER HAMMER.

The illustration shows a "pneumatic power hammer" as it is termed, which is well known in Europe, and is being made and sold in this country by the Nazel Engineering and Machine Works, Philadelphia, Pa. In this machine many of the advantages of the power and the steam hammers are combined. Briefly, the construction comprises two cylinders, one of which contains a piston worked by a crank and connecting rod, while the other carries the striking ram or plunger. The latter is reciprocated by the alternate compression and vacuum produced by the power operated piston.

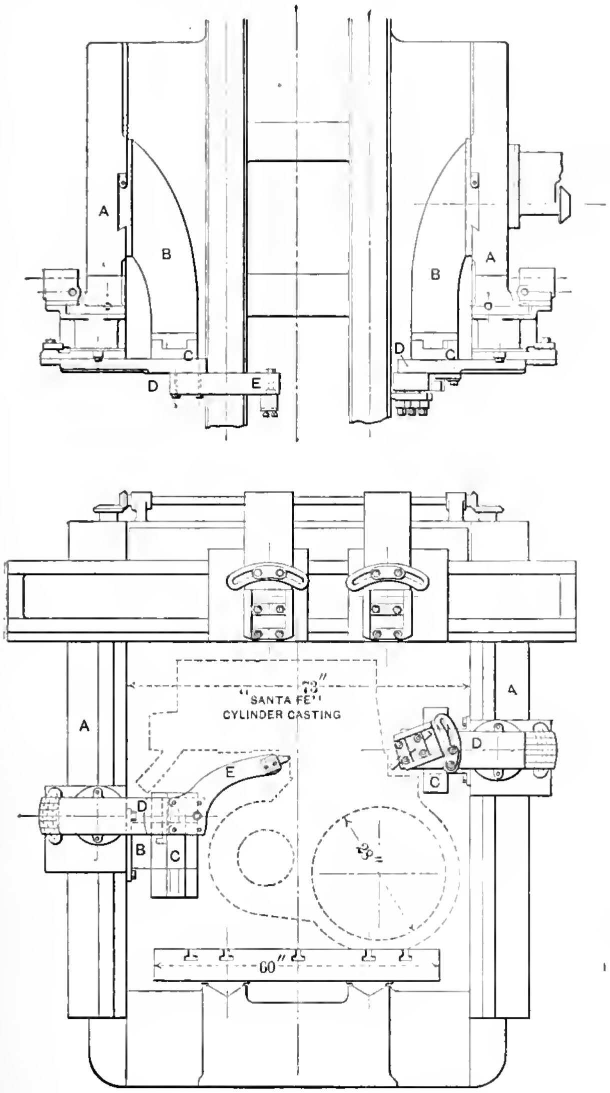

Fig. 2. Plan and Elevation of Special Planer Attachments, showing Use on a Difficult Job.

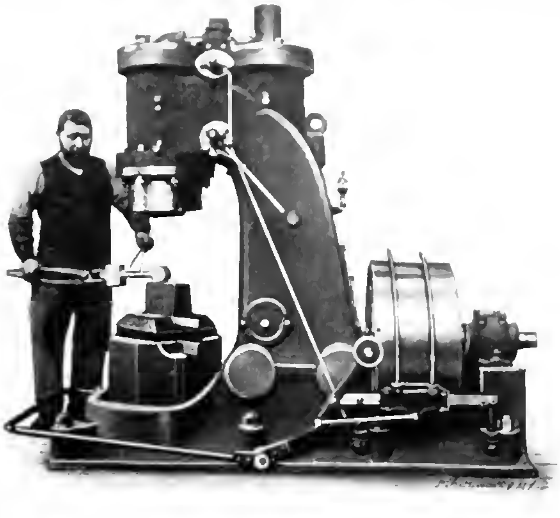
The construction of the hammer is very simple. The frame is made in a single piece, bolted to the bed-plate; the anvil block is separate. The power crank shaft has mounted on it, a heavy fly-wheel and it may be arranged to be driven either by belt power or by electric motor. The ram or hammer head in the other cylinder slides vertically on closely fitted guides. The whole mechanism is enclosed, so that no destructive forging dust or other foreign matter can reach the working parts. All the movable parts and both the cylinders are lubricated automatically. The hammer is easily operated, and by means of the air regulating valves it is possible to hold the ram suspended at any height, and to instantly change from a very light blow to a heavy one. On closing the valve, the ram remains immovable in its highest position. Suitable connections are made so that fresh air is admitted at every stroke, thus preventing the hammer from being overheated. The operating levers are so arranged that the workmen can control the machine and handle his work at the same time.

The uses of this hammer are numerous as it fills the requirements for general smithing and forge work. A large variety of work which is done on drop hammers can also be effected under the Beche hammer with great rapidity and accuracy. It is especially adapted to the welding and forging of axles, shafts, etc.

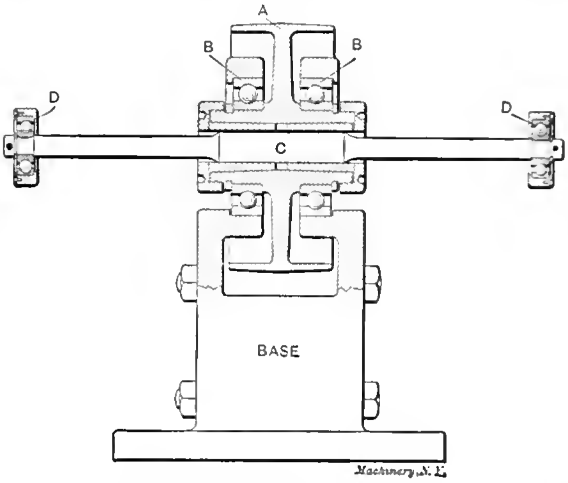


A Pneumatic Hammer, operated by a Direct-connected, Power-driven Air Cylinder.

The claims for this hammer are: Simple and rigid construction; easy adjustment; a quiet but forcible squeezing blow; lack of jar or vibration to the operator; long ram guides; enclosed construction; suitable speed; minimum power; long stroke; belt or motor drive; automatic oiling; and separate bed, with a rigid anvil block. It will be furnished in seven sizes, ranging from 66 to 660 pounds for the weight of the ram. Over a thousand of these machines are in constant use on the Continent.

WHITE-SOUTHER ENDURANCE TESTING MACHINE.

Tinius Olsen & Co., 500 North Twelfth Street, Philadelphia, Pa. have recently placed on the market the White-Souther endurance testing machine, whose construction is shown in the accompanying line engraving. This machine is intended to give dynamic tests of materials in a way which is at once convenient and effective. The deflection of the specimen is effected by a rotary, instead of by a reciprocating motion.



Machine which tests the Endurance of a Specimen by loading it at its Ends and Revolving it.

In the engraving, *A* is the driving pulley of the machine, mounted on ball bearings *B*. The hub of this pulley is provided with a split bushing arrangement for firmly clamping the test specimen *C*, which may be double ended, as here shown, or single ended only. The use of a double specimen has practically the effect of making

a check test, if a flaw exists in one end, the other end may be sound, so that a normal result is obtained. It should be noticed that it is possible to machine a standard tensile specimen from the central and unstrained portion of the sample after the dynamic test is completed.

The alternating strain is produced by rapidly rotating the specimen, which is weighted at its outer, or free ends. The loads are in the form of direct weights, supported on ball bearings *D*. A revolution counter is provided at each end to give the number of reversals of the strain in the test. The connection between the revolution counter and the end of the specimen is such that no damage results to the instrument from a sudden rupture of the specimen. 1300 revolutions per minute is the customary speed at which this machine is run in the laboratory of the inventors.

NEWTON CUTTER GRINDER ATTACHMENT FOR ROTARY PLANER AND FACE MILLING HEADS.

In the April, 1906 issue of MACHINERY, we illustrated and described a self-contained grinding attachment for automatically sharpening the blades in a rotary planer head. This attachment was designed by Mr. Riddell, and was used in the Schenectady shops of the General Electric Co. of which he is superintendent. In using it, the planer head was revolved slowly past the wheel, which ground each tooth as it passed by, and was swung in and out to give the proper clearance to the cutting edge. This machine is now being made in an improved form by the Newton Machine Tool Works, Inc., of Philadelphia, Pa., as shown in the accompanying half-tone and line engraving.

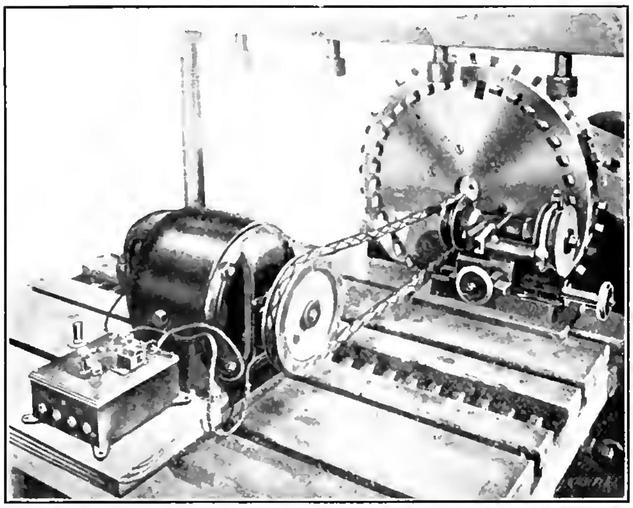


Fig. 1. The Riddell Portable Milling Head Grinder as built by the Newton Machine Tool Works.

The wheel *A* has its outline formed to give the desired shape of cutting edge to the inserted teeth. It is mounted on carefully protected ball bearings at either end of the spindle, in a swinging frame *B*, pivoted at *F*. The dog *C* extends over the wheel in line with the teeth, which strike it successively as they pass by. The swinging movement thus given the dog is transmitted through the rock shaft on which it is mounted to slotted link *E*, which engages an adjustable block in an arm cast solid to swinging frame *B*. By this means it will be seen that as the planer head revolves, each successive tooth operates the rock shaft in such a way as to force the wheel in to grind the clearance on each cutting edge, and bring it out again ready for the next tooth. The clearance is adjusted by shifting the position of the block along the solid arm on which it is mounted.

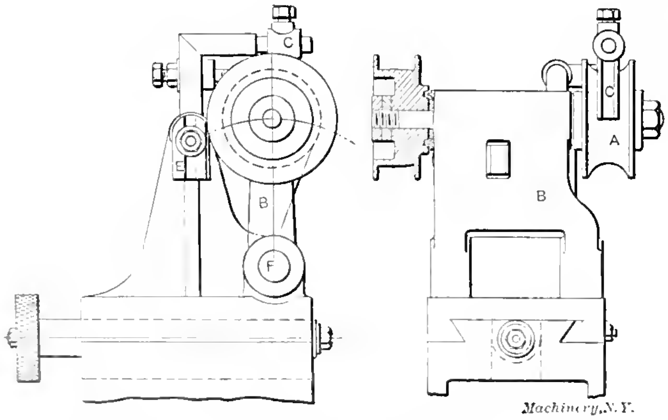

Fig. 2. Details of Grinder Similar in Construction to that shown in Fig. 1, but differently Mounted.

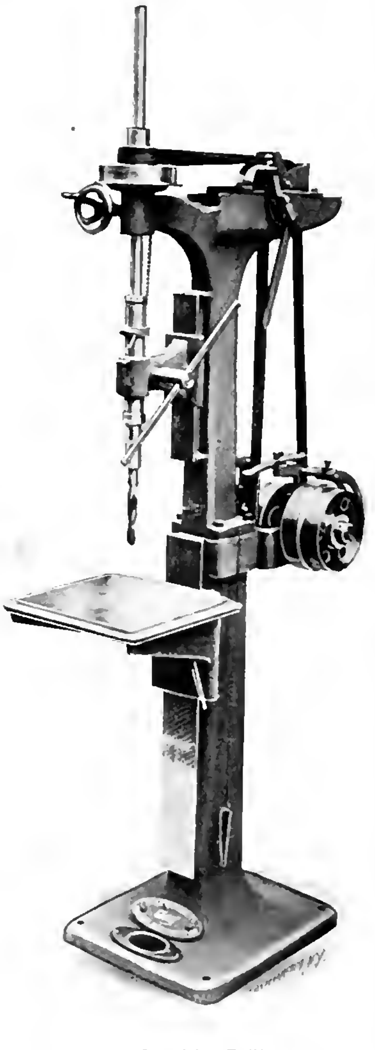
The slide carrying the spindle has an in-and-out adjustment of 3 inches, and a cross adjustment of 5½ inches. The motor shown is larger than necessary for the work, being a half horse-power direct current motor, running at 2,500 revolutions per minute. In using the device for grinding the teeth on a vertical spindle mill, (as illustrated in the description of the Newton four spindle milling machine, in the department of New Machinery and Tools of last month's issue of MACHINERY) finger *B* is adjusted to the opposite quarter. For grinding teeth that are too close together to permit withdrawing the wheel, a double pawl is provided, which permits skipping every other tooth.

The makers of this device have found it possible to double the feeds previously obtained, by grinding the blades in the cutter head in place. A smoother finish to the cut is also noticeable. A test on a vertical rotary planing machine recently made, after grinding the teeth with this attachment, gave a cut 14½ inches wide and ¼ inch deep, at a table feed of 8½ inches per minute, using a 10 H. P. motor.

AVEY SENSITIVE DRILL PRESS.

The sensitive drill press shown herewith is a new product of the Cincinnati Pulley Machinery Co., Cincinnati, Ohio. Aside from general good design and workmanship, some special features have been introduced in this machine; among them the driving arrangement will be particularly noted. Convenience, range, strength and speed are stated as factors sought for in the design.



The Avey Sensitive Drill Press.

The machine runs on ball bearings throughout. All the cones and balls are hardened and accurately ground, and have four point contacts. The spindles are of crucible steel, ground to size, and bored to fit the No. 2 Morse taper. The spindle sleeve is graduated, and is provided with a stop collet having a fixed clamp screw, requiring no wrench or screw-driver. This, in combination with the graduation, makes the use of a scale unnecessary in drilling to depth. The rack pinion and shaft for feeding are of one solid piece—an improvement over the usual separate construction. The upper and lower columns and the counter-shaft brackets are tongued and grooved, insuring proper alignment and interchangeability. If desired by the purchaser, the table will be fitted with a telescopic elevating screw, operated by bevel gearing, the construction being the same as that used in milling machines. This allows the maximum distance between the spindle and the table, and can be applied at any time subsequent to the purchase of the machine, though it is not furnished without extra cost.

The spindle has four changes of speed, which are instantaneously obtainable. A convenient handle shifts the belt on the two-step

cone pulley on the counter-shaft. Two more changes are obtained by shifting the quarter turn belt to one of two positions on the counter-shaft and spindle pulleys. To permit this shifting, the two quarter turn idlers perform different functions. The one at the left is adjusted longitudinally by the hand-wheel shown for tightening the belt to the proper tension. The idler at the right-hand side which leads the belt on to the spindle pulley, is raised or lowered to the proper position for either of the two speeds by means of the lever shown.

This machine has a spindle traverse of 13½ inches and a rack feed of 5⅝ inches. The maximum distance of the spindle to the table is 35½ inches. It is made as a single spindle machine, or with two, three or four spindles as required. The weight of the single spindle machine is 430 pounds, that of the four spindle machine is 1,220 pounds. The machine has a capacity for drilling up to 29/32 inch diameter.

VAN DORN ELECTRIC DRILL.

Fig. 1 shows the front view, and Fig. 2, a section of one of the new line of portable electric drills made by the Van Dorn Electric & Mfg. Co. of Cleveland, Ohio.

The motors for these drills are made in both open and closed designs depending on the conditions under which they are to work.

Fig. 1. The Van Dorn Electric Drill.

The example shown has ventilation holes in both heads, and in the sides of the machine. A current of air is forced through these holes by the peculiar design of the armature. The air is drawn in through the heads, and forced out at the sides, the current passing completely through the field opening at the air gap between the pole pieces and the armature. The upper and lower thrust, as shown, is taken on ball bearings. All the bearings that are not ball bearings are made of phosphor bronze. The gearing and all other wearing parts are made of steel, case hardened.

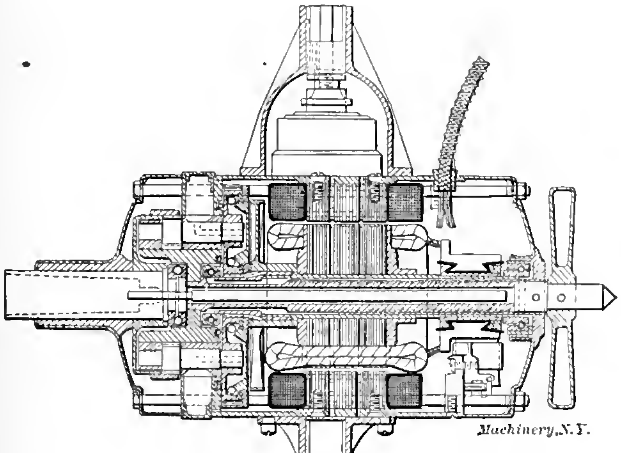


Fig. 2. Section through Drill, showing Use of Ball Bearings and the Provision for Cooling the Commutator, Armature and Field.

The tools are controlled through a switch handle operated by a knurled ring. A quarter turn of this ring will stop the machine, which is thus, at all times, under the instant control of the operator. Each machine is equipped with an armored cable. The armor of this cable is grounded in the machine, absolutely preventing the operator from getting a shock

These electric drills are built in five sizes; the smallest is equipped with a standard chuck having a capacity for any drill from the smallest up to a quarter inch in diameter. The other machines are fitted with Morse taper sockets, the largest size being bored for No. 4 taper and being capable of driving a 2 inch drill in steel. The design is the result of long experience, with a long and severe trying out in various establishments, all of which was done before the tools were placed on the market.

THE BEMIS HEXAGONAL MILLING MACHINE.

We show herewith an interesting automatic machine for milling hexagon flats on nuts, valve fittings, stuffing box glands, etc. It is a multiple spindle machine, with the work carried by an indexing spindle carrier, which leaves one station open to the operator for placing and removing the work. Except for this matter of placing and indexing the work, the machine is entirely automatic. It is built by Edgar W. Bemis, of Worcester, Mass.

The general arrangement of the machine is shown in Fig. 1, while Fig. 2 shows the details of the mechanism. The machine is driven by tight and loose pulleys on shaft *A*, which is connected by bevel gearing with the vertical shaft *B*, which extends up through the center of the machine. This shaft, in turn, is connected by bevel gearing in the cutter head *C* with the three cutter spindles *G*, which are placed at right angles with each other. These spindles are supported by outboard bearings in the overhanging arm *D*, which is clamped to cutter head *C*. This latter is raised and lowered to accommodate different lengths of work by means of a worm and worm gear *E*, operating a coarse screw *F*, threaded in the bottom of the head.

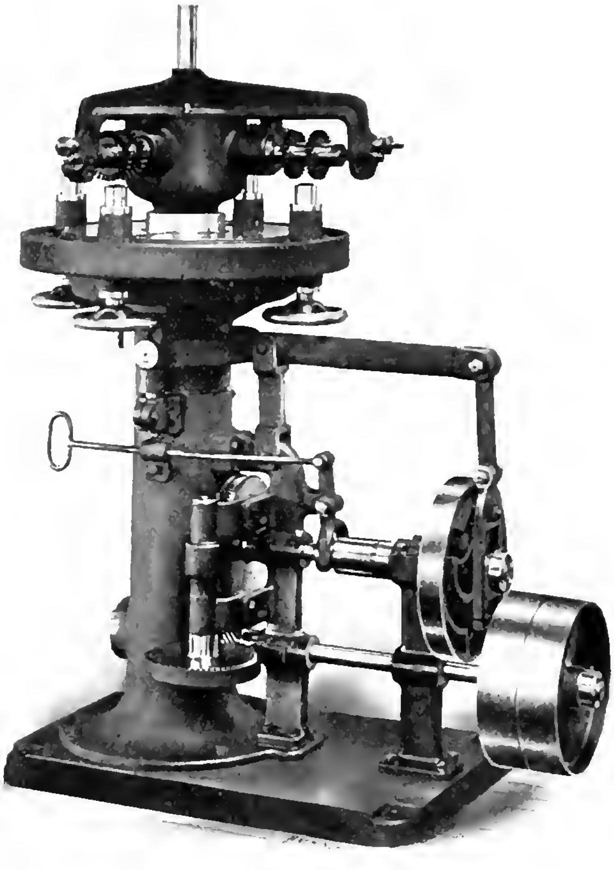

Fig. 1. A Machine for Milling Hexagon Surfaces on Valve Bodies, Nuts, etc.

The work-table *J* is supported on ball bearings on the lifting table *H*, which is moved up and down to feed the cutters into the work and withdraw them. The work spindles *M*, mounted in table *J*, have keyed to them gears *L*, meshing with the gear *K* fast to *H*. As the work-table is indexed to bring the work spindles into successive positions under the three cutter spindles, the work is indexed by gears *K* and *L* to the proper positions for cutting hexagonal sides, bringing a new pair of work faces to each set of cutters. The index ring *O* is locked by a bolt, controlled by a handle within con-

venient reach of the operator. The work spindle has an interior sliding spindle into which the work plug is secured. This interior spindle is threaded to a screw attached to hand-wheel A, and is raised and lowered by the turning of the latter. The hand-wheel thus serves to clamp the work, and its action brings it down against a solid shoulder, holding it securely in place during the operation.

Table *H*, and with it the work spindle and the work, is raised and lowered by a yoke *P*, the motion being guided by pins *Q*, which pass through lugs on the side of the column. The operation of the yoke is controlled by the cam and link movement, seen best in Fig. 1. The cam is operated by gearing from the drive shaft as shown. The feed may be thrown out at any time by a positive jaw clutch.

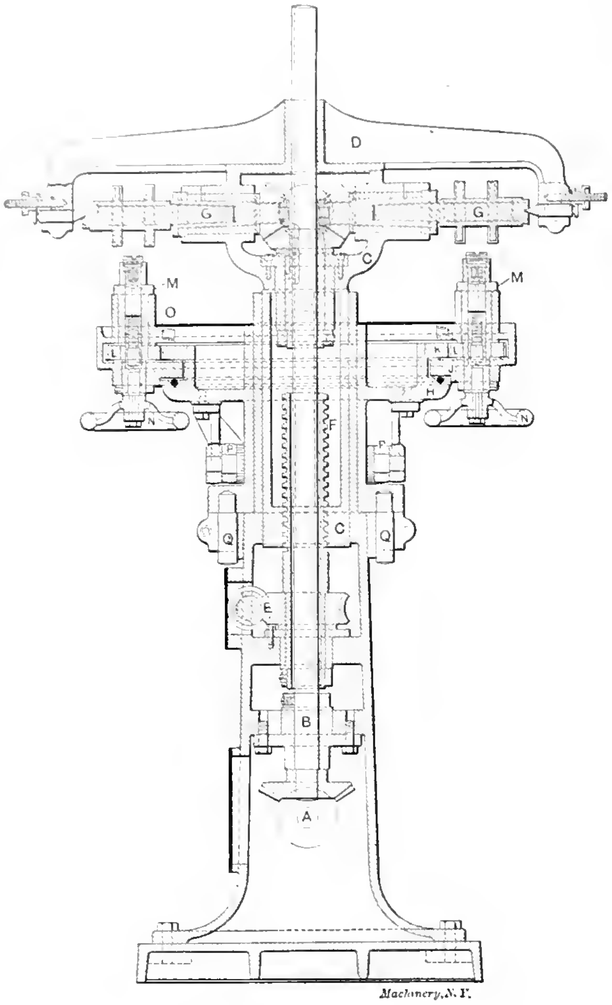

Fig. 2. Vertical Section, showing the Mechanism.

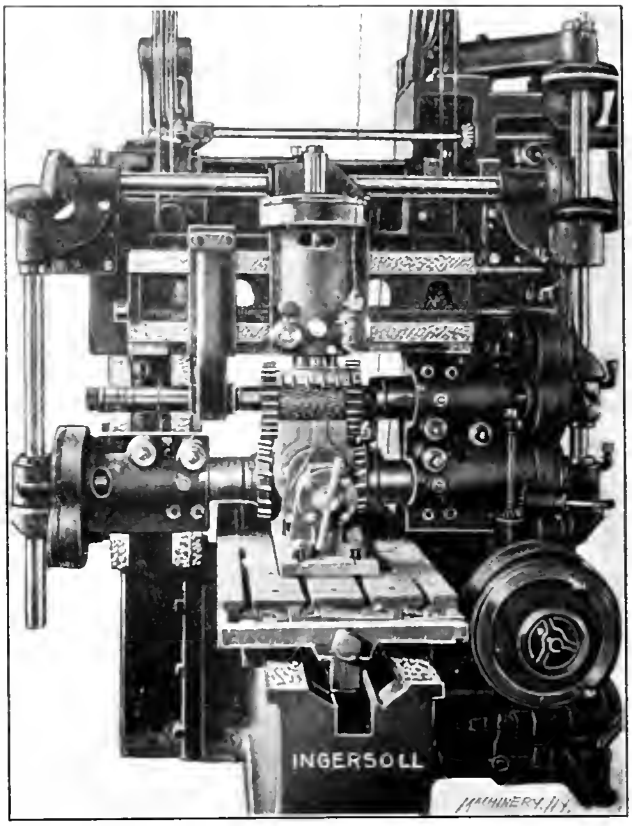
The weight of this machine is about 1,500 pounds. It is strong and substantial in construction, and has sufficient driving power for finishing nuts up to 3 inches across the flat. An output of 240 ¾-inch nuts per hour, or their equivalent in other sizes, represents the working capacity of the machine.

INGERSOLL SPECIAL FOUR-HEAD MILLING MACHINE.

The four-spindle milling machine shown herewith, illustrates the extent to which it is possible to specialize a machine of this kind by a slightly different arrangement of the spindles, without incapacitating it in any way for regular work. This machine, built by the Ingersoll Milling Machine Co., Rockford, Ill., carries two horizontal spindle heads on the right-hand upright, and one on the left-hand. There is a fourth head mounted on the cross rail; the cross rail also carries an outward support for an arbor, which may be driven by the upper of the two spindle heads on the right. When the machine is so used, this spindle head is fastened to the cross rail and is adjusted up and down with it, making the machine, to that extent, a slab miller.

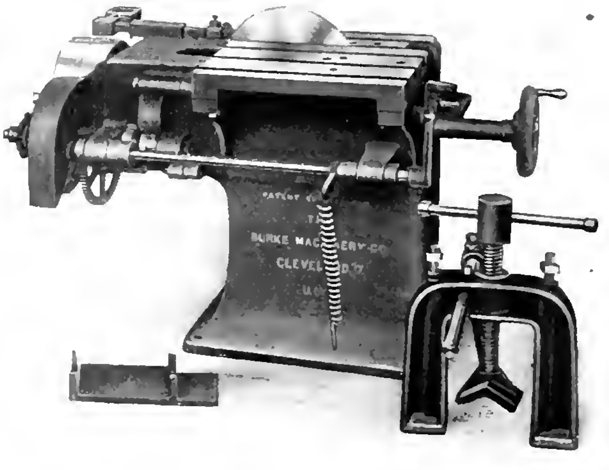
The engraving shows the tool operating on the work for which it is specially designed. The two lower horizontal heads each carry face mills. The upper horizontal head carries an arbor, which is clutched to the face of the spindle and drives a gang of cutters. The vertical head carries a face mill. This vertical head is far enough in advance of the horizontal arbor so that it is used for roughing out the cut, which is immediately finished by the cylindrical cutters on the arbor. It will be noticed that each spindle has a longitudinal adjustment.



Ingersoll Four-head Milling Machine in Operation.

IMPROVED BURKE COLD SAW.

The Burke Machinery Co., 1837 35th St., Cleveland, Ohio, has re-designed the cold-sawing machine, which we described in the June, 1908 issue of MACHINERY. Among the changes is the provision of a screw-feed, with ball-bearing thrust, in place of the rack and pinion feed previously used. This has meant an entire re-arrangement of the feed mechanism.



Improved Design of Burke Cold Saw.

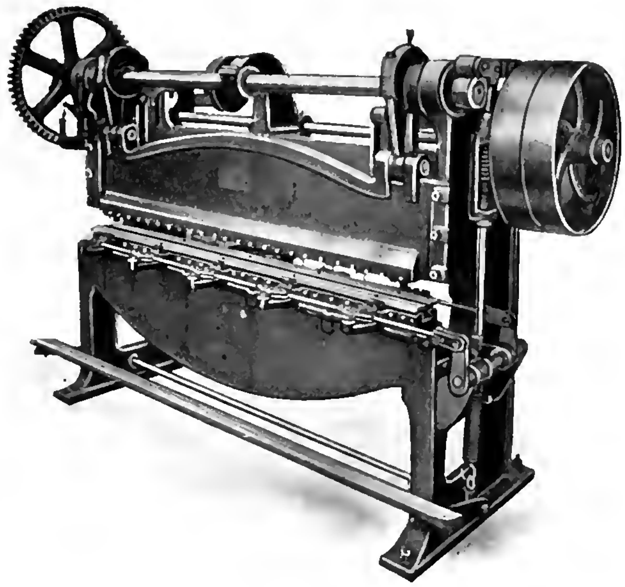
The saw blade rests upon and is bolted directly to a bronze worm-wheel. It is driven from it by three ½ inch cap screws and three ½ inch pins of hardened drill rod. These driving holes are well out from the center of the blade and give an unusually strong drive. This worm-wheel with the attached saw is mounted in a carriage sliding in suitable ways across the bed of the machine. At the front of the carriage is bolted a hardened steel casting, which acts at the same time as a guide to the saw and as a stripper

for carrying away the chips from the teeth. An automatic throwout is provided for the feed. In the train of feed gears is a loose gear, confined between two flanges lined with leather. A spring and adjusting collar tighten these flanges to the gear, and furnish the friction slip, which will give under abnormal pressure.

The machine shown is provided with tight and loose pulleys. A three-step cone with a suitable counter-shaft will be furnished in place of this, if desired. The clamps for holding round and irregular shaped stock are seen on the floor at the base of the machine. A stop for cutting to length is provided, as shown. This machine is made in two sizes, for 12 inch, and 20 inch saw blades. These have respectively a capacity for round stock up to 3 inches, and 5½ inches in diameter. The extreme capacity for rectangular stock is for each case, 3 x 5 inches, and 5½ x 12 inches. The capacity for ½ inch flat stock is 9 inches and 20 inches wide, respectively. The net weights are 500 and 800 pounds. The machines sell at the remarkably low prices of $80 for the 12-inch machine, and $160 for the 20-inch machine.

BERTSCH GANG PUNCH.

Bertsch & Co., of Cambridge City, Ind., make the multiple gang punch shown herewith. The ram and die bed are provided with a multiplicity of punches and dies, which may be set either by universal or independent adjustment to the center distances required to suit the work in hand. The machine illustrated has an automatic clamping mechanism for holding narrow bars or strips. Each machine is provided with a stripper properly designed for the particular work for which it is to be used. The machine may be furnished with the automatic clutch used on the makers' regular shears. This clutch is noiseless, positive and reliable in its action. The castings and steel parts for each machine are carefully calculated for the stresses imposed on them, particular care being given to have the bearings and gears of the right proportions. The machine is furnished by the maker in a variety of sizes for a wide range of work.



A Gang Punch with Adjuatable Dies.

NO. ½ VAN NORMAN DUPLEX MILLING MACHINE.

In Figs. 1 and 2 is shown a new design of the Van Norman duplex milling machine built by the Waltham Watch Tool Co., Springfield, Mass. The special feature of this machine, as in all of the Van Norman millers, is a movable cutter head mounted on a ram which can be adjusted in or out over the table, permitting the advantageous use of cutters for either vertical, horizontal or angular work. This particular machine meets the requirements for toolroom work, or general purpose light manufacturing.

The slides are operated by means of conveniently placed handwheels. That at the right of the knee in Fig. 2 is used as a quick return for the table. The table feed is operated by a revolving nut, the table screw being locked by a pawl which is thrown out of engagement when this feed is operated by hand. A table stop is provided, and means are furnished for clamping the table solidly when the longitudinal feed is not being used.

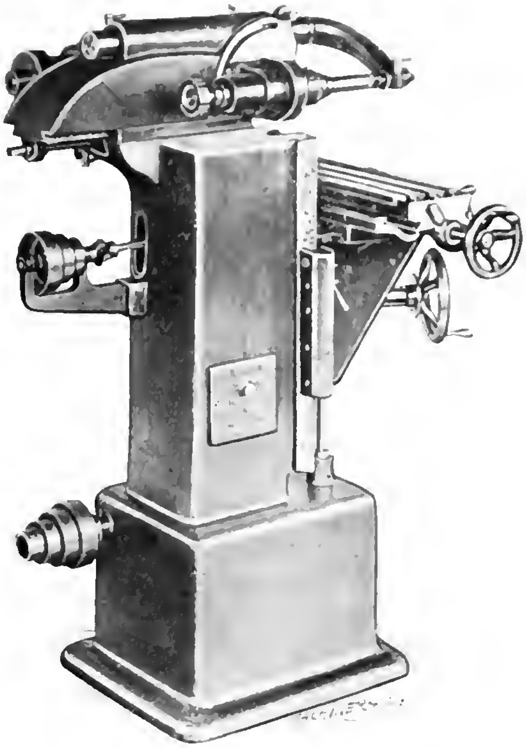


Fig. 1. Van Normen Miller, arreuged with Spindle Horizontel.

The cutter spindle holds a large split collet; large mills are mounted on a collet plug. The spindle is hardened and ground and runs in hard bronze boxes. The taper bearings are set up by an adjusting nut at the rear of the spindle. The driving cone is mounted on bearings at the side of the column. The splined driving shaft is connected to the cutter spindle by double bevel gearing. Fig. 1 shows the machine as arranged for horizontal milling, using the over head arm. Fig. 2 shows the ram adjusted forward, with the cutter spindle fixed at an angle. This machine weighs about 1,200 pounds. A semi-universal index head with draw-in collet is furnished if desired.

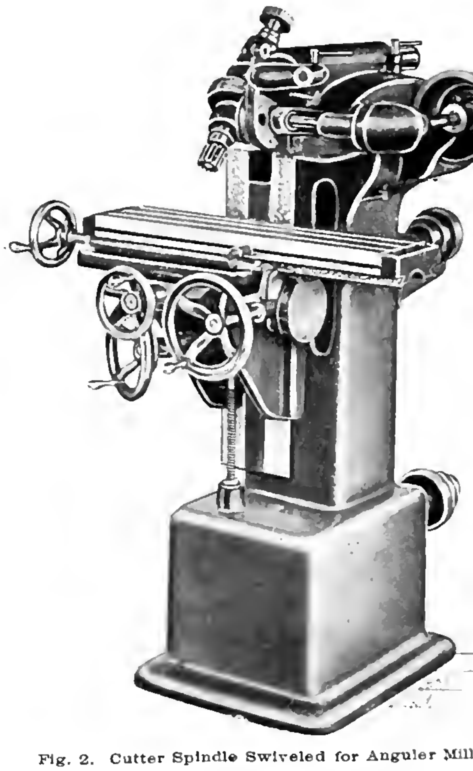

Fig. 2. Cutter Spindle Swiveled for Anguler Milling.

DALLETT AIR COMPRESSORS.

We [illegible] a new belt driven air compressor which is one of a line built by the Thomas H. Dallett Co., 23d and York Sts., Philadelphia, Pa. This line has been designed to meet the most exacting requirements for a machine of this kind. The general ruggedness of the design is plainly shown in the engraving. The following description will give some idea of the way in which the designs have been worked out.

The base is of the Tangye type; the main bearings have nearly three times the area called for by conservative calculations, and so may be depended on to run without heating and with a high overload as well, permitting the use of a larger capacity cylinder for the regular 100 pounds pressure, if desired. A flanged end is provided for bolting the cylinder to the frame; the convenience of this construction when tightening the nuts on the cylinder studs, will be appreciated by the engineer. The cylinders are of a special hard close-grained iron, cast with walls thick enough to allow for reboring when necessary.

A drain cock is provided at the lowest point on the cylinder heads, for use in cold weather. The clearance space is reduced to a minimum, and this, with the large water jacket cooling surface provided, results in a high efficiency. The lubricant is fed into the outlet passage, from which it is carried through the cylinder in the form of a fine spray. The connecting rod and crank shaft are of the marine type; both crank pin and cross head pin boxes are of high grade phosphor bronze. The crank shaft is forged from a solid billet of mild open-hearth steel.

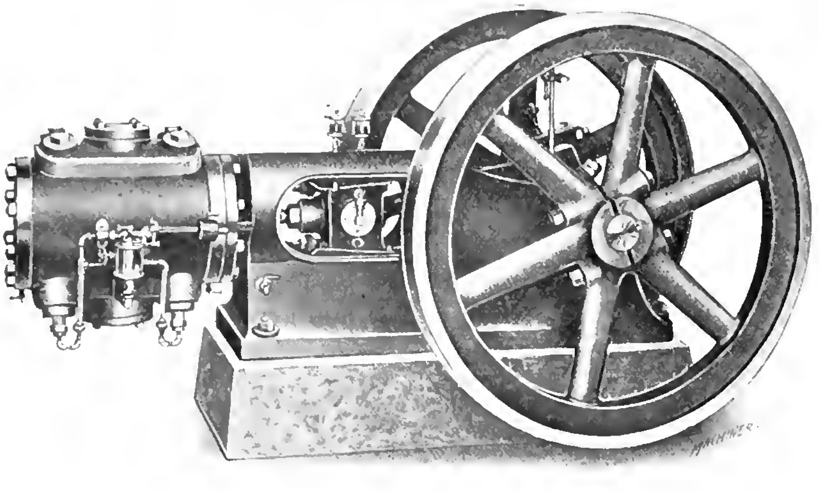

Fig. 1. A Belt-driven Example from a New Line of Dallett Air Compressors.

The air inlet and discharge valves are shown in Figs. 2 and 3 respectively. The outlet valve is a complete unit in itself, with no guides or stops to screw into the cylinder. The valve cap acts as a lock, holding the cage tight after it has been screwed down into its seat. Corrugated copper gaskets are used for forming the joints of the valve cage and cylinder, and under the valve cage cap. The valve is light, and of the proper area. The valve proper is of high-grade hardened steel with the seat and all wearing surfaces accurately ground. The tension of the phosphor bronze valve spring is carefully determined to give a light action, and yet shut the valve promptly on seating. The spring holder is of unique construction, consisting of a split taper ring set into a recess in the valve spring, and held by a solid taper ring which slides down over it. This entirely eliminates trouble from the shearing off of the spring holder, as sometimes occurs when held by a jamb nut or taper pin. The discharge valve, shown in Fig. 3, is of extremely simple design, being self-contained and having but four parts; viz: the malleable iron cage, the valve proper, the valve spring, and the cap. The latter acts as a positive stop when the valve has reached its full opening, thus obviating fluttering. Both valves are of large area and are practically noiseless in their operation. The time required to remove one from the cylinder is less than a minute.

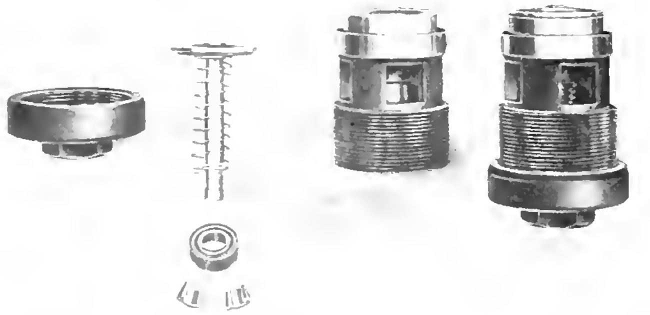

Fig. 2. The Self-contained Inlet Valve used on Dallett Air Compressors.

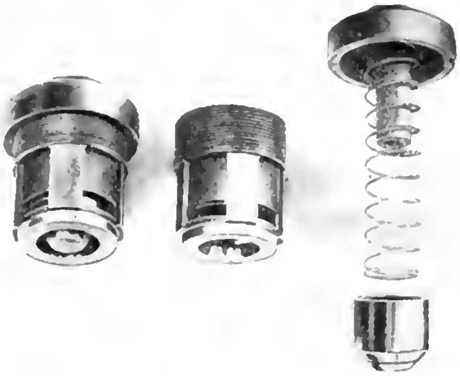

Fig. 3. Dallett Discharge Valve.

Pressure regulation is provided for in these belt driven machines, by an unloading device which automatically opens the air cylinder to atmospheric pressure when the receiver pressure has reached a certain pre-determined amount. This device holds open one or more outlet valves at both ends of the air cylinder, taking the load off the compressor, and allowing it to run light until the pressure drops in the receiver, when the valves are released and the air compression is resumed.

The makers also build a similar line of steam driven air compressors of the straight line type, either single, duplex or compound. In these a combined speed and pressure governor is used. The governor unloads the air cylinder exactly the same as on a belt-driven machine. At the same time, it controls the speed, allowing a single steam machine to just turn over when unloaded, and bringing a duplex or a compound machine to a dead stop. By this means a great saving in steam is effected, as well as a reduction in the wear and tear on working parts.

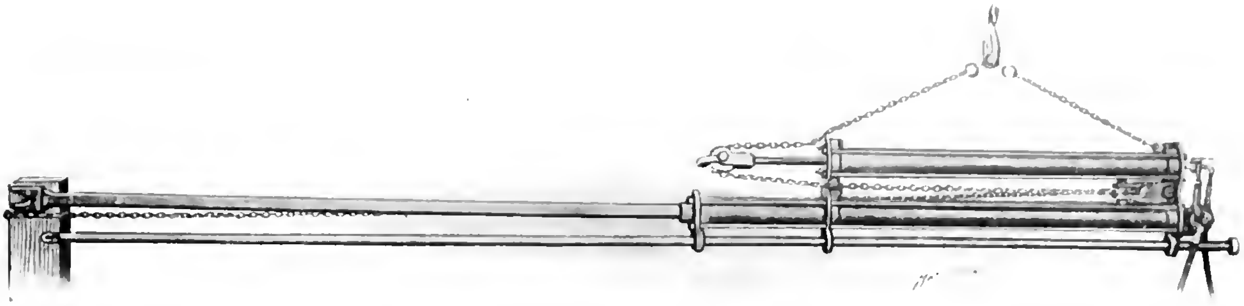
WILLIAMS, WHITE & CO.'S STAY-BOLT BREAKER.

Mr. Grover S. Lowe, a machinist in the Rock Island shops at Silvis, Ill., has invented a machine for breaking boiler staybolts, which works with rapidity and safety, so that jobs which formerly required five men's work for five days, are now done by two men in fourteen hours. It is not only useful in breaking staybolts when removing fireboxes from boilers, but can be used as well in wrecking steel buildings and bridges.

This machine, of which a general view is shown herewith, may be described as follows: It consist's primarily of two parallel cylinders securely fastened together. A valve is attached to the back end of each. The only purpose of the valve in the shorter cylinder is to act as a cut-off or a back pressure valve. The valve at the back of the longer cylinder is quadruple acting. The 100 pound striker or sledge is fitted in this cylinder. The front end is a cutting bar, with a boss welded around it at its rear end. Two lines of hose carrying compressed air are attached to the machine. One of them supplies pressure to the short cylinder, in which is fitted a piston which, by means of a chain and sheave, is made to hold the machine firmly against the cutting bar, pressing this in turn against the bolt to be cut. The machine thus moves forward automatically, taking up the slack as the bolts are broken.

The other hose is attached to the quadruple valve on the iron cylinder for operating the striker. Moving the handle of this valve in one direction admits compressed air behind the striker, sending it forward with great force, which is transmitted to the bolt to be broken. Twenty-eight 15/16-inch bolts have been broken by this means in three minutes. The machine is suspended from a crane or tripod, so as to be easily handled.

Three times the work with about ⅓ the men is the estimate as to the efficiency of the apparatus, and in the matter of safety there is no comparison. With the old methods the work of breaking staybolts is more dreaded than any other the boiler-maker is called upon to do. One of these machines is kept in constant service in the shop where it was designed, and it has displaced five other tools for the same purpose. The builders are Williams, White & Co., Moline, Ill.

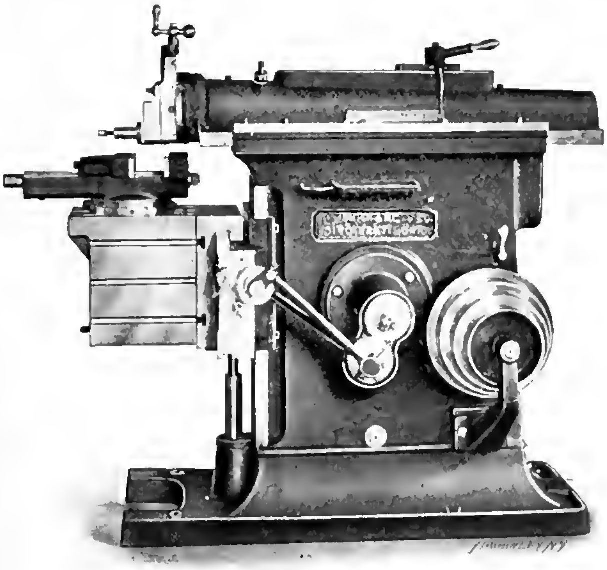


A Pneumatic Staybolt Breaker Invented by a Machinist in a Railroad Shop.

SMITH & MILLS HIGH-SPEED BACK-GEARED CRANK SHAPER.

The crank shaper made by Smith & Mills, of Cincinnati, Ohio, has been redesigned to keep pace with the increasing demands of modern service. Entirely new and heavier patterns have been used throughout. The resulting machine is shown in the accompanying engraving.

The column is of generous proportions, strongly braced and ribbed on the inside, and with projections front and back for the ram guides. The base is provided with pads for attaching a table support if required. An outside bracket supports the end of the driving shaft. The box table furnished with the machine is arranged for clamping work on either side, or at the top; it can be removed if required, allowing work to be bolted to the slotted apron. The telescopic elevating screw for the cross-rail is fitted with ball bearings. It is unnecessary to make an opening in the floor for this screw.



Smith & Mills High-duty Shaper.

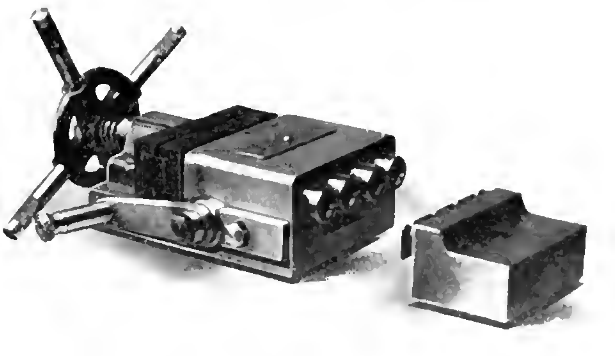
Among the new features of the machine, should be mentioned the fact that the changes of stroke, feed, speed and position of the ram are all made from the working side. The change in the length of stroke is made without stopping the machine. A locking device is provided which clamps the crank-pin rigidly, so that there is no possibility of a variation in the length of the stroke while the machine is in operation. The crank lever is adjustable to the wear of the sliding block, and is connected to the ram by a link. The automatic cross-feed of the table can be instantly changed while the machine is in operation. A new device on this machine is the automatic vertical feed for the cross-rail, which provides for raising the rail, table and work vertically, and feeding it against the tool. Micrometer dials are provided for the various movements, adapting the machine particularly to the cutting of racks, or, in conjunction with index centers, to the planing of gear teeth. A table of dimensions for rack cutting is furnished.

There are eight changes of speed on each machine. The back gears provide for this with the four-step cone. On a 16-inch machine these speeds range in geometrical progression between 6.21 and 157.15 strokes per minute. On the 20-inch machine the range is from 7 to 100.8, and on the 25-inch machine from 6.75 to 80 strokes per minute. The equipment of each machine includes a counter-shaft and the necessary wrenches, together with a swiveled jaw vise with a graduated base and steel-faced jaws. In ordinary work the 25-inch machine has removed a chip 1 inch deep, 3/16 inch thick and 18 inches stroke, at the rate of 15¼ cubic inches of steel per minute.

MILLER & CROWNINGSHIELD MULTIPLE SPINDLE INDEX CENTERS.

The multiple spindle index centers shown herewith are made by the Miller & Crowningshield Co., of Greenfield, Mass. The device is intended to be used in such work as fluting taps. The construction employed permits blanks of different lengths to be simultaneously and uniformly clamped in the four spindles by a single movement of the clamping wheel. An improved indexing device is also provided.

The tail-stock is practically a solid piece, as shown. The work is clamped by the end movement of the head-stock spindles. This end movement is effected by the screw and pilot wheel shown, which acts through a system of equalizing levers. The levers distribute the pressure over the four spindles, whether or not the four pieces of work are of equal length, within reasonable limits. It is possible with this arrangement to hold one or any number of pieces, up to four at a time, with equal firmness. The spindles are indexed by spur gears mounted on them, meshing with spiral gears on the index crank shaft, which passes through the head at a slight angle. This shaft is mounted in an eccentric bushing, which provides for adjustment in the case of wear. The ratio of the gearing is such that one complete turn of the index crank turns all the spindles in the same direction, into position for a new cut.

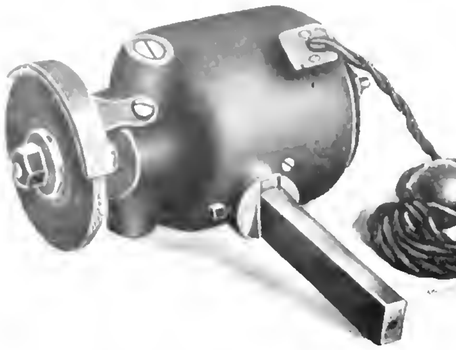


Multiple Centers for Fluting Taps, etc., provided with a Balanced Clamping Arrangement

WILLEY PORTABLE ELECTRIC GRINDER.

This grinder, made by the Willey Machine Co., Jeffersonville, Ind., is adapted to general grinding in the lathe. It can be used for plain cylindrical grinding in any lathe, or for taper grinding

in those provided with taper attachment or compound rest. The device is held by its shank in the tool post, the same as a lathe tool, and is operated by a lamp cord and socket connection with a shop lighting circuit. It is particularly useful for center grinding. On lathes having plain rests only, the centers may be ground by taking a succession of cuts the width of the wheel, finishing the centers to gage. The brushes and all the connections are enclosed and the bearings are adjustable for wear. The wheel is provided with a strong guard.



Electric Lathe Grinding Attachment.

"OMNI-PRESENT" LIGHT-HOLDER.

The Pennsylvania Specialty Mfg. Co., Cochranton, Pa., is making the "Omni-Present" light-holder, which is shown in detail in Fig. 1, and applied to a lathe in Fig. 2. This light-holder permits a lamp to be placed in any conceivable position, to which it may be instantly adjusted. It is especially useful in such work as internal threading and measuring. It may be used for the desk, drafting-room, table, machine, vise, etc.

This holder consists of a standard to which is attached a double flexible arm, connected by universal joints. An insulated swivel joint is provided for holding the lamp to the outer end of the arm. Two forms of base are provided. One of them seen just under the standard in Fig. 1 may be screwed to a table or machine. The other form, shown at the left, is used for mounting the holder in the T-slots of the milling machine, lathe, or other tool. The base of the holder may easily be changed from one end of the table to the other, or from one machine to another. These holders will be furnished with longer arms than shown at a slight additional cost. The finish of the parts is in oxidized copper, the base is japanned, giving the appliance an attractive appearance.

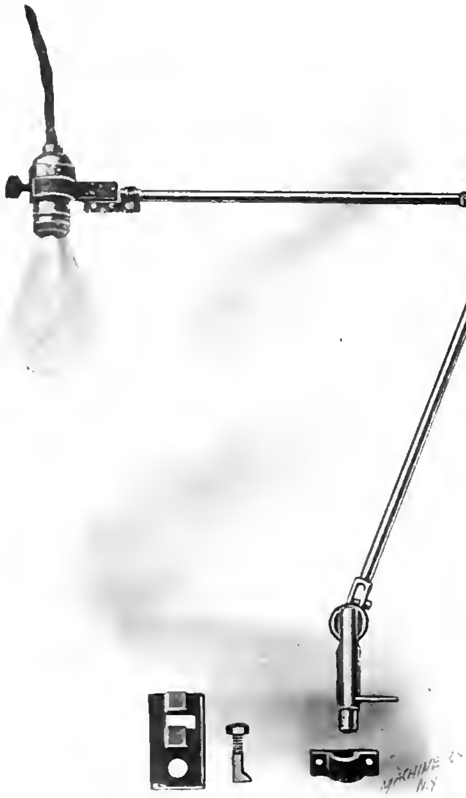


Fig. 1. "Omni-Present" Light-Holder made by the Pennsylvania Specialty Mfg. Co.

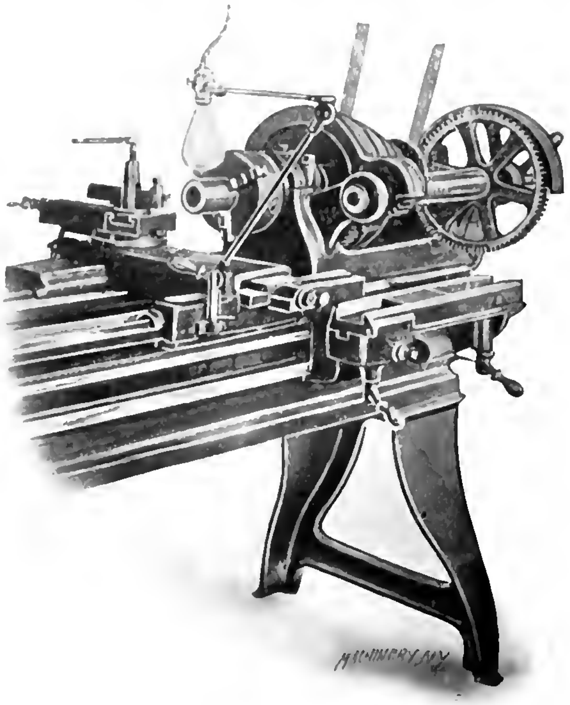

Fig. 2. Application of the Light-Holder.

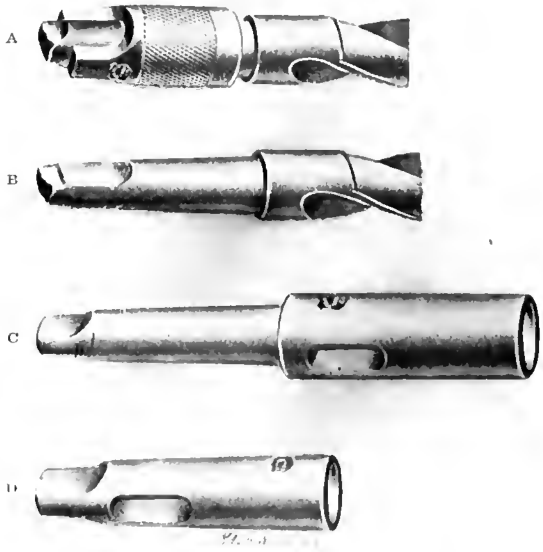
STANDARD TOOL CO.'S "ECONOMY" DRILL SOCKETS AND SLEEVES.

The Standard Tool Co., of Cleveland, Ohio, has recently placed on the market a shortened design of the regular taper socket and sleeve. This design is used for extending the life of twist drills which have failed, from the twisting or breaking of their driving tangs. Such a drill is shown at *B* in the engraving. This drill has had a new tang formed on it, it will be noticed, by milling flats further up on the taper. By the use of the gage shown at *A*, lines may be scribed, to which the flats are formed on the broken shanks; this may be done by grinding, filing or milling, as most convenient. When the broken tang is thus treated, it may be used in the socket as at *C*, or the sleeve as at *D*. The new tang is heavier and stronger than the old one, and insures an accurate and powerful drive. The shanks of the "Economy" sockets and sleeves are made of regular dimensions, and will fit the regulation Morse taper



Short Sockets and Sleeves, for using up Drills with Broken Shanks.

hole in the drill press spindle. The use of this appliance should save many otherwise useful drills from being consigned to the scrap pile.

WALKER TOOL-ROOM GRINDER.

The tool-room grinder made by the Walker Grinder Co., Worcester, Mass., is now made in a new design, which is herewith illustrated and described. This new design includes, among other improvements, a new table feed mechanism, and an improved construction of the spindle head, which allows a greater range of adjustment to the spindle without interfering with the free running of the belts.

The characteristic feature of the Walker grinder is the provision made for swiveling the cutter spindle in two planes, about a vertical and a horizontal axis. This provision allows the utmost flexibility in setting up work of a difficult character, and renders unnecessary the use of complicated and insecure holding devices for such work as grinding face mills, spiral reamers, etc. The arrangement of this well-known drive is shown diagrammatically in Fig. 2. The belt on the counter-shaft pulley A, passes down to an idler B at the head of the spindle column. From here it passes over the spindle pulley C, back to a second idler D in the column, and down through to the lower idler E in the base of the machine. The adjustment for height is effected by raising or lowering the spindle column F. The adjustment of the spindle is about axis xx in one plane and yy in the other. The adjustment about axis xx carries idler E with it, twisting the belt without materially altering its length. Similarly, the swiveling about axis yy is permitted without material change in belt length The two movements may be made simultaneously, or together, with perfect freedom.

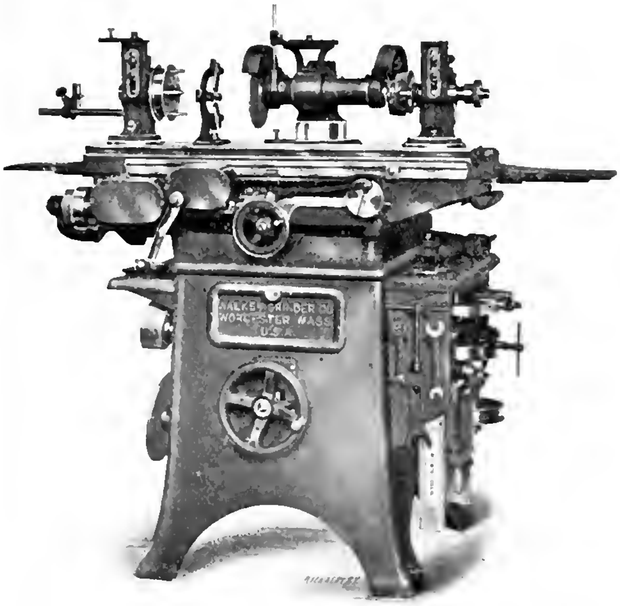


Fig. 1. The Walker No. 2 1-2 Tool-room Grinder.

The improvement at this point in the new design consists in mounting idler B (which is flanged, and of about the width of the belt) on pivot G, so that it swings in a vertical axis zz as shown; and in lengthening idler D to permit the belt to travel from one side to the other as required. This permits extreme adjustment without harmful straining of the belts, or rubbing against flanges of the pulleys.

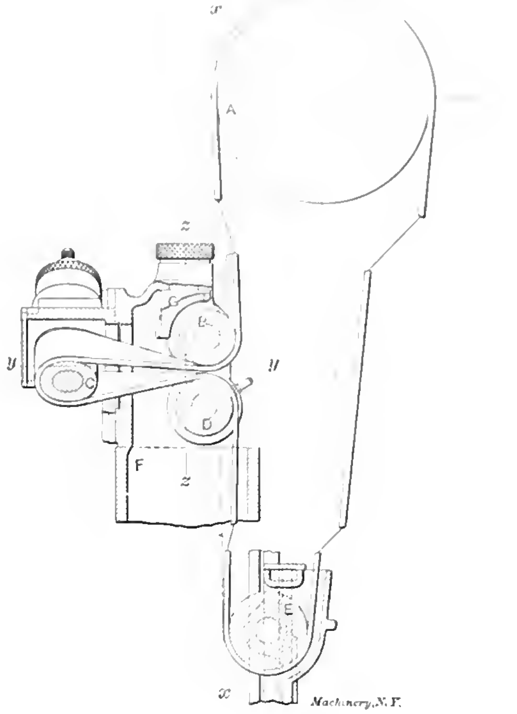

Fig. 2. The Improved Belt Drive of the Walker Grinder.

The new cross and longitudinal feed mechanism is shown in the line engraving, Fig. 3. It is driven from the main counter-shaft through a jack-shaft mounted at the side of the machine, which carries a two-step cone pulley connected with that shown at H. This, through the bevel gear and the clutch reversing mechanism J, drives the drum K. This drum, in turn, through the gearing indicated, operates the rack pinion shaft L, by means of which the table is reciprocated. A disengaging clutch is provided for throwing out the feed independent of the reversing mechanism by the longitudinal movement of pin M. The reversing is controlled by dogs N and N', adjustable in the T-slot at the front of the table. These shift slide O to the right and left alternately. Projection P and P' on slide O alternately compress springs Q and Q', which press against boss R, attached to the reversing clutch rod. As dog N pushes slide O to the left, for instance, spring Q is compressed;

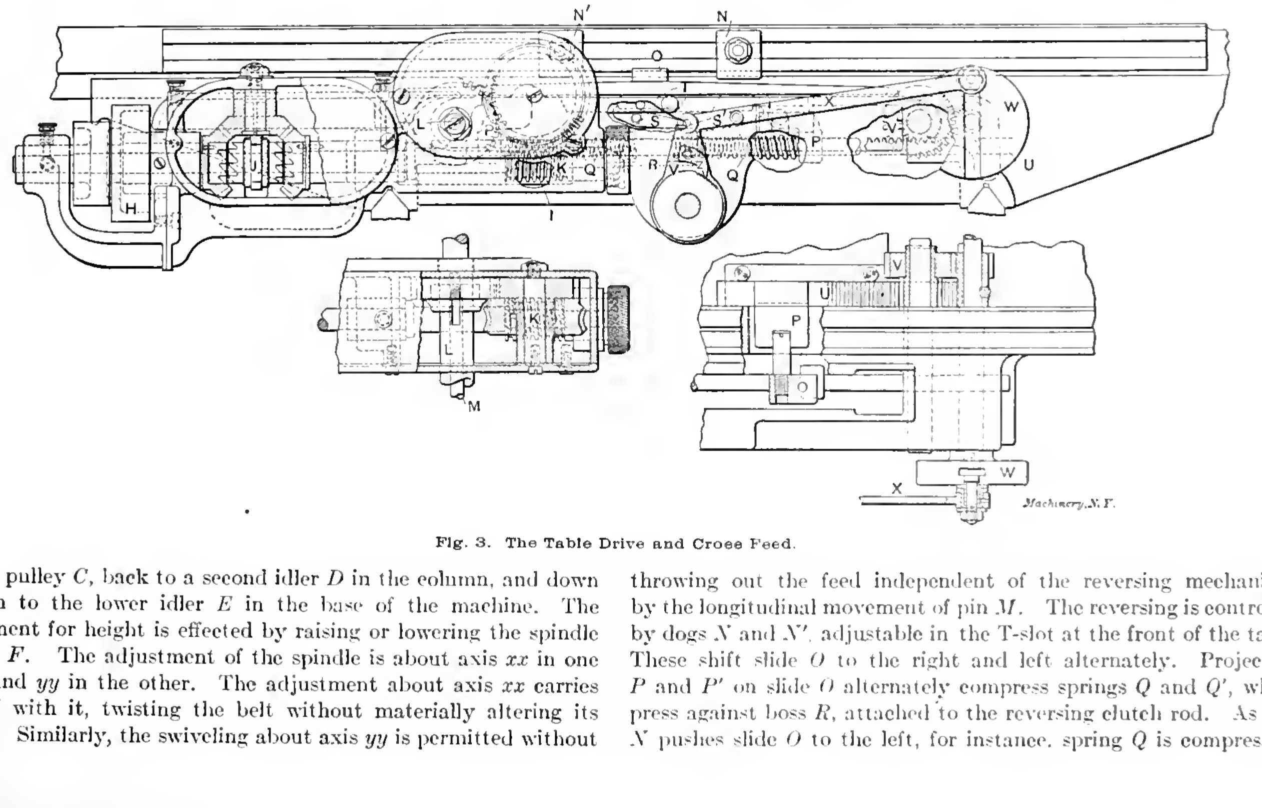

Fig. 3. The Table Drive and Cross Feed.

but R is prevented from operating the clutch rod under the pressure of the spring, by latch S. This latch is finally released by a cam T on slide O, which allows the spring to suddenly reverse the clutch. For reversing at the right of the stroke, dog N' moves slide O to the right, causing projection P' to compress spring Q'. When it has been compressed sufficiently, T raises latch S' allowing the clutch rod to be thrown over in the other direction, again reversing the mechanism. This arrangement, which is similar to others used for the same purpose, avoids the possibility of stopping on the center.

The automatic cross feed is operated by slide U, which is connected so as to reciprocate with slide O under the influence of dogs N and N'. U has rack teeth cut on its upper surface, engaging with the compound idler gear V. This, in turn, imparts at each reversal a half revolution to slotted crank disk W. The crank-pin adjustably mounted on this disk operates connecting rod X, which thus gives a back and forth angular movement to a bell crank which, in turn, by means of pawl Z, gives a ratchet feed to the cross-feed screw at each reversal of the stroke. The amount of the feed is regulated by the position of the crank-pin in the slot on the face of crank W. For reversing the feed, a similar ratchet to the one shown is mounted behind the bell-crank; it, however, has teeth pointed in the opposite direction. When one pawl is thrown in, the other is out, and *vice versa*.

In this new design, the best features of the previous machines have been retained. The overhead works is of the multiple speed type, with no step-down of the revolutions per minute, and providing for a wide range of adjustments between the maximum and minimum. The machine is furnished, as shown, completely equipped for cutter grinding, or for cylindrical and surface grinding, thus making it especially useful for tool-room work.

DIRECT BELTED GRINDER WITH SELF-OILING LOOSE PULLEY.

The Artisans Guild, Benton Harbor, Mich., is building the direct drive grinder shown herewith. The spindle of this grinder is provided with tight and loose pulleys, so as to make a countershaft unnecessary. As may be seen, the column is of rigid construction with long bearings and a heavy spindle, adapting the machine to the severe service that is likely to be required of it.

The principal novelty in the construction of this machine is the loose pulley. This pulley is self-oiling, and has a reservoir for lubrication, which requires refilling not oftener than five or six times a year. Its construction will be understood from Fig. 2, which shows a sectional view through the hub and oil reservoir. This journal, it will be seen, is ring-oiled, but on a different principle from the usual form, since the bushing is the revolving part, while the shaft remains stationary. The ring is of such diameter as to ride on the bottom of the revolving oil chamber, and almost touch the top of the stationary shaft. As the pulley revolves, it thus rotates the ring, which carries the oil up to the top of the shaft, from which it finds its way into the bearings on either side. After working its way through the bearings to the outer ends of the hubs of the pulleys, it is collected in an annular groove, and returned by centrifugal force through the ducts shown back to the central reservoir again.

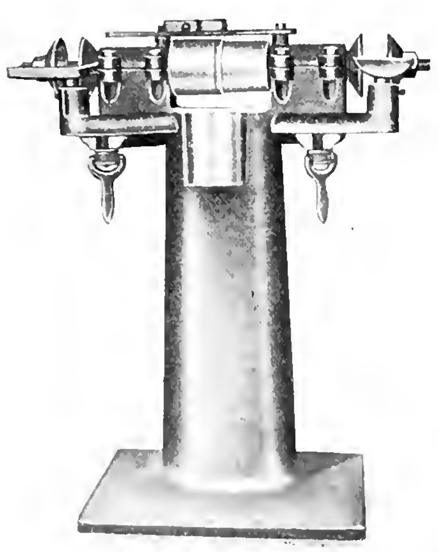

Fig 1 Grinding Stand made by the Artisans Guild.

This oiling arrangement may also be furnished in the form of a self-oiling bushing, to be applied to loose pulleys already in use.

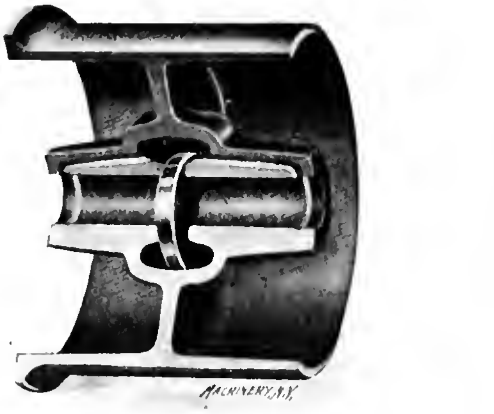

Fig. 2. Ring-oiling Loose Pulley used on the Spindle of the Grinder.

In either form, one of its chief merits is its inexpensiveness as compared with other devices designed for the same purpose. The parts are few and easily made, and the device is automatic in its action, only requiring filling the oil-well at intervals of two months or thereabouts.

CUTLER-HAMMER HAND LIFTING MAGNET.

A novel electrical appliance has just been placed on the market by the Cutler-Hammer Clutch Co., of Milwaukee, Wis., whose large lifting magnets are widely used in the iron and steel industries for handling pig iron, scrap, etc. The new device is a hand magnet weighing only about 7 pounds, but capable of lifting castings of from ten to fifteen times its own weight. The magnet is designed for operation on 110 volt, direct current circuits, and is furnished with a drop cord and attachment plug, so that it may be readily connected to any ordinary lamp socket. The push-button, mounted on top of the magnet and operated by the thumb, closes the circuit to the coils and makes the magnet operative. On releasing the button the poles become demagnetized and the load is released.

Fig. 1. A Hand Lifting Magnet.

Fig. 2. Handling Long Nails.

The first of these little magnets was built for use in the manufacturer's own shop, where it proved so useful and attracted so much attention from visitors that it was decided to manufacture it in quantities for the market. It seems to be capable of many useful applications. In machine shops it is used for clearing chips and borings out of the machinery, or removing them from parts of the work not easily accessible—as for instance from the bottom of a deep cylindrical casting. Dropped tools, bolts, boring bars, etc., are easily recovered with the aid of the magnet from places from which it would be difficult to fish them by ordinary means.

In shops where large quantities of brass and iron filings accumulate, which it is desirable to separate before selling as waste

material, the magnet is especially useful, since brass is not attracted by the magnet, like iron, thus enabling the two metals to be separated by merely passing the magnet through the mixed metals. In the same manner tacks or nails can be separated instantly from brass screws with which they may have become accidentally mixed. In foundries this magnet may be used to pick up hot or awkwardly shaped castings; smooth plates, which are sometimes difficult to secure a hold on when laying on a flat surface; or for cleansing the molding sand of minute particles of metal.

Suspended with its two poles immersed in the liquid, the magnet will attract to itself any particles of iron or steel which it may be desired to remove from the tubs in which paints, glazes, chemicals, etc., are mixed. One purchaser, who uses several automobile trucks in his business, has put this magnet to a novel use. He is paving an alley in the rear of his store with ashes, and finding that many nails from packing boxes, burned under the boilers, were mixed with the ashes, he is now guarding against punctured tires by employing a magnet to remove the nails from the ashes before strewing them in the alley. In the shipping departments of large establishments many hundreds of nails are recovered daily by hand from the sweeping. For work of this sort, or for handling nails, nuts, screws, etc., in hardware stores, this little magnet should prove useful.

HIGH-DUTY SIX-FOOT SURFACING GRINDER.

In the manufacture of its regular product, the O. K. Tool Holder Co., of Shelton, Conn., has to do a quantity of surfacing on metal parts of various kinds, much of the work being hardened steel. Various methods of doing this surfacing were tried, among others, finishing the parts on the commercial disk grinder. This was not altogether satisfactory in this particular instance, as the emery disks were quickly rubbed smooth, and much time and expense was involved in keeping the wheels supplied with new surfaces. The final solution of the problem of doing this work is shown in concrete form in Figs. 1 to 3, which illustrate a large steel wheel with narrow segmental faces of abrasive. This wheel has proved so efficient from the standpoints of output and cost of upkeep, that its maker has decided to place it on the market.

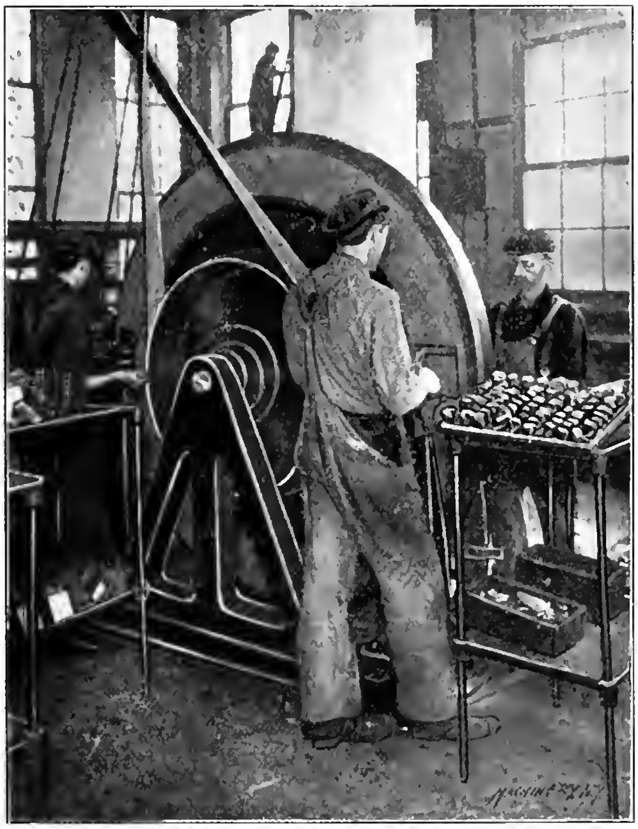

Fig. 1. A Face Grinding Wheel of Unusual Size.

The disk is of solid steel, and runs on Timken roller bearings, which are carefully protected from grit, and can be renewed at a slight expense. The driving pulley is 36 inches in diameter for a 6-inch belt; it should drive the wheel at about 250 revolutions per minute. The spindle is mounted on rigid frames and base. Four swinging work tables, similar to those used on the regular disk grinder are provided, so that four men can work simultaneously, as in Figs. 1 and 3. These work tables are pivoted at the base of the machine.

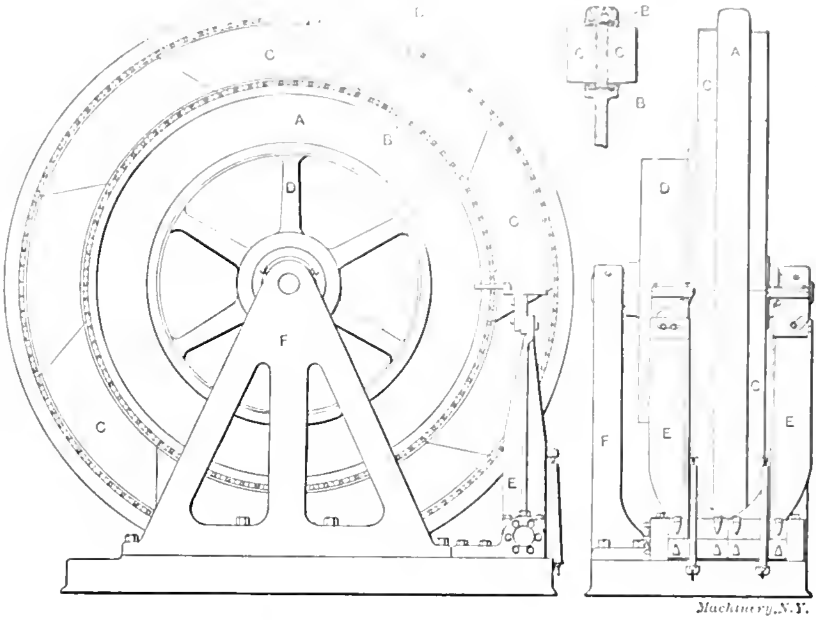

Fig. 2. Construction of the Grinder.

On each face of the rim of the disk is machined a wide, shallow groove, in which segments of abrasive material are set. There are nine segments on each face, each 8 inches wide and 4 inches thick. Before mounting in place, the backs of the segments are carefully surfaced, so that there is no danger of cracking them when they are being clamped into place. They are held by a series of small wedges, which grip the beveled edges of the abrasive, and draw it down firmly into place. To prevent the crumbling of the brittle material when clamping, thin strips of sheet lead are laid between

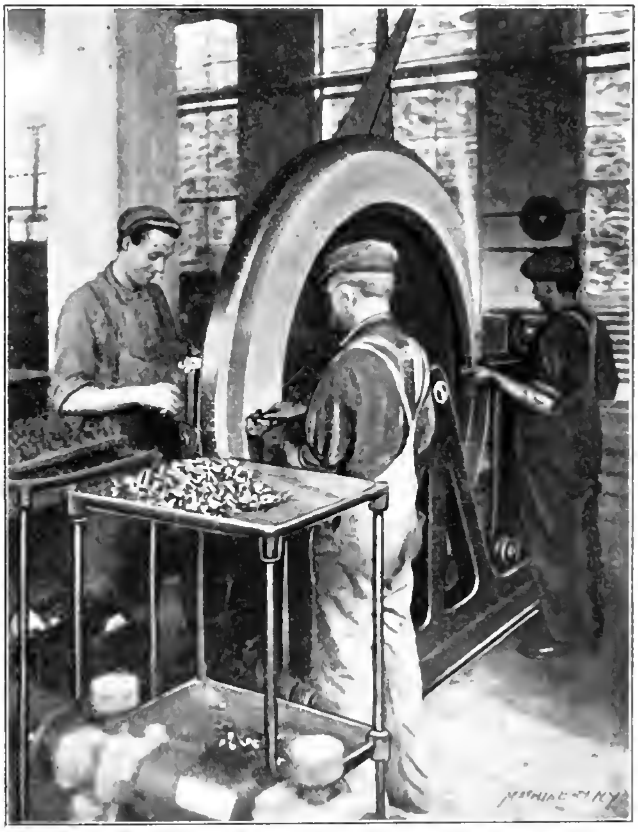

Fig. 3. Four Men at Work—the Usual Complement of Operators.

the wedges and the segments. To obviate the remote possibility of the work's catching in the joints between the segments, these joints are not made radial, but at a considerable angle, as shown. The method of fastening will be seen to be absolutely safe, as the only possibility of failure is by shearing, and that is highly improbable at any speed which is safe for the solid steel disk.

When the blocks become worn, from 4 inches thick down to $1\frac{1}{2}$ inch, they are packed out by placing wooden strips behind them, after which they may be used down to $\frac{1}{2}$ inch thick, thus wasting but $12\frac{1}{2}$ per cent of the material.

The builders make the interesting statement that they are able to grind on this machine three times as fast as on a wheel of the same grain and grade, running at the same peripheral velocity, but of one third the diameter. Two reasons are advanced for this increase of output. For one thing, the velocity of the abrasive is practically constant throughout the whole width of the 8-inch face, while on the face of the smaller wheel, the speed of the effective face varies from the maximum down to one half or one third of that amount, as the center is approached. This limits the efficiency.

Another point in favor of this 6-foot wheel is its enormous power storage capacity. Momentary pressure, which would slow up a smaller wheel, has not noticeable effect on the speed of this one. All four operators may force their work on the wheel simultaneously, but the stored-up energy carries the wheel around with no perceptible decrease in velocity; in other words the percentage of speed variation is very low.

THREAD MILLING ATTACHMENT FOR "CATARACT" BENCH LATHE.

In Figs. 1 and 2 a thread or worm milling attachment is shown applied to the "Cataract" precision bench lathe, manufactured by Hardinge Bros., 1031-1040 Lincoln Ave., Chicago, Ill. The special mechanism comprises a worm drive for the main spindle and a milling cutter spindle and bracket mounted on the tool-slide. The regular threading attachment is employed. Fig. 1 shows the front side of the machine thus equipped, and Fig. 2 the rear.

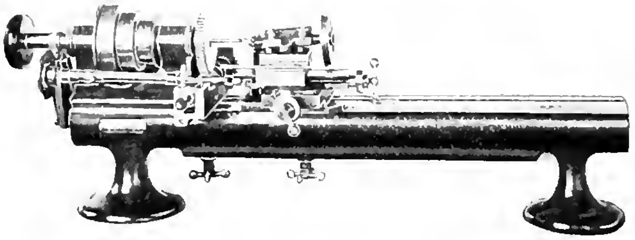

Fig. 1. Thread Milling Attachment used on Precision Lathe built by Hardinge Bros.

To the T-slot in the back of the bed is bolted a support for a supplementary driving-shaft with a cone mounted on it, identical with the regular spindle cone on the machine. This is driven from the same counter-shaft pulley used for driving the main spindle. The driving shaft is connected by bevel gears with a worm, which in turn drives a worm-wheel mounted in place of the face-plate on the nose of the spindle. This wheel is connected with the spindle by an arrangement which makes it possible to drive it in either direction without unscrewing from the nose. On the tool-slide is mounted a bracket carrying a cutter spindle. This spindle is held by the block at the required threading angle for the particular job in hand, and is driven from a separate pulley on the front shaft. The regular threading attachment, as mentioned, is used for connecting the main spindle with the tool-rest to give the desired pitch of thread. This attachment is applied to the upper screw of the compound rest, which is set parallel with the axis of the lathe for this purpose. When the required length of thread has been milled, an adjustable stop on the rest strikes a trip which allows the worm to drop out of mesh with the worm-gear on the spindle, thus stopping the machine.

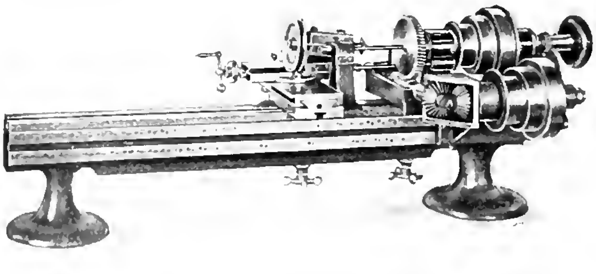

Fig. 2. Spindle Drive for Thread Milling Attachment.

Fig 1. The Stromberg Chronograph or Electrically-controlled Time Stamp.

This attachment has been found of great service in manufacturing work on such parts as are required for electric meters, anemometers, small taps, etc. The cutter spindle may be used interchangeably with brackets of various angles for threads of various pitches and diameters.

STROMBERG ELECTRIC CHRONOGRAPH.

The use of time stamps in shop accounting and other systems, is not a new idea. So far as we know, however, the Stromberg Electric Mfg. Co., 23 South Jefferson St., Chicago, Ill., is the first one to apply the time stamp to such work without using a clock in the instrument itself. In this new electric "chronograph," as its makers call it, the dies which stamp the time are controlled from a master clock which may be located anywhere in the establishment, and may be used to control synchronously any number of stamps. This insures uniformity of records throughout the establishment; reliability of operation is assured, since there is only one clock to look out for, and that may be of the highest grade; there also results a simplicity in construction of the stamps themselves. It is not necessary to buy a special clock as the proper connections may be applied to any existing time-piece.

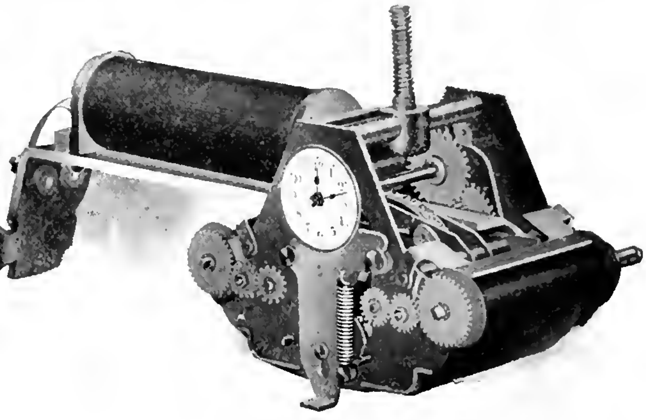

Fig. 2. Interior Mechanism of the Chronograph.

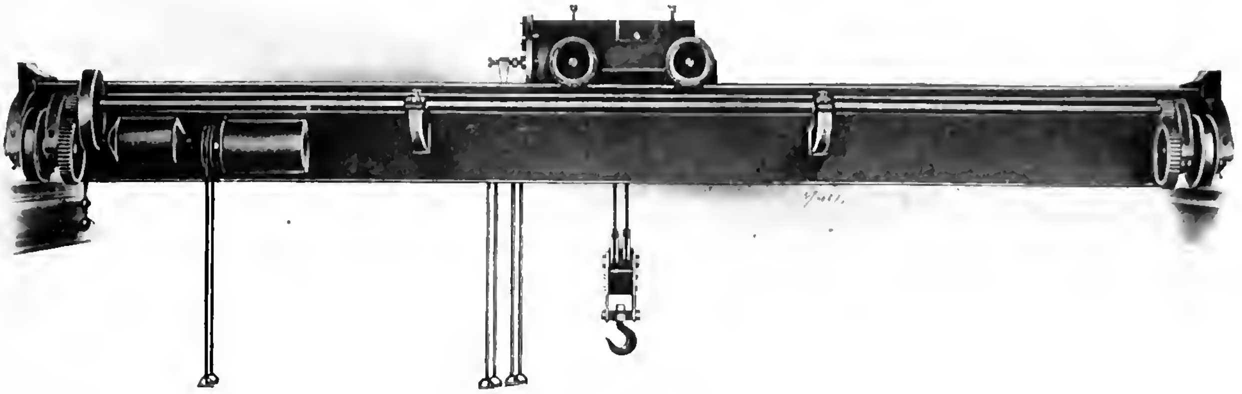
This chronograph is furnished as a plain time stamp for general use, or with such gaging and locating devices or special stamping dies as may be required for special uses. For time card stamping, for instance, gages are provided for locating the records in proper columns and on the proper lines for weekly or monthly records of employes' time. The only change in the device necessary is that of setting the gage from day to day.

This instrument prints right side up. It is provided with an automatic reversing ribbon feed which will give 150,000 impressions without a change of ribbon. The printing wheels and the hands at the side of the dial are moved by a simple magnetic action controlled by an automatic make and break device attached to

the clock. This stamp can stand hard usage without affecting its accuracy, which would not be possible if a delicate clock movement were contained within it. The chronograph mechanism contains no pawls, springs or dogs. It has a positive action and locked printing wheels, which can not be moved except by the interior magnetic mechanism, making it impossible for employes to tamper with it. The instrument requires only a monthly setting.

NORTHERN FLOOR-CONTROLLED ELECTRIC TRAVELING CRANE.

We illustrate herewith a small floor-controlled electric traveling crane built by the Northern Engineering Works, Detroit, Mich. This crane, which can be furnished in either the 1-, 2-, or 3-motor design, is adapted to loads of from 1 to 5 tons, and spans ranging from 12 to 40 feet. As regularly made, it consists of a double-girder bridge upon which rests a trolley, supporting an electric hoist of a type furnished by the makers. Any standard motor will be furnished, however, for either direct or alternating current.



Northern Floor-controlled Electric Traveling Crane.

The trolley is so arranged that it may be operated in either high, medium or low positions, thus adapting it to any height ceiling or any established distance from rail to truss cord. The hoist is equipped with both mechanical and electric brakes, and has an automatic limit stop for the block to prevent overwinding. The mechanical brake not only assists in holding the load but effectually controls the lowering operation as well. The automatic limit stop is operated by positive contact and does not depend on the hoisting ropes for its operation. The hoisting gearing is of the spur geared type, no bevel worm or planetary gearing being included in the crane. It is entirely enclosed in an oil-tight case.

The controllers have ample resistance for giving a wide range of speed, thus making the crane well suited to delicate handling such as is necessary over foundry floors, and in riveting work, etc. While it is regularly furnished to be controlled from the floor by ropes or levers, it can be arranged, if desired, to be controlled either from a cab attached to the bridge, or from a fixed operating stand on the floor.

TEMPERED, POLISHED AND BLUED STRIP STEEL.

The illustration shows a roll of interesting product, for which Edgar T. Ward & Sons, 23-25 Purchase St., Boston, Mass., are the American agents. It is a roll of 2-inch by 0.002-inch tempered, polished and blued strip steel, true to gage, and suitable for making fine springs and other parts of machinery for which a tempered stock is required. Many other uses for thin metal of this order will be found in the manufacture of small machinery. The company carries in stock 180 sizes ranging in thickness from 0.0015 inch to 1/16 inch, and in widths from 1/8 to 6 inches.

The company also sells approximately the same assortment of cold rolled steel not tempered, but of a carbon content capable of taking a high temper. This metal is suitable for formed springs, machine parts, circular cutters, saws, etc. Another grade of thin metal of lower carbon is supplied in rolls which will not harden.

Tempered, Polished and Blued Strip Steel.

SCREW CUTTING ATTACHMENT FOR ELGIN PRECISION LATHE.

The device shown in the accompanying engravings, built by the Elgin Tool Works of Elgin, Ill., for cutting threads with its precision lathe, is of the design which gives the greatest simplicity and directness of construction. It consists of a set of change gears mounted on a sector at the rear end of the bed, and connected with the feed-screw of the compound rest by universal joints and a telescopic shaft. No special lead-screw is required.

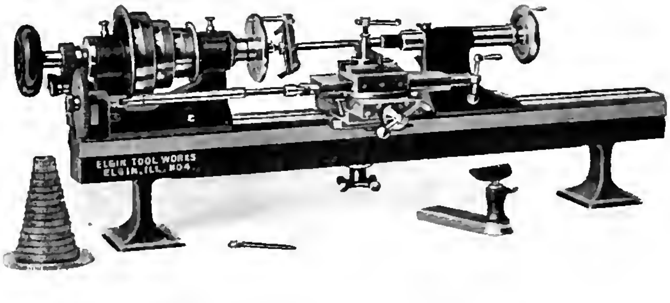


Fig. 1. Screw Cutting Attachment operating on the Feed-screw of the Compound Rest.

The sector is clamped to the lathe bed by a T-bolt. It carries the necessary studs for the change gears, which mesh with a driving pinion mounted directly on the spindle. The change gears provided cut English or metric threads as required. The range of English threads is from 10 to 150 per inch. The upper slide of the compound rest is made of extra length, permitting the cutting of long threads. So long as this lead-screw is set parallel with the ways of the lathe, which it has to be to cut a straight thread,

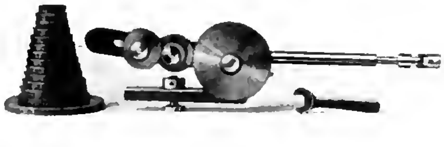

Fig. 2 Elgin Screw cutting Attachment Dismantled, showing its Simplicity.

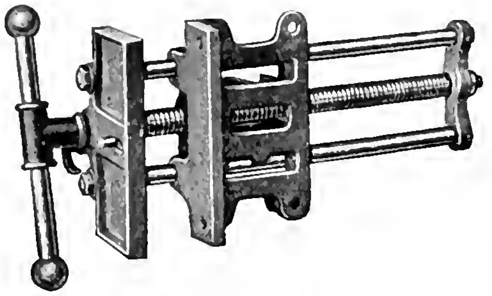
the simple universal joint connection provided will give it a rotation uniform with the spindle.

Fig. 2 shows the parts of this attachment disassembled, and illustrates the extreme simplicity of its construction.

YOST QUICK-ACTING MANUAL TRAINING VISE.

The G. M. Yost Mfg. Co., Meadville, Pa., has recently devised the quick acting vise shown in the accompanying illustration. It is particularly adapted to the needs of manual training schools or other wood working plants, where a quick acting vise at a reasonable cost is required. This vise is of the combination type, since it can be used either as a regular screw vise or with the quick acting feature. It is unnecessary to reverse the handle in releasing the quick acting movement. It is very simple in construction, having only eight parts in all. The vise is made with either wood or leather face jaws as required. It can be furnished also with a taper attachment to the front jaw, permitting tapered or irregular work to be clamped securely. The rods are of cold drawn steel, and the screw is of high grade tool steel; the jaws are gray iron castings. It is made in eight different sizes, with jaws up to 10 inches long and 4 inches deep.



A Simple and Inexpensive Quick-acting Vise for Wood-working.

* * *

NEW MACHINERY AND TOOLS NOTES.

Screw-Driver: Elmore Tool Mfg. Co., Hartford, Conn. This screw-driver is drop-forged in one piece with the handle, which has wooden grips rivetted to it, jack-knife fashion. The shank is square so that a wrench may be used with it if required.

"Gravity" Level for Machine Shop and Tool-Room Use: Risdon Tool Works, Inc., Waterbury, Conn. This level is of the type in which a pointer, moving over a graduated dial, is connected with a hanging weight in such a way that a slight movement of the latter gives a multiplied movement to the pointer.

Light, Rapid Action Punch: Rock River Machine Co., Janesville, Wis. This tool is intended for light steel punching, in plate up to ⅜-inch in diameter. It may be also fitted for shearing arrangements for bar or round iron and for angles. It will shear angles up to 2 x 2 x ⅛ inch. The frame and the floor standard are cast in one piece.

Universal Cam Cutting Machine: Kearney & Trecker Co., Milwaukee, Wis. This is an adaptation of the builders' standard milling machine; it is provided with a special table and work feeding and controlling apparatus, which fits it for the cutting of either face or pheriphery cams. Like all machines of its kind, a form or master cam is employed for giving the desired shape to the work.

Power Press With Automatic Feeding Mechanism: V. & O. Press Co., Glendale, L. I. This firm has recently brought out a line of inclinable power presses for automatic production of parts in sheet metal, fiber, etc. A recent equipment includes all the machinery necessary for making an improved four-part, metal bottle cap.

Cold Bend Testing Machine: Messrs. Tinius Olsen & Co., Philadelphia, Pa. This machine is used for the "cold bend" testing of specimens of iron and steel. The machine is provided with an electric motor of such power that specimens up to 1 inch square or its equivalent may be bent cold in about three minutes to an angle of 180 degrees. Bending dies for stock of any size up to 2 inches may be used; the smaller dies are reinforced to withstand the bending pressure.

"Rochester" Helve Hammer: West Tire Setter Co., Rochester, N. Y. This Helve hammer is of the type which employs a wooden beam with the pivot at one end, and the upper die or hammer head at the other. It is reciprocated by a crank and connecting-rod, attached to the beam by a flexible spring connection. A handle within convenient reach of the operator makes provision for altering the length of stroke.

The Woggle Punching Table: Standard Bridge Tool Co., Pittsburg, Pa. The punching table combines a swinging support for holding the work and presenting any portion of it to the punch, with a combined indicator and stripper, which serves to locate the work with reference to a paper or sheet metal templet.

Set of Tool Makers Scrapers: J. E. Poorman, 1722 St. Paul St., Philadelphia, Pa. This set of three scrapers for tool makers use is provided with handles of knurled steel tubing, and has blades of high grade steel, tempered, ground and polished. Three shapes are provided. One is triangular, hollow ground on all sides; one is rounded and curved, and the third one flat, for plain surface scraping.

Rapid Action Automatic Vise: Quick Automatic Vise Co., 236 Mill St., Rochester, N. Y. In this quick acting vise the jaws are adjusted in the usual way to suit the work. The first piece being clamped in this way, the vise may then be opened and closed for succeeding pieces of the same size by the action of the operator's foot on a pedal. On lifting the foot from the pedal the jaws close as firmly as before. It should prove an efficient tool in manufacturing bench work.

Improved Friction Clutch: Messrs. A. L. Schultz & Son, Chicago, Ill. This clutch is made in sizes from 6 inches up to 72 inches in diameter, transmitting from 3 to 500 H. P. at 100 revolutions per minute. It may be used as a clutch coupling to connect two shafts of the same or different diameters, or it may be attached to pulleys, gears, etc. It operates by the clamping of an internal flange on the driving member between two radial wood-faced surfaces on the driven member. The pressure is applied by a toggle mechanism.

Bench Legs: Frederick Pearce Co., New York City. These bench legs are designed for machine shop or laboratory use. They are particularly rigid when used as center benches, away from the walls. The frame is designed to hold two shelves, the upper one for files or tools, the lower one for boxes of stock, work, etc. The leg is 2 feet 10 inches high, and 24 inches across the top. It weighs 52 pounds. The makers are prepared to furnish these bench legs in either cast iron or in a non-magnetic alloy for laboratory use, where iron would be objectionable.

Motor Driven Speed Lathe: J. G. Blount Co., Everett, Mass. This tool is intended particularly for manual training schools. The motor, which is of the constant speed type, is mounted under the leg at the head stock end of the machine, and carries a cone pulley on the armature spindle, which is belted to the spindle cone above; the spindle is carried by a head stock of a shape which permits this arrangement of belting. The spindle runs in ring oiling bearings.

High Speed Steel Cutting-Off Machine: Colton Combination Tool Co., Easthampton, Mass. This machine employs a thin abrasive wheel of carborundum, running at 2,500 revolutions per minute. This is employed for cutting steel into sections for use in tool holders. It has the special advantage of doing this with a minimum of waste, and without starting the minute fractures which are caused from nicking and breaking the bars, and which result in the cracking of the cutting edges in use.

Self-Adjusting, Friction Sensitive Drill: Barry & Zecher Co., Lancaster, Pa. This drill press provides a friction disk drive mechanism in which the pressure is constantly maintained at the proper point. The feed change and the starting and stopping of the machine are both controlled by foot levers, so that the operators hands are free. The machine is started and stopped by lowering and raising the friction disk so that no counter-shaft is necessary. The machine will be furnished with either standard or right angle drive.

Light Riveting Machine: H. B. Townsend Mfg. Co., 32 Union Pl., Hartford. Conn. In this riveting machine the rivet is struck a large number of rapid blows per minute. The head of the spindle lies in a path of a series of rolls, loosely carried on pins in the face of a rapidly rotating disk. These rolls act as hammers, in striking the riveting die on the work, as the latter is raised into contact with it by pressing a treadle on the base of the machine.

BORING JIGS USED BY THE QUEEN CITY MACHINE TOOL CO.

In the present issue of MACHINERY, Mr. Einar Morin shows several interesting designs of boring jigs in his article entitled, Jigs and Fixtures. The two accompanying illustrations, Figs. 1 and 2, are of special interest in this connection, showing as they do, two boring jigs in operation, and illustrating the very features which have been brought out in the articles on the principles of jigs and fixtures. These two boring jigs are employed in the manufacture of shapers in the shops of the Queen City Machine Tool Co. (Station V), Cincinnati, Ohio. The illustration, Fig. 1, shows a boring jig for shaper columns. By means of this jig it is possible to get all the holes through the column in perfect alignment, and to provide for interchangeability. The jig is of the full box pattern, both ends of the boring bars being supported in the jig. The boring bars are connected with the driving spindle of the machine by universal or knuckle joints; two cuts are taken, the roughing cut leaving but a thin film of metal to be removed by the finishing cut.

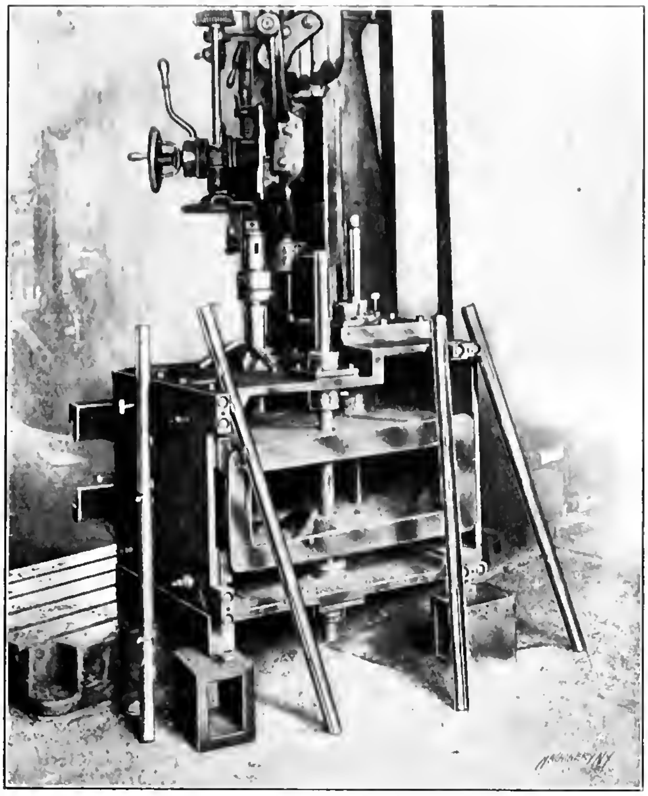


Fig. 1. Boring Jig for Shaper Columns.

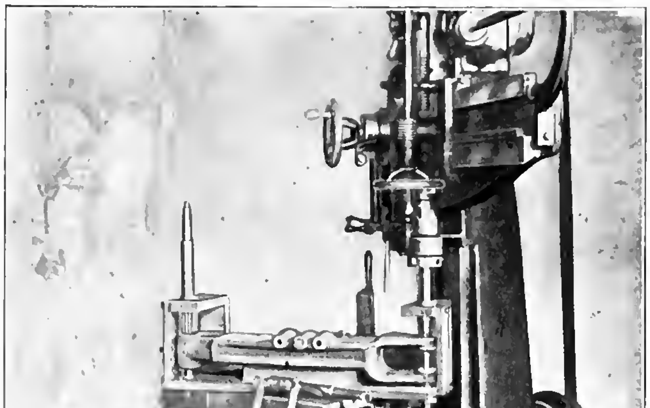

Fig. 2. Boring Jig for Boring and Reaming Holes in Rocker Arm.

In Fig. 2 is shown a boring fixture for boring and reaming the top and bottom holes in a rocker arm. These must be carefully bored at right angles to the sliding block bearing. It will be seen from the illustration that the rocker when finish planed is located on a projection of the jig, which is carefully planed at right angles to the guide holes for the boring bars. By this means it is possible to obtain bearings in the arm which are in proper relation to the sliding surface.

It is of great importance in the manufacture of these parts of the shaper, that the tools and fixtures employed fill the requirements for high-grade work, as otherwise twisting strains will be produced in the finished shaper, which are liable not only to injure the machine itself, but to cause inaccuracies in the work being performed on the machine. The influence of rigidity on the efficiency of a machine was ably demonstrated by the interesting experiments on the milling machine, undertaken by Mr. A. L. De Leeuw, and described in a paper read before the last annual meeting of the American Society of Mechanical Engineers, which paper was abstracted in the December issue of MACHINERY (engineering edition). These experiments were undertaken on a milling machine, but the necessity for rigidity, is, if anything, even greater on a shaper. There are so many joints, so much over-hang, so many parts subjected to twisting stresses that it is absolutely necessary in the machining of shapers, to use jigs and fixtures which will insure accurate work and perfect alignment, if the best results are to be obtained.

* * *

PERSONAL.

William Lonsdale, formerly assistant superintendent of the Knox Auto Co., assumed the superintendency of the same concern on January 1.

Frank S. Waters, president of the Lyon Metallic Mfg. Co., Aurora, Ill., maker of steel racks and factory equipment, has been spending a few weeks in Texas and Cuba, recuperating.

George H. Baush, sales manager of Hill, Clarke & Co., Inc., Philadelphia, Pa., has resigned his position, to take effect February 1, and will go with the Fay Machine Tool Co. of Philadelphia as general sales manager.

Augustus Brown, for the past six years superintendent of the Monarch Emery & Corundum Wheel Co., Camden, N. J., is now assistant superintendent of the American Emery Wheel Works, Providence, R. I.

Harry H. Mason, recently promoted from machine foreman to apprentice instructor in the A. T. & S. F. Ry. shops, has again been promoted to the position of bonus demonstrator, on the Middle and Oklahoma Divisions, with headquarters at Newton, Kansas.

OBITUARY.

George W. Shotwell, president of the Diehl Electrical Mfg. Co., Elizabethport, N. J., died at his home in Bayonne, N. J., January 22.

Prof. Benjamin Franklin Clarke, Professor Emeritus of mechanical engineering at Brown University, died December 29 of pneumonia at his home in Providence, R. I. Prof. Clarke was born in Newport, Me., in 1831, and since his graduation from Brown University in 1863 had been connected with the faculty. He was twice acting president of the university.

Henry Wallace Caldwell, president of H. W. Caldwell & Son Company, Chicago, Ill., died December 22 at Redlands, Cal. He was born in Kentucky in 1843. After creditable service in the civil war, he engaged in business in Indianapolis and later in St. Louis, becoming particularly interested in grain elevator management. This led to the invention of the Caldwell conveyor and the business of designing and erecting elevators. He later moved to Chicago, where he devoted his entire attention to the making of screw conveyors and other machinery for the conveying and elevating of materials and the transmission of power.

CHARLES H. BESLY.

Charles Howard Besly, head of the firm of C. H. Besly & Co. of Chicago, died at the Henrotin Memorial Hospital in that city December 31 from the effects of an operation. Mr. Besly was born in Milwaukee in 1852, educated in the Chicago public schools, and began his business experience with Marshall Field & Co. Afterwards he went with S. D. Kimbark & Co., and later with the predecessors of Crerar, Adams & Co. In 1873 he became manager of the Bergen Tool Co., Batavia, Ill., and in 1875 started in for himself as a broker in machinists' supplies. The firm of C. H. Besly & Co. was established in 1881, and comprised Mr. C. H. Besly and Mr. David J. Kennedy, being located at 175 Lake St. In 1886 Mr. Kennedy retired from the business and since that time Mr. Besly has been the sole owner. In 1891 he removed to 10-12 North Canal St., continuing there until he built the present building in 1903, at 15–21 South Clinton St.

In 1886 the Beloit factory was established in a small way for the manufacture of die-stocks, and was gradually increased for the production of various specialties, including the Besly disk grinders, "Helmet" temper taps, etc. This branch of the business grew as rapidly as the merchandise end and necessitated the erection of new and extensive buildings in 1905. Mr. Besly also owned the business of Brown & Besly, established in 1884, for the manufacture of letter files, filing cabinets, etc. This business has increased in like proportions with the others and now occupies a building of its own at 139 Besly Court, Chicago.

Mr. Besly was a graduate in chemistry of the Rush Medical College of Chicago, and also spent a year in a mechanical school in London. He was a member of many societies and clubs, including the American Geographical Society of New York, and the Engineers and Machinery Clubs of the same city; the National Machine Tool Builders' Association, and the Union League and Athletic Clubs of Chicago.

Mr. Besly was first married in 1884 to Minnie Zilpha Welles, who died in 1893, leaving one daughter. In 1894 he married Kathleen M. Healy, daughter of G. P. A. Healy, the celebrated portrait painter. Mrs. Besly, with the eldest daughter and three younger daughters survive him

Mr. Besly was widely known among Chicago business men and to the machinery trade all over the country. While he was a shrewd and successful business man, he gave liberally and unostentatiously where his sympathies were enlisted, and when he thought his help would be of practical benefit. He was an unusually well-read man, and his keen observation enabled him to present his knowledge in an attractive way which is not often found with men who so closely apply themselves to business. These traits and his jovial disposition made him many warm friends to whom his death was a heavy loss.

Mr. Besly's large interests were left in a strong financial and physical condition, and will be continued as heretofore under the general management of Mr. Edward P. Welles, his nephew, who has been connected with the firm of C. H. Besly & Co. for the past twenty-two years, and as general manager since 1896.

* * *

Next to gold, silver is the most malleable and ductile metal. It may be hammered into foil 0.0001 inch in thickness, and a single grain can be drawn into wire over 400 feet long.—*Brass World.*

HILL, CLARKE & CO.'S "FAMILY PARTY."

The "family party" given annually by Hill, Clarke & Co. of Chicago to the manufacturers they represent and to their organization in the West, took place on January 11th at De Jonghe's restaurant in Chicago. There was everything one could think of to eat and drink, speechifying and music—and no casualties. Those present were: Mr. Bosch of the Western Tool Works, Holland, Mich.; Mr. J. N. LaPointe of the LaPointe Machine Tool Co., Hudson, Mass.; Mr. Ralph LaPointe of the Universal Boring Machine Co., Hudson, Mass.; Mr. Wood of the Wood Turret Machine Co., Terre Haute, Ind.; Messrs. Adt and Case of the Geometric Tool Co., New Haven, Conn.; Mr. H. E. Flather of Flather & Co. and Mr. E. J. Flather of the E. J. Flather Mfg. Co., Nashua, N. H.; Messrs. Kearney and Trecker of the Kearney & Trecker Co., Milwaukee, Wis.; Mr. August Marx of the Gray Planer Co., Cincinnati, Ohio; Messrs. Sibley and Workinger of the Sibley Machine Tool Co., South Bend, Ind.; Mr. Thwing of the Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass.; Mr. Van Hyning of the Pignall & Keeler Mfg. Co., Edwardsville, Ill.; Mr. Carlton of the Consolidated Press & Tool Co., Hastings, Mich.; Mr. O'Brien of the South Bend Machine Tool Co., South Bend, Ind.; Messrs. Clarke, Wigglesworth, Mons, Ditfurth, Hale, Wendland, Kimball and Brandes of Hill, Clarke & Co., of Chicago, and Mr. Luchars of MACHINERY.

* * *

COMING EVENTS.

February 1-6—Second Annual Hartford Industrial Show of machinery, tools, accessories, supplies, etc., will be held in Foot Guard Hall, Hartford, Conn. R. B. Jacobs, general manager, Hartford Conn.

February 9.—First regular meeting of the National Gas and Gasoline Machine Trades Association at the Auditorium Hotel, Chicago, Ill.

March 27-April 3.—Mechanical and Electrical Exhibition, under the auspices of the Worcester County Mechanics Association, in Mechanics Hall, Worcester Mass. The exhibition will include machinery in operation manufacturing goods, and is under the direction of Mr. H. F Campbell, superintendent, room 6, Mechanics Hall, Worcester.

May 18-20. American Foundrymens' Association convention. Cincinnati, Ohio, Hotel Sinton, headquarters. Richard Moldenke, sec'y, Watchung. N. J.

June 16-18.—Annual convention of Railway Master Mechanics Association on Young's Million Dollar Pier, Atlantic City N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 16-23.—An exhibition of machinery, tools and supplies for the railway supply trade will be held under the auspices of the Railway Supply Manufacturers Association. Membership dues in the association are $25.00 per year and carry one badge only. Additional badges may be obtained by members for $5.00 per badge. Contracts have been let for the erection of exhibition structures covering 59,000 square feet, exclusive of aisles. The charge to exhibitors will be 40 cents per square foot, to cover the cost of erection, etc. The association has prohibited the distribution of souvenirs. Application for space should be made immediately to Mr. Earl G. F. Smith, secretary, 345 Old Colony Building, Chicago, Ill.

June 21-23.—Annual convention of the Master Car Builders Association on Young's Million Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

NEW BOOKS AND PAMPHLETS.

COMPARATIVE TESTS OF RUN-OF-MINE AND BRIQUETTED COAL ON LOCOMOTIVES. By W. F. M. Goss. 57 pages, 6 x 9 inches. Published by the Department of Interior, United States Geological Survey, Washington, D. C., as Bulletin No. 363.

The report includes torpedo boat tests and some foreign specifications for briquetted fuel. The locomotive testing plant of the Pennsylvania R.R. at Altoona, Pa., was the scene of the locomotive tests made by Professor Goss; and the pamphlet is illustrated with halftone and line drawings showing the characteristic features of the plant. The results of the test will be studied with much interest by those interested in the fuel problem.

HANDBOOK OF SMALL TOOLS. By Erik Oberg. 526 pages, 5½ x 8 inches, 282 illustrations. Published by John Wiley & Sons, New York. Price $3.00.

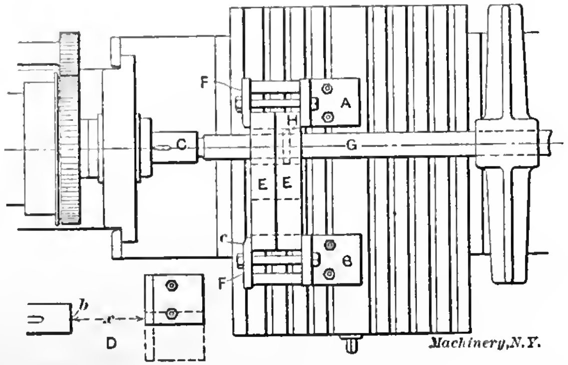
The advent of this work on threading tools, taps, dies, cutters, drills, reamers, counterbores, hollow mills and other accessories of the machine shop and metal-working trades emphasizes the specialization which marks American mechanical development, and the genius for classification that has made that development possible. The old-school mechanical engineer considered the details of small tools a matter scarcely worthy of his distinguished consideration, being something that could safely be left to the whims, vagaries, ideas—good, bad and indifferent—of the machinist, toolmaker and other mechanics using them. But the same human faculty that enables the scientist to classify all animal life, from bugs to elephants, placing each representative of type in its respective class, can be profitably employed to organize and classify every detail of manufacture. Nothing is too small or insignificant to be overlooked. The surprising fact is learned in such work, that the small things are the real factors that make for success or failure. The importance of small tools in the mechanical trades is expressed by a word—indispensable; the efficiency of production depends as much on them as on the machines and men. The author has treated his subject principally from the manufacturing point of view, giving the details of standard manufacturing practice in the matter of pitch lead, diameter, angles, rake, clearance, numbers of teeth, shape of flutes, sizes of squares, dimensions of shanks, taper per foot, and the thousand-and-one other details that are important in the manufacture of small tools. The book contains 134 tables of valuable data, most of which are for the first time published herein, or were originally published by the author in MACHINERY. The formulas for obtaining the dimensions of tools are largely of the author's own derivation. The following table of contents will give an idea of the scope and value of the work to manufacturers, tool-makers and others concerned with the making and maintenance of small tool equipment: Screw-thread systems; methods and principles of thread-cutting; measuring threads; threading tools; definitions of taps; hand taps; tapper taps and machine taps; screw machine taps; hobs and die taps; taper taps; miscellaneous taps; threading dies; plain and side milling cutters; miscellaneous milling cutters; reamers; drills; counterbores; hollow mills; lathe arbors. The work is not a treatise on tool-making practice, but rather a collection of data, elaborated and fully explained. It tells *what to do* rather than *how to do it.*

Supplement to MACHINERY, March, 1909.

Operations for the Article in this number entitled "Machine Shop Practice—Machining a Three-throw Built-up Crank-shaft."

SHOP OPERATION SHEET NO. 91.

W. Burns. MACHINERY, March, 1909.



Machining a Three-throw Built-up Crank-shaft—Boring the Webs.

NOTE.—As the crank-shaft is of the built-up type, the crank-pins and parts of the shaft proper are fitted into the webs after the latter are bored; therefore this operation, which will be performed on a horizontal boring mill, will be considered first.

1. First plane the webs on their sides to the finished width, and then lay them out as illustrated in Shop Operation Sheet No. 92. As the webs are to be machined in pairs, it will only be necessary to lay out three, or half the whole number.

2. Bolt angle-plates *A* and *B* to the table, spacing them far enough apart to clear the finished holes in the web, as shown. Move the table until one side of the plate *A* is opposite the spindle *C* as shown at *D*. Then caliper the distance *x* from a point *b*, say on the lower side of the spindle, to the plate. Move the table until the angle-plate is in the position indicated by the dotted lines, and, without moving the calipers, again measure the distance *x* from the same point *b* on the spindle. Adjust the angle-plate until the calipers just touch it on either side.

3. When angle-plate *A* is set, move the table across the bed until the plate *B* occupies the position shown at *D*; then, with the calipers set to the distance *x* last used when setting plate *A*, set plate *B*.

4. Place two webs *E* against the angle-plates, with the laid-out side of one next to the clamps *F*.

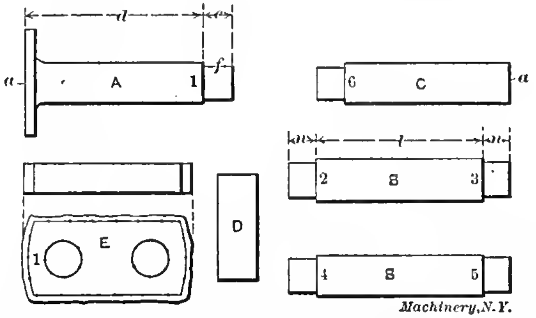
5. Set the circles representing the holes to be bored, the same height above the machine table, using the surface gage.

6. Start the holes, if the webs are solid, with a small drill, say ½ inch; then enlarge with a larger drill, say 2 inches. A short cutter bar with a cutter in the end may then be used to remove enough material to let the boring bar *G* pass through.

7. Set one of the scribed circles on the web concentric with the spindle *C*, using hermaphrodite calipers, and finish the hole with double-ended cutters *H*. Draw a line *c* across one side of the table to some point on the saddle. Move the table until the distance between the line on it and the line on the saddle, equals the center distance of the two holes to be bored. Then finish the second hole.

SHOP OPERATION SHEET NO. 92.

W. Burns. MACHINERY, March, 1909.



Machining a Three-throw Built-up Crank-shaft—Rough Turning the Parts.

NOTE.—The crank-shaft, as before stated, is of the built-up type, which means that instead of being a solid forging, it is made by machining the several parts and shrinking them together in proper relation with one another.

1. The parts *A*, *B*, and *C*, of the shaft proper, and the three pins *D*, are first centered, preferably in a centering machine. The end parts *A* and *C* should be provided with large centers at *a*, as the entire shaft will be supported upon these during the finish turning operation.

NOTE.—In order that the location, in the assembled shaft, of the parts shown in the illustration above may be understood, the reference letters, for a given part, in this and the succeeding illustration are the same.

2. Rough turn the parts *A*, *B*, and *C* to within about 3/16 inch of the finish diameter, and face the ends, leaving the forgings full length. These parts should be rough finished to the same size, as uniform diameters will aid in assembling the shaft.

3. Number the shaft holes of the webs from 1 to 6, using preferably small steel stamps; then number each piece *A*, *B*, *C*, as shown, on the rough bearing.

4. Finish the end (1) of the flanged part *A* as indicated by the finish mark *f*, making it a shrink fit in web number 1. When cutting the shoulder, set the tool a distance *d*, from the rough-turned face of the flange, equal to the dimension given on the drawing, plus one-half the difference between the thickness of the rough and finished flange. Face the end of the shaft until the distance *e* equals the thickness of crank web number 1.

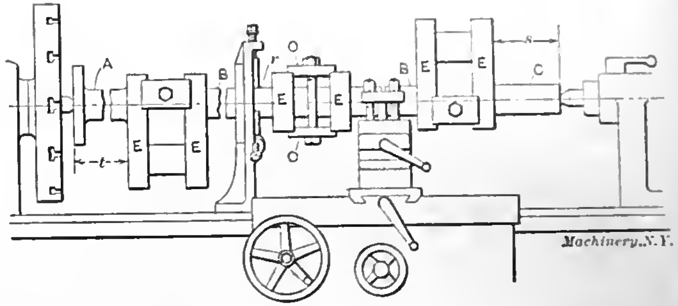
5. Turn the ends 2 and 3 of part *B* to a shrink fit in webs 2 and 3, respectively, making the bearing length *l* to correspond with the dimension on the drawing. Face the ends until the distance *n* equals the thickness of the respective webs. In a similar manner finish the second part *B* and the end piece *C*.

NOTE.—The numbers on the webs and the corresponding numbers on the shaft parts, enable the one who finally assembles the crank-shaft to place each end in the hole to which it was fitted.

6. Turn and fit the crank-pins *D* to shrink fits in the webs, numbering them as described for the main parts of the shaft.

SHOP OPERATION SHEET NO. 93

W. Burns. MACHINERY, March, 1909.



Machining a Three-throw Built-up Crank-shaft—Turning the Journals.

NOTE.—It is assumed that the edges of the webs have been machined (a simple slotting operation) and the parts shrunk together, with the shaft and pins properly keyed in position. As it would be impracticable to attempt to get the parts *A*, *B*, and *C* in perfect alignment when shrinking the shaft together, these pieces are rough turned and then finished after the shaft is assembled, as described in the following:

1. Fit packing pieces *O* between each pair of webs, as shown. These pieces are held in position by a bolt which passes through them, and their purpose is to prevent the springing of the shaft, which would occur were it placed between the lathe centers with no supports between the webs.

NOTE.—The distance between each pair of webs should be measured with an inside micrometer gage, or calipers, before and after the packing pieces *O* are fitted in place, to make sure that the webs have not been sprung apart, as a very small amount would throw the shaft out of true.

2. Place the shaft between the lathe centers after greasing or oiling them, and fix to the head-stock end a suitable dog for driving.

3. Start the lathe and test the journals *A*, *B*, and *C* to see if they run fairly true. The two center pieces *B* are often slightly out, but if they will finish to the required size, this will not matter.

NOTE.—It will not be necessary to bolt weights on the face-plate for the purpose of counterbalancing this shaft, as the cranks, being equally spaced, balance each other.

4. Turn a small spot about 2 inches long at *r*, leaving it about 1/32 inch over the finish size, and place a steady rest at this point. Light cuts should be taken when turning this spot, to obtain a true surface and also to prevent the tool from gouging into the unsupported shaft.

5. Finish one of the journals *B* and the journal *C*, and polish with emery cloth. Face the end of the part *C* to the dimension *s* given on the drawing.

6. Reverse the position of the shaft between the centers and support it by setting the steady rest against the finished bearing *B*. Take a finishing cut over the parts *A* and *B*, and finish the coupling flange to the dimension *t*, and to the required diameter.

III.—STEAM PIPE SIZES FOR HEATING SYSTEMS.

D'Arcy's formulas for flow of steam in pipes, used for calculating Table I.

$$Q = c\sqrt{\frac{(P-P_1)\,d^5}{wL}}, \qquad W = c\sqrt{\frac{w(P-P_1)\,d^5}{L}},$$

$$d = \sqrt[5]{\frac{W^2 L}{c^2 w (P-P_1)}}, \qquad P-P_1 = \frac{Q^2 wL}{c^2 d^5},$$

Q = Cubic feet of steam per minute,

W = Pounds of steam per minute,

w = Weight per cubic foot of steam at pressure P_1

P = Initial pressure,

P_1 = Terminal pressure,

$P-P_1$ = Drop in pressure,

d = Diameter of pipe in inches,

L = Length of pipe, in feet,

c = Constant.

MACHINERY

March, 1909.

ORGANIZATION AND EQUIPMENT OF AN AUTOMOBILE FACTORY.

CONSTRUCTION AND DESIGN OF THE PRODUCT.

C. B OWEN *

THE Leland, Faulconer & Norton Co., of Detroit, Mich., was formed in 1890 for the purpose of building machine tools and special machinery. The incorporators were H. M. Leland and C. H. Norton of Worcester, Mass. (both of whom had been with Brown & Sharpe for many years), and R. C. Faulconer and C. A. Strelinger of Detroit. Special milling machines, a lathe center grinder, a well-known wet tool grinder, and some special machinery were built. Later the manufacture of wood trimmers for pattern shop use was undertaken; and next, during the development period of the bicycle industry, a line of machinery for making hardened and ground bicycle gears was developed. As the bicycle business declined, the company began building gas engines for motorboats, which were then rapidly rising in popularity. Mr. Norton severed his connection with the company in 1894, and returned to Worcester, where he later became interested in the Norton Grinding Co. A large foundry was completed in 1895, which has run steadily ever since, doing a large outside business.

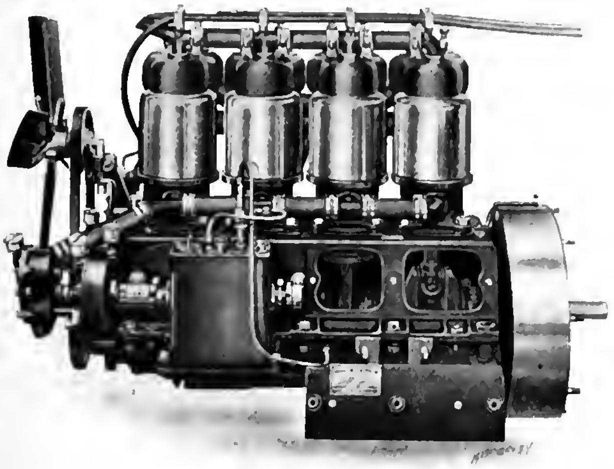

Fig. 1. Left Side of Cadillac 30-horse-power Engine.

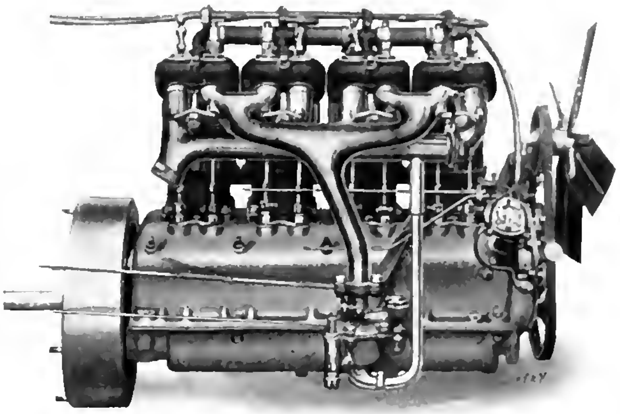

Fig. 2. Right Side of the Engine, showing Carburetor, Commutator, etc.

The natural step from the marine to the automobile type of gas engine was made in 1901 to 1902, when the motor now used in the Cadillac car was produced. The firm's previous experience enabled it to build an engine which was thoroughly standardized and accessible for adjustment or repairs and for the replacing of worn parts. A stock company formed by Detroit business men about this time for the manufacture of automobiles, made arrangements with the Leland & Faulconer Co. to build the engines. The car made its first public appearance in September, 1902, at the time the city was celebrating its bicentennial, and the car was called the "Cadillac" in honor of La Mothe Cadillac, who founded the city in 1702. In 1904, Mr. Leland was made general manager of the Cadillac Co., and in the next year the stock of the Leland & Faulconer Co. was absorbed and both plants united to form the present Cadillac Motor Car Co. From 1902 until the present time about 21,000 cars have been turned out, 17,000 of which were single cylinder 10 H. P. machines, and the rest four cylinder cars, rated at 30 H. P.

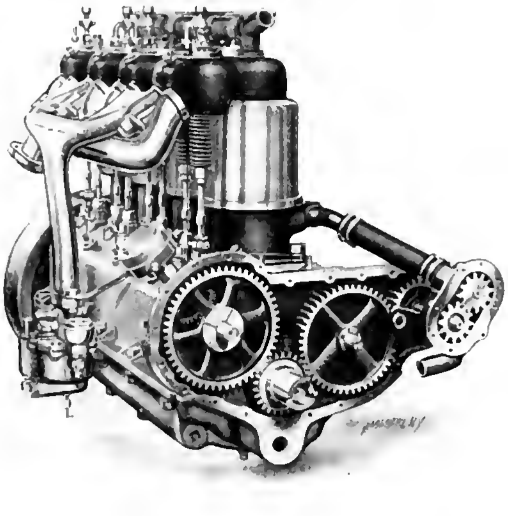

Fig. 3. Front View of the Four-cylinder Engine.

The first automobile, made in 1902, was a runabout containing a 10 H. P., single cylinder, four cycle, horizontal engine, of 5-inch bore by 5-inch stroke. This engine was found to be so satisfactory that it has been retained practically unchanged up to the present time, and its general features have been adopted, so far as possible, for the vertical four cylinder engines of the 30 H. P. machine. A number of original features were employed on this engine which have proved their value in actual practice. One of the most interesting of these is the cylinder construction, best seen in Fig. 9. This cylinder, which is a fine-grained gray iron casting, has a flange near the forward end, which enters and fits a bored and faced seat in the frame. The copper water jacket slips over the cylinder, and is flanged to match its outer face. Both it and the cylinder are held in place by a ring which passes around the outside of the copper jacket, and is tightened down by the studs shown screwed into the frame. In this way the copper jacket forms its own gasket. The cylinder head or valve chamber is held in place by a hollow steel nut (or nipple, rather) which is threaded externally right- and left-hand, and screws into both the cylinder and the valve chamber. The upper end of the copper jacket is clamped between the two, and thus serves for a gasket at this joint also, forming the only packing needed. Parts are kept in alignment by a dowel, and suitable openings connect the jacket space of the cylinder and the head. Among the advantages of this construction over the usual cored jacket are lighter weight, greater water space, more uniform thickness of cylinder walls, facility in cleaning the jacket space, elimination of trouble from freezing the cooling water, and low repair cost for broken parts.

The exhaust valve is placed in the cylinder head with its axis vertical, and it is operated from the cam shaft by a push-rod and bell-crank. The inlet valve is of the inverted

* Address: 857 Lincoln Ave., Detroit, Mich.

type, located directly above the exhaust valve. It is operated by a lever with a roller on its outer end which, in turn, is actuated by a push rod riding on a roller mounted on one arm of a short lever. The push-rod is connected with an eccentric on the cam shaft. The lever on which it rides is under the control of the driver, so that the timing of the valve and the amount of lift may be varied according to the work required. The throttling is thus effected by the inlet valve gear. The carburetor (shown in Fig. 10) is formed in one piece with the inlet valve mechanism. As may be seen, the inrush of air lifts valve *M* and allows the escape of the oil, which falls into the wire mesh basket *K*, where it is vaporized. The lift of the valve may be regulated to give the desired richness of mixture.

The motor frame is made in three parts—the frame proper, and the top and bottom plates. The main shaft, which is offset, is a nickel steel, center-crank forging, finished all over by grinding. It is carried in babbitt lined bronze bearings, fitted in bored and reamed seats in the motor frame. These are held in place by cap plates, which can be adjusted without opening the motor. The cam shaft is carried in bronze bushings inserted in the bottom plate. This plate and the cam shaft may be removed at any time without disturbing the crank shaft.

The transmission of the 10 H. P. machine is of the planetary type, providing for two speeds forward and a slow reverse. As shown in Fig. 11, the gearing is all enclosed in an oil-tight casing. On the high-speed forward gear the whole transmission revolves as a unit. The driving pinion is of 40 point carbon steel and is case-hardened, as are also the idler pinions, which have bronze bushings pressed into them after hardening, and run on hardened and ground pins pressed into the gear case. Power is transmitted to the rear axle sprocket by a Whitney roller chain. An assembled view of the engine is shown in Fig. 8.

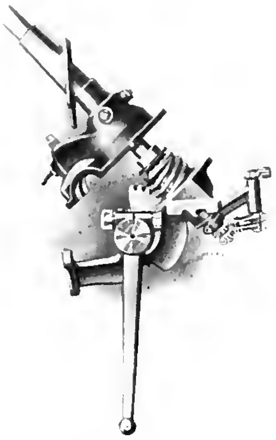

Fig. 4. The Cadillac Steering Gear.

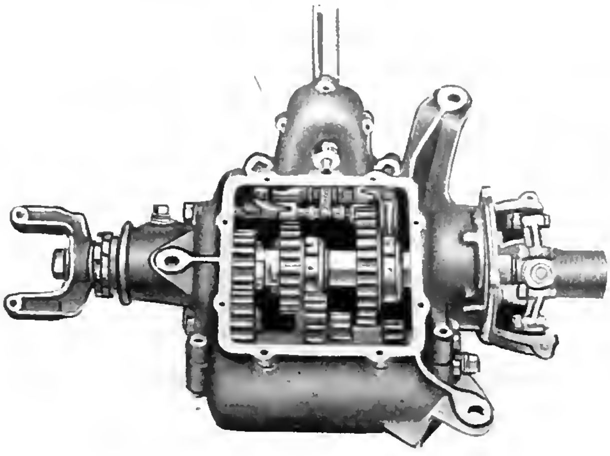

Fig. 5. Selective Type Sliding Gear Transmission

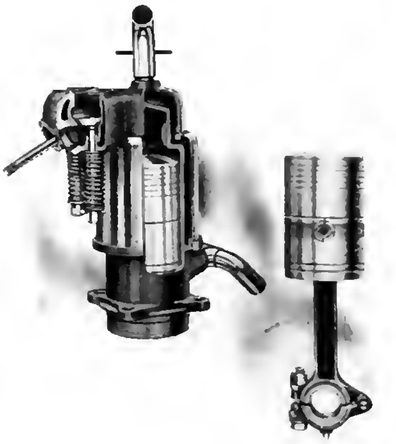

Fig. 6. The Cylinder and Piston.

The later vertical four cylinder engine for the 30 H. P. machine is shown in Figs. 1 to 7 inclusive. This engine has been built, as far as practicable, on the lines of the horizontal machine. As may be seen in Fig. 6, the same arrangement is used for clamping together the cylinder, the copper jacket and the cylinder head, although a somewhat different joint is used at the lower end of the jacket. In this engine also the crank-shaft is offset; the construction of the crank case and base is different, of course, as shown in Fig. 7. A leather-faced cone clutch in the fly wheel transmits power to the sliding gear transmission (see Fig. 5) which gives three speeds forward and one reverse. The gears and shafts are of oil-treated chrome-nickel steel, and are carried on ball bearings. The gear case is oil-tight, as is also the universal joint housing and the rear axle casing. The rear axle carries an oil-treated chrome-nickel steel bevel gear and pinion, and the gear mounts are adjustable for wear of the teeth. The steering gear (see Fig. 4) is of the worm and sector type, treated in the same ways as the transmission and differential gearing.

The Plant and its Organization.

The main or Cadillac plant is located on both sides of Cass Ave., and has a double siding connected with the Belt Line Railroad, thus giving ample shipping facilities. The factory buildings are of brick and reinforced concrete construction, lighted by large windows. Heat is supplied by a live steam system. The boiler-room contains three water tube boilers, with room for another if it is needed. Light and power are furnished by electric current supplied by the Detroit Edison Co. Electric driving is used throughout the plant, with motors connected with each line shaft, and occasional installations with direct connected tools. A large compressor furnishes air at 125 pounds pressure for the penumatic hammers in the frame department, and for use in the various assembling departments, for cleaning parts, running air drills, etc. Five large elevators in fire-proofed brick shafts convey materials and parts between the various floors. An automatic sprinkler system is installed, supplied by four tanks on the roof. These tanks are filled by a large fire pump which operates whenever the level of water in the tanks is reduced. This same system supplies water for lavatory and wash-room use. There are two large wash-rooms, each having 600 bowls and 1,000 lockers. Soap is furnished by the factory.

The old Leland & Faulconer plant comprises a foundry building of brick, steel and glass, supplied with cupolas and a hydraulic jib crane; a pattern shop and pattern storage building; a brass foundry building; a brick building for the case-hardening department; and a large three-story brick building for the power plant and the sheet metal and brass working departments. The building is lighted by both gas and electricity, has a hot air heating system, and is provided with large wash-rooms on each floor.

The organization of the plant is divided into the following departments: First, the general manager; second, the secretary; third, the sales department; fourth, the advertising department; fifth, the purchasing department; sixth, the time-keeping and cost-keeping department; seventh, the superintendent and his assistants; eighth, the engineering and designing departments, who produce the new models, tools and fixtures, and in conjunction with the experimental department, test the new cars before placing them on the market; ninth, the foremen and their assistants in the forty-four manufacturing departments; and six other special departments, some of which will be mentioned later. While the reader will be most interested in the departments devoted strictly to manufacturing, the work of the engineering and purchasing departments is worthy of some notice.

The designing-room is separate from the general drawing-room and is used by the chief engineer and two designers. Suggestions for new designs and improvements in old ones may be made by any one on suitable blanks. They are all considered and passed upon by a mechanical committee, consisting of the general manager, the chief engineer, and the two designers. When approved, such changes are made immediately on the tracings, and new blue-prints are made and sent to the departments concerned in producing those parts. This keeps the blue-prints up-to-date, and avoids loss in the carrying through of parts of obsolete design. A well-organized experimental department is provided, having the necessary apparatus for testing new designs. The work

of the general drawing-room includes the detailing of new designs, and the drafting work on the necessary tools, gages, jigs and fixtures needed to produce new parts or models. Filing cabinets are provided for current drawings, as well as for those which are obsolete, of which a full record is kept.

The Purchasing Department, the Stock-rooms and the Gasoline Storage.

The purchasing agent has final authority on all matters concerning the actual buying of material used in the cars, and the care of this material until it goes to the machine or assembling departments. Purchasing orders are made out in quadruplicate. One copy goes to the seller, one to the receiving office, one to the bookkeeping department, and one to the file in the purchasing office. Small commercial parts, such as nuts, rivets, etc., are stored in bins in the general stock-room, which also receives the finished and inspected parts turned out by the manufacturing departments. The stock-room record is kept on a card index system, and material is delivered by the stock keeper only on presentation of a requisition from the foreman of the department where it is to be used. Bulky parts and materials are kept in a large warehouse, which is also under the care of the purchasing department. A separate stock-room is required for repair parts. These are kept in stock for all models, clear back for the first one placed on the market, and they are replaced as fast as sold out.

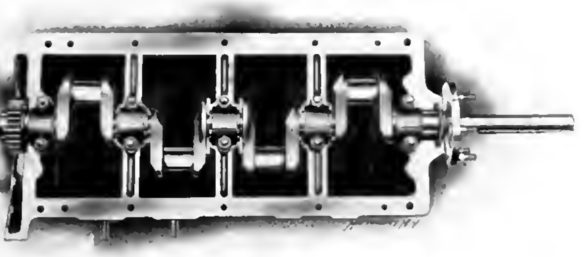

Fig. 7. Top View of Motor Case and Crank-shaft.

The gasoline used in testing the cars is also considered as stock, and a very carefully planned storage system is provided for it. Four cylindrical tanks of 15,000 gallons capacity each are buried in concrete near the siding, with the tops of the tanks about five feet below the street level. They are connected at top and bottom by separate cross piping. The system of storage is such that these tanks are always full of water or gasoline, or both, so that air is always excluded, making explosion impossible. The upper cross pipe permits the free passage of gasoline between the tanks, while the lower pipe performs the same function for the water. A suitable arrangement of automatic valves lets in water as fast as gasoline is removed, or permits the escape of water as gasoline is introduced.

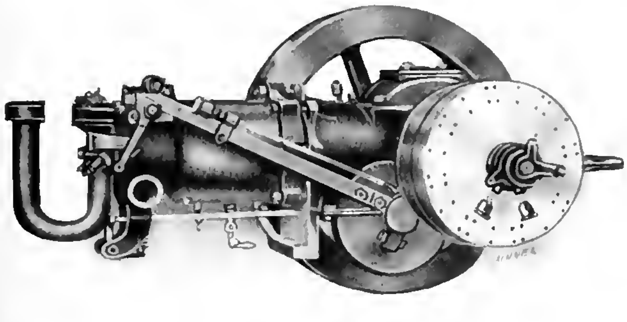

Fig. 8. The 10 H.P. Engine of the Single-cylinder Car.

A notable safety provision in the outlet piping for the water, positively prevents the escape of gasoline into the sewer. The outlet pipe is formed into a long U-bend, which extends vertically to a depth of 70 feet, inside of an 18-inch casing. From this it returns and discharges through a trap into the sewer. The depth of this bend is such that the column of water on the outlet side will balance a column of gasoline having a height corresponding to the head obtainable from a tank car on a grade 5 feet higher than the present siding. The water thus furnishes a permanent seal against the discharge of gasoline.

The distribution of the gasoline is also carefully safeguarded. It is supplied to the various testing rooms and to the factory garage through piping from the storage system. It is retailed by Bowser registering pumps which are kept locked when not in use. As a further safeguard, all the piping is enclosed in concrete, and the whole system is so arranged that it may be flooded with water to a depth of five feet in case of fire in any building which might later be built over it.

Tool and Tool Supply Departments.

The tool department is located on the top floor and at the north side of the building, where the best light is obtainable. It is devoted to the manufacture of the jigs and fixtures and many of the gages employed in the factory. The equipment consists largely of Reed and Hendey & Norton lathes, Hendey shapers, Brown & Sharpe milling machines, and Brown & Sharpe universal and surface grinders. The high degree of interchangeability required in the product demands a high standard of workmanship in this department. At the time Fig. 12 was taken, some manufacturing was being done here. A wire enclosure at the right contains the tool inspecting department. The tool steel stock and tool grinding rooms are at the further end of the picture.

The tool supply department is closely allied with the toolroom. Its work is principally that of caring for, sharpening and recording the various jigs, fixtures and cutting tools. All these tools are looked out for by a card index system, which shows where they are used, and what repairs if any have been necessary. This department orders all the small commercial tools, and keeps a debit account with each branch tool-room for the supplies furnished it, giving credit for all tools worn out in legitimate use or broken in unavoidable accidents. A perpetual inventory is thus kept of all the special and commercial tools kept on hand. A card index inventory of the machine tools is kept in the purchasing department.

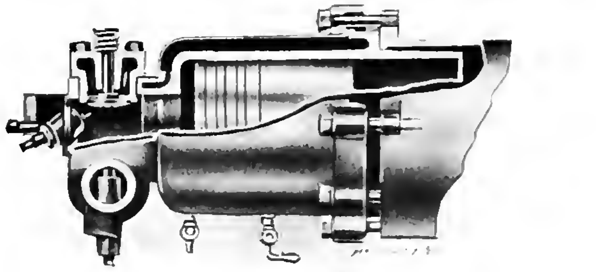

Fig. 9. Section through Cylinder showing the Water Jacket Construction.

Forge, Foundry and Sheet Metal Departments.

It will not be possible to more than briefly mention that part of the equipment of the forty-four manufacturing departments, which is concerned with the actual work on the parts. The blacksmith shop is small, owing to the extensive use of drop forgings, but it is finely fitted up with Buffalo down-draft forges, a tool forge with a coke magazine, gas furnaces, water jacketed dipping tanks, and an electric welding machine. The bulk of the work consists of tool dressing, and the making of forgings for jigs and fixtures and for special car equipment. The case-hardening department has ten large Frankfort gas furnaces equipped with pyrometers, connected by a switch-board with a galvanometer reading to degrees Fahrenheit. Oil and water dipping tanks with steam and cooling water jackets are provided. These are piped to a steam pump to give positive circulation. Square and oblong pots are used for small machine parts, while round pots with central holes, to insure uniform heat, are used for the large rear axle bevel gear.

The iron foundry is provided with a large and a small cupola. The latter is used largely for heats of a special

nature. The most approved methods for testing and chemical analysis are employed to keep track of the output. This is necessitated from the fact that the foundry furnishes castings for other motor car builders besides the Cadillac Co. The brass foundry furnishes the necessary castings for the bronze bushings, carburetor and lubricator parts, small valves and fittings, etc. These are finished in the brass machine shop, which is equipped with forty Warner & Swasey screw machines, besides several Fox lathes, drill presses, milling machines and several special lathes. All the lubricators, gasoline valves, carburetors and bearings used are produced here.

In the sheet metal department are made the vertical tubular radiators, gasoline tanks, dashes, fenders, etc., as well as small punchings, such as washers, clips, etc. The pressroom has a complete equipment, ranging from foot presses up to 20 ton power presses, capable of cutting and forming parts up to 36 by 48 inches. Gas furnaces are used for heating the soldering irons and work when assembling the radiators. The radiators and tanks are tested by compressed air while submerged in water. The frame department is equipped with gas furnaces and pneumatic hammers for riveting and heading.

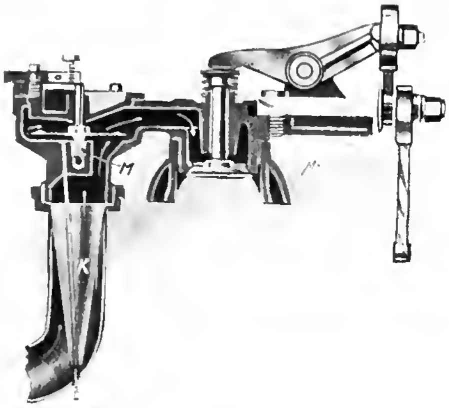

Fig. 10. The Cadillac Carburetor.

Equipment of the Machine Departments.

For convenience in handling the work, all the engine parts are drilled and milled in two separate departments in one large room, while the similar operations on the chassis parts are performed in another room, which is shown in part in Fig. 13. The equipment of this department includes a large number of Cincinnati drill presses, Cincinnati and Brown & Sharpe milling machines, and a Beaman & Smith cylinder boring machine, arranged for handling transmission cases and axle housings. The engraving shows the large use of multiple spindle drills, quick change drill sockets and jigs.

The equipment of the motor drilling department is somewhat similar, ranging from a sensitive bench drill to a 24 spindle motor-driven Baush machine. This is used in drilling the 24 holes for studs, cap screws, etc., in the lower half of the motor frame. These holes are all drilled at one time, and have to accurately match similar holes in the upper half. This, it will be seen, requires a high grade of workmanship. The milling department for motor parts employs several Whitney hand millers, Brown & Sharpe horizontal millers of various sizes, several vertical machines of the same make, and six heavy motor-driven Cincinnati machines. There are also to be found here two milling machines built by Leland & Faulconer, which are unusual in that the table has longitudinal and cross feeds only, the vertical adjustment being applied to the spindle. High-speed steel inserted tooth cutters are in general use.

The screw machine department is one of the largest in the factory, occupying a floor space of 80 by 200 feet, and containing 62 machines, exclusive of the tool grinders. Brown & Sharpe, National, Acme, Davenport and Cleveland machines are used for making cap screws, nuts, studs and other parts up to one inch in diameter. Gridley machines are employed for larger work. Jones & Lamson flat turret lathes are used for shafts, spindles and some gear blanks. The Potter & Johnston automatic machine is employed for much of the chucking work in combination with the Gisholt and Steinle machines, which are used mostly for machining clutch and gear mounts. A group of Bardons & Oliver machines are used on certain engine parts, which have to be held in face-plate fixtures and finished largely by hand labor. The larger Acme machines are direct connected.

While most of the round parts are finished complete on the screw machine, a lathe department is necessary for some work which has to be turned on arbors. Fly-wheels and some long axle shafts are also finished here. The equipment includes Reed lathes, a Bullard boring machine for finishing fly-wheels, and two Beaman & Smith double-spindle horizontal boring machines for roughing out the cylinders. The latter are similar in design to that described in the department of New Machinery and Tools of the October, 1908, issue of MACHINERY, being provided with turntable fixtures, so that two cylinders may be set up while two others are being bored. After the cylinders are roughed out, they are tested under hydraulic pressure and sent to the grinding department.

The grinding department finishes practically every round part on the car except the crank-shaft, which comes finished from a firm making a specialty of that work. Heavy Norton and Brown & Sharpe grinders are used for finishing long parts. Medium sized Landis and Brown & Sharpe grinders take care of work up to 3 inches in diameter and 8 inches long. Special Brown & Sharpe and Heald grinders are used for finishing the cylinders, which are held exactly as they will be on the assembled engine, so that clamping strains are duplicated. The pistons are finished in one of the heavy Norton machines. The group of Heald machines is used exclusively on internal work, and an equipment of face grinders finishes the washers and flat disks used in the cars. The square shafts which carry the sliding members of the transmission are ground to size on a group of Brown & Sharpe surface machines, fitted with suitable index fixtures. In contrast to the heavy Norton grinders with their 24-inch wheels, is a bench grinder purchased from the Waltham Watch Tool Co., for finishing internal ball races. This little machine uses a wheel about the size of a five-cent piece, and may be set to grind to a radius of ⅛ inch. Careful attention is given to providing suitable racks for ground work to avoid injury in handling.

In Fig. 14 is seen a partial view of the gear-cutting department. A Gleason bevel gear generating machine is here shown at work cutting a rear axle gear. The complete equipment includes thirty standard machines, and four others of special design, besides four testing machines. The list includes fifteen Brown & Sharpe automatic gear cutters, one large Gould & Eberhardt machine, two Fellows gear shapers for internal gears, one Bilgram and three Gleason bevel gear planers, two imported French machines for special pinion work, and a Pratt & Whitney worm milling machine. One of the testing machines, that for bevel gears, is seen at the extreme right of Fig. 14. The testing machine for spur gears is provided with a vernier scale for reading center distances to thousandths of an inch.

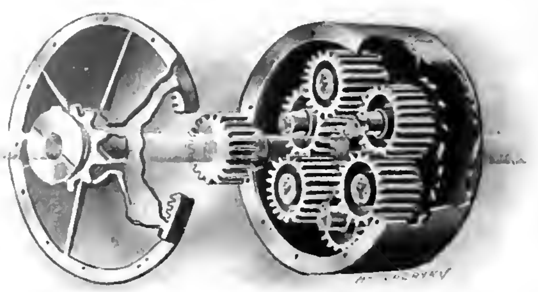

Fig. 11. Planetary Transmission used on the Single-cylinder Engine.

Inspection and Assembling Departments.

The inspection department consists of a chief inspector and his foremen, and the men under them, who together form a corps of over one hundred men. These men inspect commercial parts as they go through the receiving department, the output of each manufacturing department as it goes to the

assembling, the final assembling of the parts in the chassis, and the finish of the completed machine on both the mechanism and the body. The inspectors are furnished with all necessary appliances for doing this work accurately. Drop forgings are examined for visible flaws, and sounded for invisible ones. Springs are tested on machines especially built for the purpose. Every machine department has its inspection bench, provided with the necessary plug and snap gages for the entire range of its output. Micrometer calipers up to the 6-inch size are in general use. Thread micrometers are used in place of ring thread gages wherever possible. For testing turned and bored parts for concentricity, Brown & Sharpe testing centers and indicators are used. Suitable surface plates, V-blocks and height gages are provided. The inspectors in the grinding department are furnished with strong reading glasses for use on certain work. These inspectors are outside the jurisdiction of the other department-heads, and have full authority to throw out all parts and materials not up to the standard.

Fig. 12. A Partial View of the Tool-making Department.

Fig. 13. The Chassis Drilling and Milling Departments.

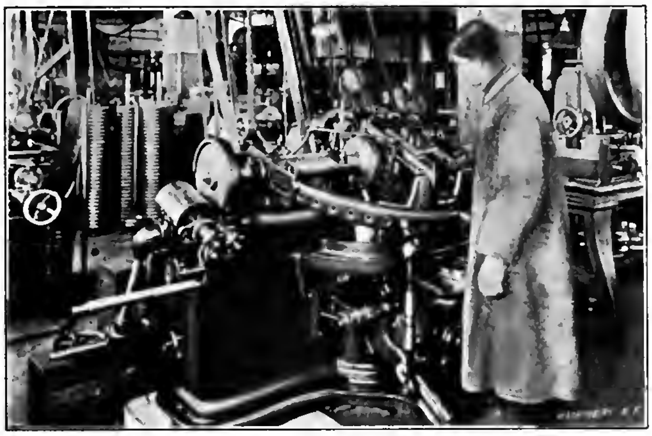

Fig. 14. A Corner of the Gear-cutting Room.

Fig. 15. The Four-cylinder Engine Assembling Department

The work of assembling is divided between several gangs, each of which does its own particular work. One group of assemblers scrapes the crank-shaft bearings to fit, and "runs them in" by a belt on the fly-wheel. Another assembles the cam-shaft members. Still another assembles the piston, its rings, pins, connecting rod and bearings, while the "cylinder gang" assembles the cylinder and cylinder head and copper water jacket. The final assembling is then done on stands as shown in Fig. 15. This consists merely in bolting the various parts together, setting the cam gears (which are marked in a jig), timing the valves, adjusting the bearings, and testing the water connections. The points of valve opening and closing are marked on the rim of the fly-wheel, and a fixed pointer shows the central position.

The Testing Department and its Equipment.

From the assembling room the engines are taken to the testing department, where they are placed on iron stands and connected with the gasoline and water supplies, and to the electrical connections for the ignition, which are shown plainly in Fig. 16. The engines are run at moderate speed until they get down to work, when the speed is gradually brought up to the maximum. A brake horse-power test of each chassis is made, and those which fail to come up to the requirements are returned to the assembling department for reconstruction. As a check on this test, stock engines are sent to the experimental department at regular intervals, and tested there by connection with a dynamo fitted with suitable electrical measuring instruments. After the testing the engines go into stock, or to the chassis assembling department.

All the parts necessary for the completed chassis are brought to this assembling department. The order of assembling is as follows: The frames are first laid on horses and the mechanism dust shield is put on. The springs and axles are next attached, and then the engine and transmission gearing are set and lined up. The engine is supported at three points, and is connected by a universal sliding joint with the transmission gearing, thus permitting weaving of the frame without danger of disalignment. The universal joint between the transmission and the differential gearing is practically straight when the car is loaded, and runs at a very slight angle when the car is light. The exhaust pipe and muffler are next connected, and then the controlling and brake levers and the pedals. The radiator and water connections come next, followed by the steering gear. The placing of the mahogany dash in position permits the mounting of the electrical apparatus; and the bolting on of the gasoline tank and its connections completes the chassis, except for the wheels and tires. An old set of these are put on the car in the assembling department, to be used for the road test. The method of assembling is practically the same for the single cylinder car.

Two separate testing departments are provided—one for the single cylinder cars, and the other for the four-cylinder cars. The former were given road tests for the first two years of their manufacture, until all the weak points in the construction had been eliminated. The testing-room shown in Fig. 17 was then built, and the cars have since been tested here. Fifteen stands are provided. The rear wheels rest on a pair of 48-inch pulleys, mounted on a shaft which carries a fan about 72 inches in diameter by 36 inches wide, projecting through the floor in the sheet iron casing shown. In addition to the resistance thus offered by the fan, a brake is mounted on the shaft between the pulleys, controlled by the hand-wheel

of the stand shown projecting through the floor at the rear of each machine. By this means it is possible to work the engine against any desired resistance, even to the extent of stalling it. The chassis are held by padded hocks, fastened by ropes or chains to the brake wheel stands. The blast of air produced by each fan is led through a sheet metal conduit and directed against the radiator of the engine, thus giving the same cooling effect that would be experienced at corresponding speeds on the road on a still day. The speed in miles per hour is read from Schaffer & Budenburg tachometers.

The four-cylinder testing stands are similar in principle, though somewhat differently arranged, as the fans are placed beneath the front of the machine, being connected with the driving shafts by sprockets and chains. After being run here a sufficient time to make sure of their adjustment and running condition, temporary bodies are placed on the chassis and each car given a thorough test by reliable men on the country roads outside the city. After this has been done to the satisfaction of the foreman of the department, the testing body is removed and the chassis is washed successively in water and gasoline, and dried by an air jet.

Finishing.

The painting and finishing of the chassis, bodies and wheels is done in separate departments. The bodies receive one coat of rough filler, and fifteen more coats of filler color and varnish, before completion. A view of the trimming departments for the bodies is shown in Fig. 18. Fenders, hoods, brackets, etc., are enameled and baked. Fig. 19 shows some of the pipe frame trucks used to hold these sheet metal parts during the baking.

The chassis, bodies, hoods, fenders, etc., finally go to the large finishing-room on the ground floor, where the final assembling and testing of the complete car is done. Each complete car is driven out by a final inspector to make sure that all adjustments are correct. Before shipping, a detailed record is made of each car, beginning with the motor number, and giving the dates of motor assembling, motor testing, all the various painting, finishing and shipping dates, together with any information of a special kind, such as size and color of body, etc. This record has been found of the greatest assistance to the repair order department in filling poorly written orders.

Interchangeability.

In connection with this subject of repair orders, mention should be made of the high degree of interchangeability attained by the Cadillac Co. This was illustrated by a test made last March by a committee of the Royal Auto Club of England, who selected by lot three Cadillac cars of the same 10-horsepower model, disassembled them under the eyes of an inspector of their own appointment, placed the disassembled parts (721 from each car) in a pile, and mixed them up indiscriminately, 81 parts were then taken out and replaced by 81 repair parts from stock. The cars were thereupon reassembled from this mixed pile by the use of wrenches, screw-drivers, etc., but without the use of scrapers, files or even emery cloth. Only one part, a cotter pin, was injured in reassembling. These three heterogeneously reassembled cars were each given a 500 mile reliability run on the Brooklands track, at an average speed of 33 to 34 miles per hour, without developing the slightest defect. This test speaks well for the organization of the factory.

The whole Cadillac plant is now devoted to the production of the four-cylinder, 30-horse-power car, the "Model 30" as it is called. The machine departments are run twenty-two hours a day, employing a total of 3,000 men in all departments. Thirty-six complete cars a day are produced.

* * *

So-called black oil finish on steel may be produced in several ways, but the *Brass World* states that the following method is one of the best. The article to be finished is heated in a furnace to a cherry red heat, and is then plunged into lard oil. It is immediately removed, and the oil is burned off in the furnace. When this has been done, the object is immersed in water. After the immersion in water, the surface of the steel will be black and will not rust. In order to bring out the best surface, a light film of linseed oil may be applied to the article after it has been removed from the water.

GEOMETRICAL PROGRESSION FOR SPINDLE SPEEDS.

FRANCIS W. SHAW *

The utility of the data sheet table of geometrical progressions for spindle speeds, published in the November, 1908, number of the engineering edition, is unquestionable, but in the writer's opinion, it is not confined to the use suggested by the author. I have now had several years' experience in the use of a similar table, and have designed many gear systems, but I have never yet been able to make use of its labor saving properties in getting out a series of speeds in geometrical progression, except as will be described herewith. The required speeds have never happened to correspond in their percentage of decrease with any of those given in the table.

The chief use I have made of the table is to find roughly the percentage of decrease, which is done as follows: A pair of dividers is set so that the points span a distance from 1 in the "Number of Speed Changes Required" column to the number corresponding to the number of speed changes required—say, for example, 16. Having decided upon the maximum and minimum speeds, the dividers as previously set are used to find in the percentage column, by trial, two speeds 16 spaces apart, which most nearly correspond with those required. The tables, from my point of view, would have been much more useful had the differences between the adjacent columns been smaller, say ½ per cent.

In designing a speed-varying mechanism for a machine tool drive, it is usual to consider first what limit speeds are necessary to meet the requirements of the work, then the number of speeds. As a matter of fact, however, the latter point is usually governed by some set design already applied, it may be, to other sizes of the same class of machine. Oftentimes, the productions of our competitors cause us to draw the lines a little wider, as we must have as many talking points as possible.

Having decided the points enumerated and chosen the limit speeds, there appears to the writer no good reason why they should not be adhered to; why be content with an approximation when to secure the ideal is so simple? The difficulty of applying the table has been admirably obscured by the author in the example quoted, by taking 250, an aliquot part of 1,000, as one of the limit speeds. Had he chosen, say 346, as the highest speed, he would have been under the necessity of multiplying each number by 0.346. To do this operation for, say 16 speeds, would involve practically as much labor as to arrive at the result by the logarithmic process. A method by which any reasonably simple geometrical progression can be found in less than half an hour, is shown in the following working of a suppositious example. The requirement is 16 speeds varying from 6.5 to 270 R. P. M.. To find the common ratio, *i. e.*, the number by which 6.5 must be multiplied to produce the second speed, and by which the second or any other speed must be multiplied to produce the next higher speed, it is necessary to use the well-known formula, modified a little to suit the method of working, *viz.:*

$$r = \sqrt[n-l]{\frac{l}{a}}$$

in which

r = common ratio,

l = last term,

a = first term,

n = number of terms (not means).

For the benefit of the beginner, the following graphical proof may be followed with profit. Examine the following series in geometrical progression: 2, 4, 8, 16, 32. In this progression the common ratio obviously is $4 \div 2 = 2$, 32 is the fifth term (l), and 2 the first term (a). If these terms only are known, the common ratio is found by extracting the fourth root of $32 \div 2$ which equals 2. The root, it will be noted, (4) is the number of terms $n - l$. In our suppositious case

$$l = 270$$
$$a = 6.5$$
$$n - l = 15$$

$$r \text{ therefore is } \sqrt[15]{\frac{270}{6.5}}$$

the value of which expression may be found logarithmically thus:

$$\log \sqrt[15]{\frac{270}{6.5}} = \frac{\log 270 - \log 6.5}{15} = \frac{2.4314 - 0.8129}{15} = 0.1079$$

$= \log r$. Continued addition of $\log r$ (or 0.1079) to log 6.5 (or 0.8129) gives the log of subsequent terms in the speed progression.

Speed.	Log	Number.	Speed.	Log	Number.
1	.8129	6.5		1.5682	
	.1079			.1079	
2	.9208	8.333	9	1.6761	47.43
	.1079			.1079	
3	1.0287	10.69	10	1.7840	60.81
	.1079			.1079	
4	1.1366	13.70	11	1.8919	77.96
	.1079			.1079	
5	1.2445	17.56	12	1.9998	99.98
	.1079			.1079	
6	1.3524	22.51	13	2.1077	121.1
	.1079			.1079	
7	1.4603	28.86	14	2.2156	164.3
	.1079			.1079	
8	1.5682	37.00	15	2.3235	210.6
				.1079	
			16	2.4314	270.1

It will be noted that although four figure logarithms have been used, the error after 15 successive additions is practically negligible. The original number, obtained at the fifteenth step, is a certain check upon the accuracy of the calculation.

When the numbers have been obtained, they are set out in tabular form (useless decimal places being omitted) to suit the particular gear system. For example:

SPINDLE SPEEDS.

Levers at	Hand Wheel at A	B	C	D
1 and 3.............	6.5	8.3	10.7	13.7
1 and 4.............	17.6	22.5	29	37
2 and 3.............	47	61	78	100
2 and 4.............	128	164	211	270

These figures will no doubt require some modification after calculation of the gearing to the nearest tooth, but care in arrangement of center distances of gears always gives an approximation within about 2 per cent.

MALLEABLE VS. STEEL HAMMERS.

In the discussion of the paper by Mr. Raffe Emerson, presented before the New York Railroad Club last fall, the assertion was made that it is nonsensical to supply enginemen with good cast steel hammers. It appears that the New York Central experimented some years ago in this direction to save expenses. First, a hammer made of a steel casting was used with satisfaction, and finally one was made still cheaper by using ordinary malleable iron.

We do not know what the feelings of the average engineman are when required to use a malleable hammer, but we think that if he has had the mechanical training proper for the position that he would regard it as an insult. In the first place a malleable hammer is likely to be a dangerous tool; chips are liable to fly from the face when struck against a steel surface, which may injure the sight, and in the second place the cheapness and crudity of such a tool would tend to destroy the pride an engineman should have in keeping up his tool equipment. The importance of this depends largely on the personal equation, but the point is that there are wasteful economies, and we believe that the malleable hammer is a horrible example. The amount that a railroad corporation can save in one year by using such hammers in place of good steel hammers is so inconsequential that it can hardly afford to offend the sensibilities of its employes by such substitution.

SIZES OF WORKING DRAWINGS.*

WILLIAM L. BREATH †

William L. Breath ‡

Manufacturers do not have any universal standard of sizes for working drawings. From time to time there have been recommendations made by various societies regarding standard sizes, but these recommendations have had little effect in bringing about any generally accepted standard in drafting-room practice. Many firms use large and unwieldy drawings, which are as difficult for the draftsmen to work on, as they are cumberscme to handle by those who are to use them. Of course, most drafting-rooms have their own standard sizes for the sheets. There is usually a small sheet for sketches and details and then larger sizes which are multiples of the detail size. These larger sizes are used for the assembly drawings and for detailing large pieces. It is, however, difficult to take care of all these various sizes of drawings, a difficulty which can be avoided by having only one size sheet of a convenient size for both the draftsmen and the shop.

The size of the sheet to be adopted should be chosen first of all with regard to economy in cutting the sheets from commercial sizes of paper and tracing cloth. Tracing cloth comes in rolls 30, 36, 42, or 48 inches wide, and there is thus a wide range to choose from. The standard sheet used by the U. S. Navy department, and, the writer believes, also by other departments of the government, is 21 by 27 inches. All manufacturers working on orders for the Navy must send tracings of their work on this size sheet, and some manufacturers, therefore, have adopted this size as their own standard. It can be cut without waste from a roll 42 inches wide, but it is, however, too large to be convenient for the draftsman, as it makes his work much more tiresome than a small sheet where all corners can be readily reached from one position. Besides, this sheet gives more room than is necessary for detailing one piece of ordinary size, and therefore, as many as twenty pieces are often detailed on one sheet. This is an inconvenient system, as it often happens in the shop that two or more men must refer to different details on the same drawing, and often the blue-print will be cut in pieces so that each man gets the part on which he is working. This is a common-sense way of avoiding the inconvenience of having two men working on the same blue-print, and also is a hint to the drafting-rcom to have but one detail on each sheet. A convenient size sheet could be obtained by cutting the size mentioned in two, making a size 13½ by 21 inches. Even a somewhat smaller sheet, say 18 by 12 inches would be better.

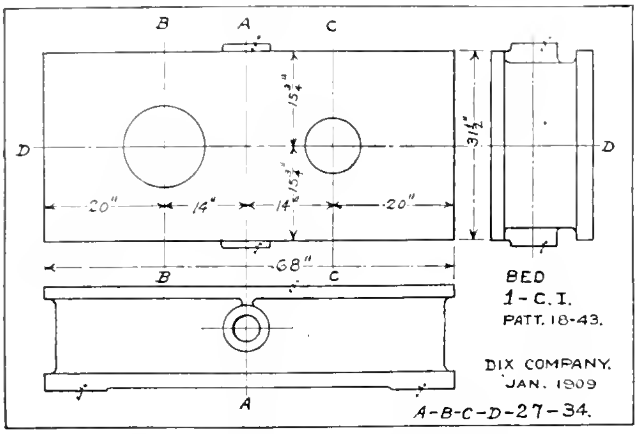

Fig. 1. Master Drawing of Simple Machine Bed.

To use a small size sheet for all assembly drawings and for detailing of large pieces, requires a method somewhat different from those ordinarily in use in drafting-rooms, but it does not add to the complication of the work of the drafting-room. Fig. 1 shows a 13½ by 21-inch sheet, and on it is drawn a bed of simple design. The bed is drawn only in outline, and shows a plan, elevation and end view. The main center lines are also drawn, as well as the main faces. The drawing is numbered according to the regular system of the drafting-room. The center lines are lettered *A-A*, *B-B*, *C-C*, *D-D*; *A* refers to a second sheet of the same size on which is drawn to a larger scale the section *A-A* of the bed. On this sheet are put all dimensions, notes and instructions necessary. In the same way sheets *B*, *C* and *D* are drawn until the bed is fully detailed. The master sheet, Fig. 1, has in the title corner the letters *A*, *B*, *C* and *D*, showing at a glance how many sheets there are in the complete set. The next piece in the construction would be detailed in a similar way, the master sheet taking the number 27-35, and having as many supplementary sheets, *A*, *B* and *C* as necessary.

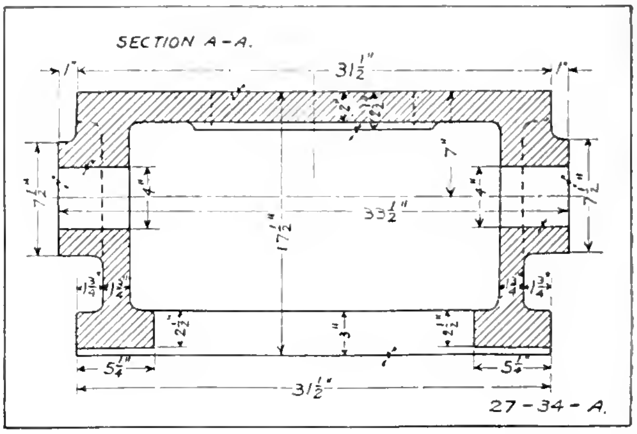

Fig. 2. Detail Section of Bed in Fig. 1.

In case there is room on one sheet for more than one detailed section, these sections will be noted on the master drawing by the letters *A-A*, *A-B*, *A-C*, etc., the letter *A* being used for each section on sheet *A*. If the piece to be detailed is too large or complicated to have the three views clearly outlined on the master sheet, then each view will be made on a separate sheet, and the plan view will be considered the master drawing; the other master drawings have the same serial number, with a number added, as for instance, 27-34-1, and 27-34-2. In this way every part of the machine will be fully shown, as well in its relation to the other parts as in detail. In fact, the main purpose of the master drawing is to show the relation of the different parts of the machine to each other. When the master and detail drawings of a machine are fully completed, they can be bound together by any suitable loose-leaf method, and if desired for reference, an index of the pieces can be made on a standard sheet, and bound with them.

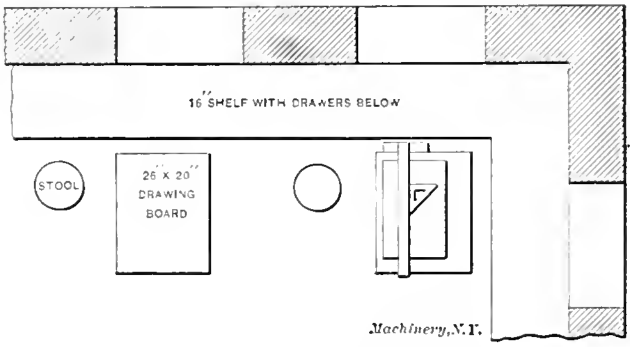

Fig. 3. Convenient Arrangement of Drafting-room.

Fig. 3 shows a convenient arrangement of a part of a drafting-room, where the small sheet system has been adopted. The designing draftsman's board is not shown. He, of course,

† Address: 258 Lefferts Ave., Brooklyn, N. Y.

‡ William L. Breath was born 1859. He has been a draftsman, working for the Atlas Engine Works, Indianapolis, Ind.; American Tobacco Co., New York; Standard Motor Construction Co., Jersey City, N. J.; Power and Mining Machinery Co., Cudahy, Wis.; Pneumatic Torpedo Construction Co. His specialty is gas power and fine machinery.

must have a board as large as is convenient for the actual designing work. Running around the room, and under the window sills, is a shelf 16 inches wide, with drawers under large enough for the standard size drawing. The draftsman's tools and books can also be kept in drawers under the shelves. Being at the left hand of the draftsman, the shelf is a convenient place for reference drawings, books, etc. The working table need be but very small, as a board 20 by 26 inches will be amply large enough. The board should be mounted on a cast stand, and pivoted so that it can revolve, as a swinging board is much easier to work on.

The system of small sheets outlined can also be used for drawings of buildings, power plants, and structual designs. One drawing gives a general outline of the construction, and then the various detail drawings show successively the details of different portions of the construction.

SOME OLD-TIME PUZZLES IN WOOD.

Among the many changes incident to the introduction of machinery and the consequent passing of the old-time hand-worker, is one that, while of no economic importance, is interesting as marking a difference between the old leisurely habits of the shops of a generation or two ago, and those of to-day.

In the old days the greenhorn apprentice was subjected to a variety of tests which taxed his temper, and also his ingenuity and gumption, and a number of these, all of which are interesting and ingenious, were recently described and illustrated in *Wood Craft*, and are herewith reproduced.

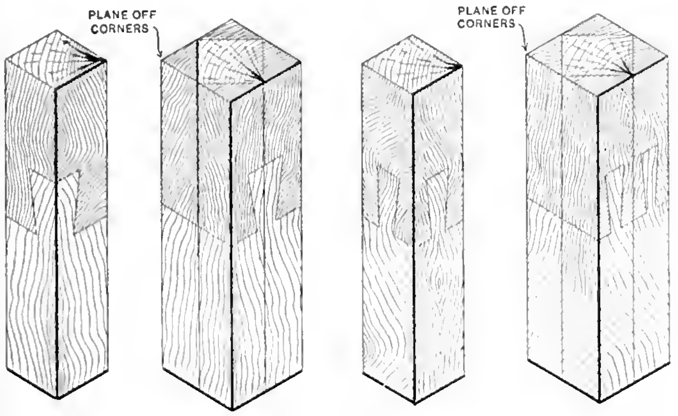

Fig.1 Fig.2 Fig.3 Fig.4

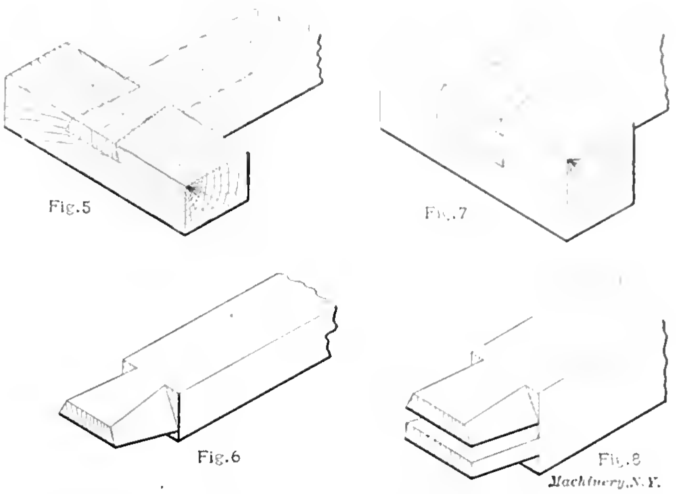
Figs. 1 and 2. Finished Dovetail Joint and the Way in which the Joint is made. Figs. 3 and 4. Finished Joint with Two Dovetails, and the Method of making the Joint, which is the same as for Fig. 1.

The tests of the learner's skill and ingenuity were of a useful nature, and generally in the direction of some little problems in tool-work lying outside the everyday tasks of the shops. Very often these took the form of a puzzle joint, one of the first to be shown to the budding craftsman being the mystifying dovetailed splice shown in Fig. 1. When formed of two different kinds of wood having a sharp contrast in their colors, this joint presents a very puzzling appearance, especially if glued up so that it may not be taken apart. If left loose, however, the mystery vanishes, for it is then readily seen that the joint is a simple dovetail running diagonally through the pieces. The fitting of such a joint would be a difficult matter if the dovetail pin and socket were cut diagonally, as shown in the finished joint, but is an exceedingly simple thing if done as illustrated in Fig. 2, across the square way of the pieces. The joint is fitted thus, and after being put together, the corners of the square block are planed down to the center lines as indicated by the lines on top of the piece, thus giving the completed joint the appearance so puzzling in Fig. 1.

Fig. 3, which shows a complete dovetail on each face of the finished joint, is a more difficult-looking puzzle, though made in a manner precisely similar to the joint illustrated in Fig. 1. This joint is made by fitting a pair of dovetails side by side as in Fig. 4, the corners being afterwards planed off as in the case of the first joint. Care must be taken to lay out the dovetails evenly on each side of the central line of the blocks. Of course, it should scarcely be necessary to add that a good fit throughout is required, or yawning joints will give the trick away when the piece is planed off at angles of 45 degrees to the original faces of the block.

Another dovetail puzzle is shown in Fig. 5, which is a T-joint apparently put together in an impossible way. Fig. 6 reveals the secret of its construction, which needs no further description. Sometimes this T-joint has a tenon in addition to the dovetail, and appears as in Fig. 7, the details being made plain by Fig. 8.



Figs. 5 and 6. A Deceptive Dovetail and the Way in which it is made.

Figs. 7 and 8. A Joint Similar to the One shown in Fig. 5, with the Addition of a Tenon.

Some years ago an enterprising firm of soap manufacturers whose name is a household word on several continents, gave away as an advertisement some millions of another wood puzzle that was a favorite among the old hand-workers in days gone by. A sketch of it is shown in Fig. 9, and it will be seen to consist of a hammer-headed key-piece inserted through another piece, both being absolutely solid, and without joints. The apparently impossible task of passing the large hammer-head through the narrow mortise, is accomplished by selecting a piece of soft white pine for the key, and thoroughly boiling or steaming one end of it until it is quite soft. It is then squeezed in the jaws of a powerful vise, and slipped quickly through the mortise, when it immediately begins to swell and with a little soaking will resume its former size and shape.

The concluding example is notable because of the fact that it has found its way from the workshop to the pages of more than one treatise on descriptive geometry. The puzzle, as usually stated, says that three holes are to be cut in a piece of wood—one round, one square, and one triangular, and another piece of wood is to be cut so that it will fit each hole. A piece about ¼ inch in thickness is selected, and the holes, *a*, *b*, *c*, cut in it as in Fig. 10. The circle *a* is equal in diameter to the side of the square *b*, which is equal to the base and altitude of the triangle *c*. A cylindrical block is then turned or planed to fit the circular hole. By cutting this cylinder *a*, Fig. 11, to the same length as its diameter, it will just fill the square hole *b*, and by paring off on opposite sides until it is triangular in section in one of its dimensions as at *c*, the third condition is fullfilled, and a piece is formed which will fit each hole. Fig. 11 shows the required block for the purpose, *a* being the cylinder to fit the circle at *a*, Fig. 10, *b* the square plug, and *c* the triangular piece.

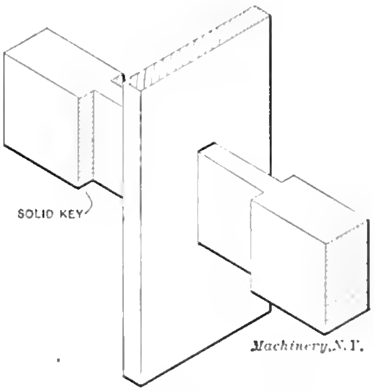


Fig 9 A Combination which seems Impossible.

THE ENGINEER AND THE PEOPLE.*

In a paper read before the American Society of Mechanical Engineers, entitled "The Engineer and the People," the author, Mr. M. L. Cooke, proposed a plan for obtaining a larger measure of cooperation between the society and the general public, which should receive the endorsement and aid of every member. The present-day conditions which seem to demand a broadening of the lines of professional activity, were pointed out, and specific recommendations made which, if adopted, would doubtless greatly extend the engineers' field of usefulness and make him a "special conservator of the public's interest in matters involving engineering." Said the author, in speaking of the object of the society: "The distinguished authors of the constitution of the A. S. M. E. stated its object in a way to permit of an almost indefinite expansion of function. 'The object of the society is to promote the arts and sciences connected with engineering and mechanical construction.' "That the constitution, however, imposes no duties on the membership, except those of a purely professional interest, witness as follows": 'The proper means for this purpose shall be the holding of meetings for the reading and discussion of professional papers and for social intercourse; the publication and distribution of its papers and discussions; and the maintenance of an engineering library.' "The library may be made in the future to minister to the requirements of the laymen interested in technical matters, but up to this time its direct influence on the interests of the people is almost negligible. A radical and in every way salutary change can be brought about in the society's relations with the general public by the appointment of a committee to be known as the "Committee on Relations with the Public." The work of this committee would, of course, have to be done within carefully thought out and definitely prescribed limits. It would doubtless seek to establish such relations with the lay press as would make its device and help sought when engineering matters are up for public discussion. It would also doubtless seek to give publicity to the fact that the society stands ready to offer disinterested advice through its council to government officials—municipal, state or national. In most cases, of course, this assistance would not be so much to answer engineering questions as to counsel with government officials to the proper procedure to obtain answers. This committee might also provide for a course of lectures for the general public, to be given under its supervision in the Engineering Societies' Building in New York, or under the auspices of local engineering societies at other places. Another important part of the work of such a committee would be to arrange that a fair proportion of professional papers presented at the various meetings of the society should be of direct use and value to the public as well as to the mechanical engineer. The cumulative effect of these, and of such other lines of work as would soon suggest themselves, would be very marked.

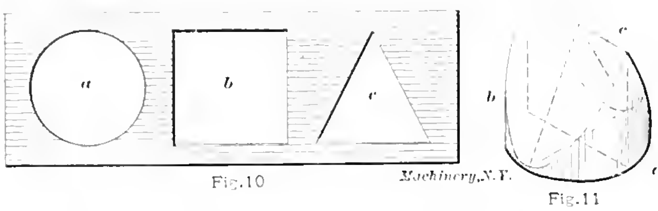

Fig.10 Fig.11

Figs. 10 and 11. Piece with Round, Square, and Triangular Holes, and Plug which fits them all.

"The matter of the conservation of our natural resources will afford, probably for years, a practically limitless field for investigation and earnest discussion. The questions involved are so momentous as to warrant the engineer in seeking ways of cooperation with the national and state governments for their solution. No better way could be found for our society to assist in this work than to provide in its meetings and publications a forum for the discussion of those phases of the general problem in which the mechanical engineer is especially qualified to speak. The records of engineering in the early days of the last century show that engineers had not then learned how to cooperate with one another. Up to a comparatively recent date the professional knowledge of the engineer was his own property, and he felt that in imparting any of this knowledge to another engineer that he was doing himself a decided injury. The large number of engineering societies, with the fundamental object of the free exchange of engineering data between their members, shows how thoroughly engineers have learned that the general policy of giving freely of their knowledge to their fellow practitioners, increases rather than diminishes their effectiveness and, in proportion, their earning power. In proposing the appointment of this new standing committee, the writer suggests only the extension of this cooperation to include the public. There is good reason to believe that engineers have as much to gain from cooperation with the public as they have undoubtedly gained from the cooperation with one another. It is no longer possible for any profession or craft to corner information and hold it for its own use. Broadly speaking, those who seek information in any field can obtain it, or at least enough to answer their immediate purposes, and therein lies a danger. This danger would not in itself constitute a sufficient reason for the engineer to take the public into his confidence, for, after all, it is public opinion and not the dictum of the engineering fraternity which finally decides the large questions of engineering practice. How much better it would be to join forces with the people to work out with them their problems and to build up in the lay mind such a confidence in our devotion to the people's cause that they will be willing to let us lead in matters where our training especially qualifies us to lead. Only by educating the public to understand and appreciate the work of the engineer, can the public be made to demand the best that can be devised and executed by trained and skillful men. This will have a twofold beneficial effect on the profession, in that it will make more work for the engineer, and will give the public that general acquaintance with engineering matters which will make it suspicious of short cuts.

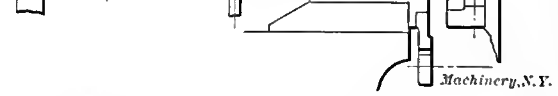
MULTIPLE SPINDLE SHAFTING LATHE.

In the December 25th issue of *Engineering* (London) is described a multiple turning and grinding lathe for finishing shafting, built by Messrs. MacDonald, Swinburne & Co., Barrhead near Glasgow. The peculiarity of the machine, as shown by the accompanying diagram, is that it holds four shafts simultaneously. One of these, at *A*, is in position for insertion or removal. The indexing of the revolving head- and tail-stocks next brings the shaft to position *B*, where it is turned. The third position, *C*, is an idle position. At *D* it is being ground by a traversing emery wheel. When it arrives at *A* again, it is removed. The shafting enters the end of the bed of the machine, below the tail-stock, being carried in by a rolled conveyor; a mechanical lifting arrangement then raises it to position *A*, where it is clamped in place. The same rolled conveyor removes the work after it has been completed. Suitable arrangements for steady rests for both turning and grinding operations are provided so that these operations may be simultaneously performed in accordance with the best practice, both as to speed and accuracy. The machine will take solid or hollow shafting up to 4 inches in diameter and 22 feet long, and will finish within a limit of 0.00025 inch.



Multiple Turning and Grinding Lathe.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—3.

GEARING.

R. B. BROWN.

The gearing may be regarded as one of the most important details of crane design, since on its merits rest the efficiency and safety of the crane. A few years ago all lifting machinery was worked by wheels having cast teeth, but with the introduction of electric driving, and higher speeds, machine-cut gearing became necessary. The adoption of cut gears has grown to such an extent that a large quantity of cranes are now supplied with machine-cut gears throughout. In deciding how many of the gears of a crane ought to have the teeth machine cut, some consideration should be given to the work the crane is likely to have to do. If the speeds are high, or the crane is going to be in continual use, it will pay to have as many of the gears machine cut as possible, because the subsequent saving in electric current will soon pay for the extra first cost.

For constantly-working high-speed cranes up to seven-tons load, it will be found the most satisfactory to have machine-cut gears throughout, including the barrel wheel and pinion. For all sizes above seven tons it is not advisable to machine cut the barrel gear and pinion even for the best class of work, partly owing to the fact that it is desirable to shroud the pinion of this pair of wheels; and as the speed is low, the loss in power due to friction is not worth consideration. For cheap cranes, and those required for intermittent working, as in engine rooms for instance, it is only necessary to have the first reduction for each motion machine cut.

Raw hide or buffoline motor pinions have been found suitable, and are to be recommended for the first reduction for cranes up to twenty-tons load. The gear with which this pinion meshes should be of cast iron, since it has been found that the strength of raw hide and cast iron teeth are about the same. The principal advantages of raw hide pinions are that they run almost noiselessly and do not require any lubricant. A gear case need not be provided for this reduction unless the crane is working in a very damp location. For cranes above twenty tons the motor pinion ought to be of machine steel, running with a cast iron or steel gear, preferably in an oil bath, the latter taking the form of a cast iron gear case.

It is generally found advisable to make small machine-cut pinions of machine steel, the blanks usually being cut from ordinary rolled bar, or forged to size. When this is done, the pinion teeth are considerably stronger than those of the gear, if this is made of cast iron, and about equal in strength to those of a cast steel gear.

For cranes up to twenty tons the barrel gear and pinion can be of cast iron; above this size cast steel is preferable, and in all cases above seven tons the pinion should be full shrouded, thereby making the teeth about equal in strength to those of the gear. For cranes above twenty tons it is considered good practice to make all pinions of steel, whether they are machine cut or not; while for cranes which are very severely handled and constantly on full load, as for instance steel works and forge cranes, the purchaser will probably find it most satisfactory in the end to have steel gears throughout for all motions. It will be found satisfactory for ordinary work to have cast iron gears for cranes up to twenty tons, and above this size and up to forty tons to have all pinions and the barrel gear of steel and the remainder cast iron. Cranes above forty tons should preferably have steel gears throughout.

In order to keep down the size of the crab in every way, the pinions should be kept as small as possible consistent with smooth running, but at the same time no pinion should ever have less than twelve teeth, since below this size pinions run badly and are very weak, and cutters for a smaller number of teeth are not usually on hand.

Strength of Teeth in the Gears.

The most important question concerning the gearing lies in the strength of the teeth, and a great variation is found in practice in the stress to which the material is subjected. Upon examining the practice of various firms, one finds that while some stress the cast iron barrel gear teeth to one ton per square inch, and the steel gear teeth to three tons per square inch, others work to as much as three and six tons per square inch, respectively. Now the average ultimate strength of cast iron and cast steel subject to bending as in a tooth is eighteen and thirty tons, respectively, but it is possible for either of these values, and particularly that of cast iron, to be considerably reduced by a lack of homogeneity in the metal, which may never be detected even if it is not wholly internal. With due consideration to the above fact, one is justified in allowing a factor of safety of 8 for cast iron, and 6 for steel for slow running.

Several convenient tables have been compiled for rapidly arriving at the pitch and width of the teeth, but before referring to these it is advisable to calculate the strength. The teeth of gearing used for crane work are of the involute pattern with radial flanks which gives a fairly short tooth with a broad root, and are consequently of the greatest strength.

Prof. Unwin states that the load which falls upon one tooth lies between one-half the full load and the total load, and is generally taken at two-thirds the full load, but if the pinion is small, it is common practice to consider the full load as taken by one tooth. When the pinion is of steel and the gear of cast iron, or the pinion is full shrouded, the gear teeth can be considered weaker or equal to those of the pinion, and the strength calculated accordingly to suit the shape of the teeth in the gear. Prof. Unwin also states that the agreed percentage of the full load will act, at one particular period, on the full length of the tooth, and this should be allowed for.

In calculating the strength of a tooth, it must be regarded as a cantilever, and made strong enough to resist the consequent bending moment. As an example, find the stress in the teeth of a steel barrel gear having 108 teeth of $1\frac{3}{4}$ inch circular pitch by 5 inches wide, and keyed onto the barrel of a 30-ton crane; diameter of barrel, two feet, fifteen tons load on the barrel. The diameter of the gear is approximately 5 feet.

$$\text{Load on tooth} = \frac{15 \times 2}{5} = 6 \text{ tons.}$$

$$\text{Maximum load at full length of tooth} = \frac{2}{3} \times 6 = 4 \text{ tons.}$$

$$\text{Full length of tooth} = 1.09 \text{ inch.}$$

$$\text{Bending moment} = 4 \times 1.09 = 4.36 \text{ inch-tons.}$$

$$\text{Modulus of tooth at root} = 1.03.$$

$$\text{Stress} = \frac{4.36}{1.03} = 4.2 \text{ tons per square inch,}$$

which is a suitable working stress for slow running cast steel gears.

Some makers shroud the barrel gear and pinion to the pitch line, but if the strength has been calculated as shown above, this form of shrouding does not add to the strength required to resist bending, because if the bending moment and modulus are taken at the pitch line, they will be in similar proportion to those found at the root. The principal value of half shrouding is in minimizing the tendency the teeth have to break across the corner, especially with cast gears where the teeth may not bear evenly together, or may not be parallel to each other.

TABLE VI. ALLOWABLE FIBER STRESS IN GEAR TEETH.

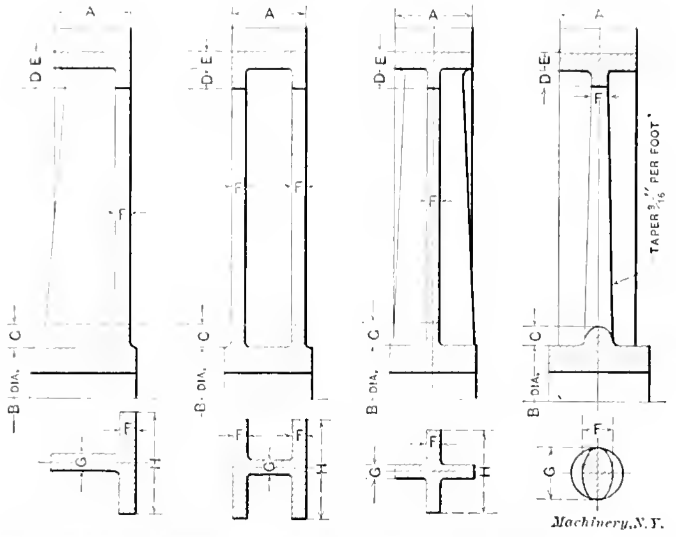
Material	Speed at Pitch Line in Feet per Minute.							
	100	200	300	600	900	1200	1800	2400
Cast iron........	4800	4200	3800	3200	2400	1920	1600	1360
Cast steel	12000	10500	9600	8000	6000	4800	4000	3400
Gun-metal	7200	6300	5760	4800	3600	2880	2400	2040
Machine steel ...	19200	14410	11200	9600	7200	5760	4800	4080

For heavy cranes, say 30 tons and upwards, double helical gears for the barrel gear and pinion have been used with advantage, since they insure a freedom from shock. That helical gearing is much stronger than spur gearing there is no

doubt, but there are many opinions as to their relative values. Since the points of contact on a well made tooth of this type at any moment are distributed over the whole of the working face, from root to point, the average leverage of the whole load is only half that of ordinary spur gears. Then, again, the developed width of these teeth is more for a certain width of wheel, and in calculating the strength, this can be taken into account. It is not safe, however, to allow in full for all these advantages over ordinary spur gears, owing to the fact that in practice it has been found difficult to make the apexes of each pair of teeth run in the same plane, and hence the load may be thrown on one side of the gear only. This difficulty may be avoided to some extent by allowing a little lateral play on the pinion shaft whereby the pinion will adjust its position to suit the gear, and consequently equalize the stresses somewhat. In the absence of any reliable data on the strength of these gears, they are seldom considered as more than one and one-half times as strong as ordinary spur gears.

TABLE VII. DIMENSIONS OF GEAR RIMS AND ARMS.

P = circular pitch; b = bore.



Form of Arm.	A	B	C	D	E	F	G	H (at rim)
T section.........	$3P$	$1\frac{7}{8}b$	$\frac{5}{8}P$	$\frac{9}{16}P$	$\frac{1}{2}P$	$\frac{1}{2}P$	$\frac{1}{8}P$	$2\frac{1}{4}P$
I-section..........	$3P$	$1\frac{7}{8}b$	$\frac{5}{8}P$	$\frac{9}{16}P$	$\frac{1}{2}P$	$\frac{1}{2}P$	$\frac{1}{8}P$	$2\frac{1}{4}P$
+-section........	$3P$	$1\frac{7}{8}b$	$\frac{5}{8}P$	$\frac{9}{16}P$	$\frac{1}{2}P$	$\frac{1}{2}P$	$\frac{1}{8}P$	$2\frac{1}{4}P$
Oval section......	$3P$	$1\frac{7}{8}b$	$\frac{5}{8}P$	$\frac{9}{16}P$	$\frac{1}{2}P$	$\frac{1}{2}G$	$2\frac{1}{8}P$	.....

In calculating the pressure on the teeth of any pair of gears, it is, with the exception of the barrel gear and pinion, more correct to allow for the load due to the maximum torque of the motor, than to take the reaction from the load, since this latter does not allow for the resistance due to the friction of the intermediate gearing.

The stresses to which gear teeth may be subjected depend principally on the pitch line speed, and the nature of the work to be done; *i. e.*, whether running under a steady load in one direction, or subject to varying loads and quick reversal, as in cranes.

The most convenient way for calculating the strength of gear teeth is by the Lewis formula. This formula is:

$$W = SPFY,$$

in which

W = force at pitch line in pounds,

P = circular pitch,

S = allowable fiber stress for the material used, in pounds per square inch (see Table VI),

F = width of face of gear,

Y = the factor known as the Lewis outline factor which varies with the number of teeth and the form of gear tooth.*

Applying this formula to the previous example, we have: $S = 12{,}000$ (from Table VI); $P = 1.75$; $F = 5$; and $Y = 0.118$ for 108 teeth and 15 degree involute gearing. Consequently,

$$W = 12{,}000 \times 1.75 \times 5 \times 0.118 = 12{,}390 \text{ pounds.}$$

Dimensions of Arms, Rim and Hub.

The proportions of the arms, rim and boss of a gear are often determined by practical considerations of casting, but at the same time the strength of the arms may be calculated and it is well to do this for large wheels transmitting heavy loads. There are several different kinds of sections of arms in use. The I-section is probably the most extensively used for machine molded gears in England, but it is not as commonly used in the United States; it is very strong but it is the most expensive, since the space between the arms must be cored. The T-section and +-section are often used, but are not as strong as the I-section. Oval and rectangular sections are coming more into use, and possess the advantages of strength, cheapness in patterns, and simplicity in molding—an advantage which, in turn, gives good castings.

To calculate the strength of the arms it is necessary to find the bending moment at the root; it is generally agreed that each arm takes its share of the peripheral load, therefore, the bending moment in each arm equals the load at the pitch line in tons multiplied by the distance from the pitch line to the root of the arm in inches, and divided by the number of arms. This quantity divided by a maximum of 2 tons for cast iron and 4 tons for cast steel gives the modulus required by each arm at the root, which can be found from the usual formulas for each section. For small gears it is hardly necessary to make this calculation, but proportion each part of the arms, rim, or boss to some function of the pitch. There are several tables of these proportions used in practice, and Table VII may be taken to represent a fair average.

The number of arms generally adopted in crane practice is:

Four for gears up to 3 feet diameter.

Six for gears from 3 feet to 6 feet diameter.

Eight for gears above 6 feet diameter.

Gears below one foot diameter are generally made with a solid plate web, possibly relieved with some holes. The thickness of this web should be about one-half the pitch, and the proportion of rim and boss should remain practically the same as for the armed wheels.

* * *

Several months ago we received a letter from an educator stating that a man was wanted to take charge of the school work of his institution, in machine design, and that the salary would be from $1,400 to $1,600. A man was required who was competent as a machine designer, being one who had had charge as chief draftsman, or in similar capacity, of all the designing for some concern manufacturing engines, pumps, machine tools, etc. In short, this man must be one who is able to design good-looking machines by the instinctive process as well as by the cut-and-dried rules of design.

It is hardly necessary to say that a first-class machine designer who not only has the qualifications gained by long experience, but also the analytical mind, the clearness of expression and magnetic quality that would fit him for a teacher, probably would be difficult to secure at double the salary offered. The low salaries offered by many leading engineering schools for important positions tend to fill the instructor ranks with men of only average ability, whereas such men should, in our opinion, be superior in education and mental force. It is little wonder that students graduating from some of our famous institutions are poorly fitted for engineering work until they have passed through a trying-out process. They have not felt the mental stimulus of a master mind.

* * *

Some experiments which will prove valuable in aeronautics have been carried out by Professor Albert Frank of the Hanover Technological Institute in Germany. The report, as given in the *Zeitschrift des Vereines deutscher Ingenieure* states that 236 square feet of side surface develop no more resistance to the air than does one square foot of front surface placed perpendicular to the direction of motion. This indicates that comparatively small propeller surfaces are required as compared with the surfaces of the planes themselves in an aeroplane, to force the machine through the air.

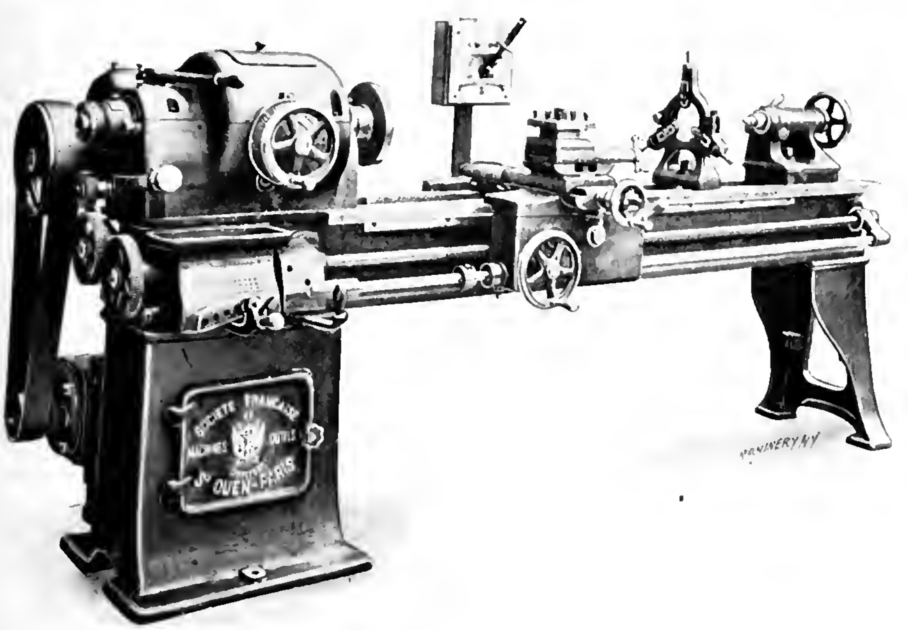
---

* A table of the outline factors used in the Lewis formula may be found in Kent's "Mechanical Engineers' Pocket-book," page 901, and also in MACHINERY'S Reference Series, No. 15, Spur Gearing, page 45, and in MACHINERY'S Data Sheet No. 22, July, 1903.

SOCIETE FRANCAISE DE MACHINES-OUTILS SINGLE-PULLEY-DRIVE LATHE.

As our readers know, a machine tool building concern has recently been organized in France for the manufacture of machine tools of the most advanced type, particularly those applicable to automobile work. It will be remembered that Mr. Kylin, in his letter in the July issue of MACHINERY, stated that they were building a geared head and a cone-head lathe, a turret lathe of the Potter & Johnston type, an automatic dowel pin machine and a spur gear planer designed by Monsieur Mardin, the manager; and that they intended to take up the making of planers and vertical boring and turning mills. We show herewith an illustration of the geared head lathe manufactured by this firm. It appears to be of original design, and presents a number of features of interest.

The first noticeable departure from American practice to strike the eye, is the use of rectangular ways in place of the V-sliding surfaces to which we are accustomed. The carriage, steady-rest and tail-center, are supported by the same flat surfaces, the carriage being guided by the outer edge of the ways, while the two heads are confined between the inner edges. This is in accordance with approved European usage. The bed is of heavy and rigid section, mounted on a cabinet base at the head-stock end.



Single-pulley Lathe with Motor Drive, manufactured by Societe Francaise De Machines-Outils.

The head-stock is of the single pulley type, and is provided with an unusually convenient arrangement for changing the speeds. The hand-wheel at the front of the enclosed head-stock gives eight changes of speed in geometrical progression, with no other movement than turning it from one position to another, as indicated by the large dial attached to its hub. The back gear arrangement doubles this number of speeds. It is controlled by the lever seen projecting forward over the rear spindle bearing. This may be used for starting and stopping the machine as well as for changing the speed. The single pulley drive has all the well-known advantages of this arrangement in avoiding the necessity for a complicated counter-shaft, allowing flexibility in the placing of tools, and making the matter of driving the tool by an electric motor a very simple one. In the case shown, the motor is mounted at the rear of the cabinet base, and is belted to the driving pulley. An ingenious and convenient feature is the mounting of the starting box on a support at the rear of the carriage. On long beds this is more convenient than mounting it in a fixed position on the machine.

The spindle is of high carbon steel and ground to size. The boxes are of hard bronze with cylindrical bearings and conical exterior surfaces, and are adjusted to fit the spindle by being shifted axially in their conical seats in the head-stock. A ball thrust bearing running in oil takes the axial pressure on the spindle.

A geared feed is provided, through the quick change box shown. This provides for six changes. The gears connecting it with the head-stock stud provide four more combinations, which give 24 changes of feed in all. This number, of course, may be multiplied indefinitely by using special gears. A splined feed rod and a lead screw are provided as in approved modern practice, it not being necessary to use the lead screw for turning, as is the case on many European makes of lathes. The feed rod has an endwise movement which operates a disengaging clutch, providing an automatic stop for the carriage. This is operated by the striking of the carriage against the adjustable stop collar shown on the feed rod. The disengaging clutch, thus controlled, is operated by the handle shown just at the right of the quick change handle. This serves also to connect the feed screw, it being impossible to throw the feed rod and the lead screw into action at the same time. The apron has double walls, giving firm support to all the mechanism which it contains. It provides for cross and longitudinal feed and for thread cutting. It is impossible to engage either of these three movements until the other two are disengaged, thus obviating all possibility of accident on this score. The use of the positive geared feed permits also, through the positive power cross-feed, the cutting of spirals on face-plate work.

The tool-post is four-sided, and may be swung like a turret to any one of four positions, in either of which it is positively locked by a bolt. This is especially useful in repetition work, as it permits the continuous changing of tools, and bringing them back exactly to their former position. As is common in foreign lathes, the compound rest is regularly provided, and is usually used for plain straight turning; when set parallel with the ways of the lathe, as shown, the workmen employ it for the fine longitudinal adjustments of the tool. The tail-stock is cut away to allow this, as is common nowadays in American practice. The tail-stock is so arranged as to permit its being released from the bed for a new longitudinal adjustment without disturbing its cross-wise adjustment.

The machine is provided with small and large face-plates (the latter being provided with holes instead of slots), the necessary gears and wrenches, a center rest, and follow rest. A reversing counter-shaft is provided for belt-driven machines, and an attachment plate for electric motors when the machine is to be electrically driven. A device for truing the centers is also furnished.

* * *

In the quarrying of granite, large laminations or sheets of granite are separated from the main rock by an interesting operation called the "lifting" process. A groove is cut to the required depth all around the section of stone to be separated from the main body of the rock. In the center of the area to be lifted a drill hole two or three inches in diameter is sunk six or eight feet in depth, according to the required thickness of the stone. At the bottom, the drill hole is enlarged into a pocket, by exploding a charge of dynamite. Then some powder is exploded in the pocket thus formed. This will start a horizontal crack or cleavage, and as new charges of powder, increasing in size, are exploded in the cavity, the drill hole being plugged at every blast to confine the gases and cause constant force to act upon the stone, the crack will extend say from 75 to 100 feet in all directions from the lift hole. A pipe connecting with air compressors is then cemented into the hole, and air, of a pressure from 70 to 80 pounds, is pumped until the crack or cleavage extends to the edge of the rock. Sheets of stone of large size can be thus lifted, thereby affording the quarrymen a plane to work to, so that the stone can be drilled and split to proper sizes for the purposes required.

CLEARANCE OF MILLING CUTTERS.*

HARRY A. S. HOWARTH†

The object of this article is to show graphically the factors that determine the clearance which should be ground on milling cutters. This will be done by drawing the cutting curves for a given cutter working under an exaggerated feed per revolution. The discussion will cover the following points:

1. A cutting edge leaves behind it, in the work, a curved path which lies within the circumference of the cutter. The angle between this curve and the circumference determines the clearance required.

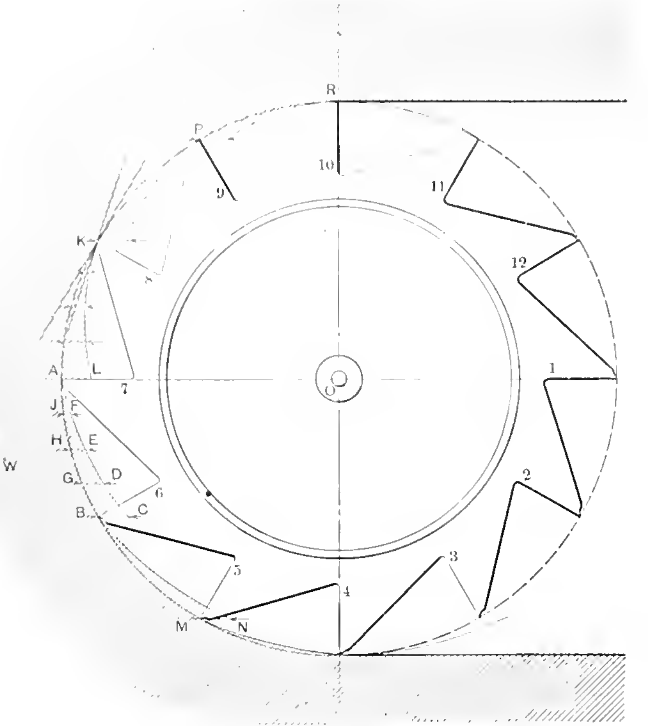


Fig. 1. Principle of Action of Milling Cutter.

2. This angle depends upon the feed, depth of cut, cutter diameter, and spindle speed.
3. Cutters with radial faces cut with a top rake equal to the clearance angle.
4. A coarse tooth cutter can mill a flat surface if it runs true.
5. Chattering is peculiarly dependent upon clearance, relation of tooth pitch to depth of cut, and combinations of pitch and spindle speed.
6. The pitch of cutter teeth depends upon the degree of finish wanted, depth of cut, amount of metal removed, and properties of the material being cut.
7. The diameter of a cutter should not be larger than that necessary to insure rigidity under the working conditions.
8. Repeated grinding necessitates an increase, each time, of the apparent clearance, it being gaged by the depth of the heel of the cutting edge below the cutter circumference. Excessive grinding necessitates slower feeds and speeds.

Clearance Angle.

In Fig. 1 is shown a cutter assumed to be 6½ inches in diameter. It has twelve teeth, and is represented cutting its way through a solid block of metal so that the teeth are cutting during one-half of a revolution of the spindle. The work W is fed against the cutter at the rate of four inches per revolution of the spindle, i. e., 1/3 inch per 1/12 revolution of the cutter.

Let us examine tooth No. 7. Its point *A*, while turning from *B* to *A* has cut the path *C D E F A* in the work *W*. When *A* was at *B*, the point *C* on the work was also at *B*. To make this clear, imagine the cutter to revolve backward and the feed to be reversed. As *A* turns to *J*, which is one-quarter the distance to *B* on the circumference, the point *F* in the work recedes to *J*. The distance *J F* is 1/4 × 1/3 = 1/12 inch. Similarly, if *A* moves to *H*, the point *E* recedes to *H*. The distance *E H* is 1/2 × 1/3 = 1/6 inch. Following up this method, we have *D G* = 1/4 inch, and *C B* = 1/3 inch. These distances are measured parallel to the direction of the feed, and the curve *A C* is part of a cycloid.

As the work feeds against the cutter each tooth thus leaves behind it a curved parth which lies within the circumference of the cutter.

At the point *K* in Fig. 1 draw a tangent to cutting curve *L K*. This represents the direction of motion of the cutting edge *K* with respect to the work at this instant. Draw also a tangent to the circumference of the cutter at *K*. This represents the direction of motion of the cutting edge *K* with respect to the spindle. The angle between these two tangents represents the minimum angle of clearance at *K* which will allow the work to advance toward the cutter at the rate of feed assumed, *i. e.*, 4 inches per revolution of the spindle.

Factors Determining the Clearance Angle.

It is evident from the cutting curves drawn that the angle between the two tangents will not be the same at *M*, *B*, *A*, *K*, *P* and *R*. It also appears that the angle is maximum at a point, above the center line *A O*, and in the neighborhood of *K*. It seems clear that tooth No. 8 requires more clearance to cut at *K* than tooth No. 6 requires to cut at *B*. Yet these teeth are symmetrically opposite with respect to the center line of the cut. This fact has a significance which will be noted later.

It is theoretically impossible to feed work at a given rate against a cutter unless the shapes of all the teeth back of the cutting edges conform to that cutting curve which makes, with the circumference of the cutter, the maximum angle corresponding to the given feed.

In order to find graphically the exact point which under the given conditions requires the greatest clearance, the single curve shown in Fig. 2 may be drawn. This represents the path that would be cut by a single tooth making a complete revolution while the work moves a distance equal to *Z R* or *U V*. Suppose the center of the arbor is at *V* and the single tooth is at *R*. Consider the cutter as advancing toward the work. When *V* moves to *X* and the cutting edge moves to *Q* directly ahead of *X*, the cutter has made a quarter turn. If the feed is 4 inches per turn, the distance *V X* = 1 inch. As *V* advances from *X* to *Y*, *R* moves from *Q* to *S* directly above *Y*, and *X Y* = 2 inches. In this manner the tooth describes the path of the cycloid *R S Z* while the spindle advances 4 inches or from *V* to *U* and makes one complete revolution.

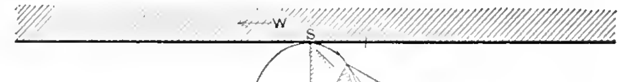

Fig. 2. Path of Milling Cutter Tooth, when Feed is less than Circumference of Cutter.

Assume the cutting edge to be at some point *A*. The corresponding position of the spindle is *B*. Construct the two tan-

† Address, P. O. Box 171, So. Bethlehem, Pa.

gents at A; $C A$ is tangent to the cycloid; $A D$ is perpendicular to the radius $A B$. Angle $C A D$ is the clearance angle required at A. A few similar constructions at points Q, E and S, etc., show by comparing the angles that the position of greatest required clearance for this case is at some point E.

The position of greatest clearance E varies with the ratio of the feed to the diameter of the cutter. If the diameter is kept constant and the feed reduced, point E will approach Q. It reaches Q when the feed is zero. Thus the limiting position of clearance E is at the center line $Q V$ when the cutting curve becomes a circle and U and V coincide. At this limit the clearance angle becomes zero.

When the feed per revolution is increased so as to equal the circumference of the cutter, the cutting curve becomes as shown in Fig. 3. Here the limiting position of greatest clearance is S_1 at the apex of the curve. At this point the clearance becomes 90 degrees.. This is shown by drawing the series of clearance angles as before mentioned.

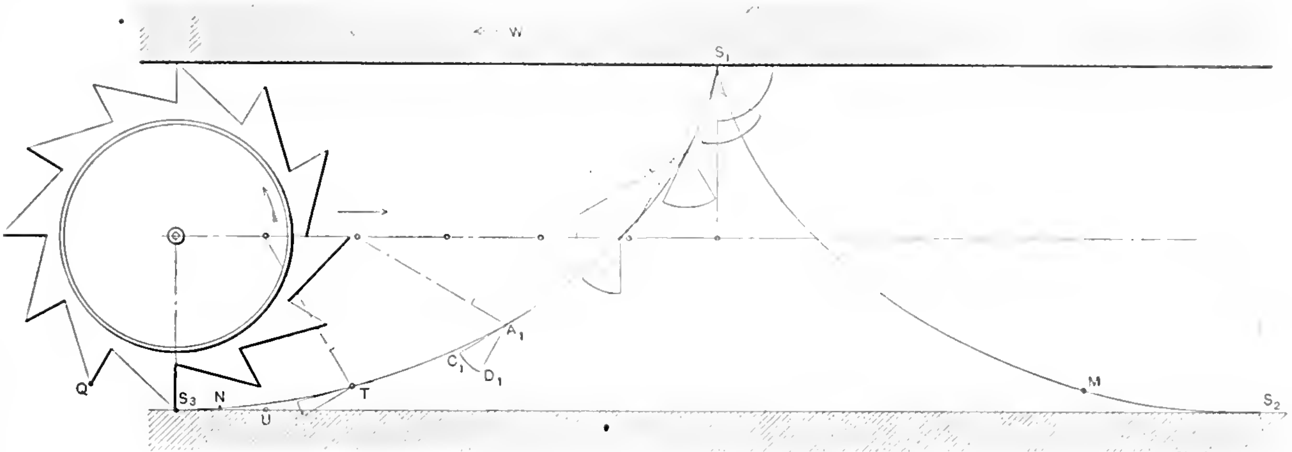

Fig. 3. Path of Milling Cutter Tooth, with en Imaginary Feed equal to the Cutter Circumference.

Of course, these two extremes are impossible cases practically, but under certain conditions they are approached, as when a cutter with no clearance whatever is put to work; and when a cutter is started in the wrong direction over a piece of work and draws the work under it at a speed equal to its circumferential speed.

The conclusions resulting from the previous discussion are as follows:

(*a*). The point of greatest clearance rises from Q to S (see Fig. 2) as the rate of feed is increased from zero to the cutter circumference per revolution of the cutter.

(*b*). The greater the ratio of the feed per revolution to the diameter of the cutter, the greater is the clearance required. This clearance does not depend on the number of teeth in the cutter.

(*c*). The cutting curves shown represent the minimum limit of the clearance which must be ground on cutters running under the conditions assumed. Practically more clearance must be used in order to avoid rubbing the heel of the tooth when cutting.

(*d*). The discussion so far has assumed the cutter to be milling a slot of a width equal to its diameter. This is not always the case. The cut may vary from the diameter of the cutter down to practically nothing. The less the depth of cut below the point K, Fig. 1, the less is the clearance required on the cutter for a given ratio of feed per revolution to cutter diameter. For light finishing cuts very little clearance is therefore necessary.

(*e*). Hence it is evident that a cutter ground for a light surface cut will not work properly on a deep cut unless the feed is correspondingly reduced. Conversely, a cutter ground for a deep cut can be fed much faster on a light cut.

Positive Rake of Milling Cutter Teeth.

Since milling cutters for steel and iron are almost all made with radial faces, the idea is prevalent that the cutting action of the teeth is much the same as that of a planer tool which has no top or side rake, cutting as shown in Fig. 4, with the face of the tool at right angles to the direction of feed. This analogy is nearly true for slow feeds; but if we examine in Fig. 2 the angle which the face of the tooth makes at E with the tangent $E H$ to the cutting curve, we see that for this coarse feed the tooth has considerable top rake as indicated by the angle a. This fact throws some light onto the reason why coarse feeds are more efficient than fine ones for removing metal. By efficiency we mean the capacity for removing metal, as measured in such terms as pounds of metal per horse-power per hour. On all tools, where practicable, rake is used because of its distinct advantage as a power saver. Consideration will be given later to the relation of coarse feed to the number of teeth in a cutter.

Milling cutters whether with fine or coarse teeth will produce a very flat surface no matter whether the feed be fast or slow. This is evident by examining the cutting curves in Figs. 2 and 3 at the point R, Z, S and S_2. They are nearly flat. In Fig. 3, as the tooth S_3 moves to T, the tooth Q moves to U in a path similar to the end of the cycloid at $M S_2$. The two curves would cross midway between U and S_3 at a point N. The height of N is very little above the line S_3U. For fine feeds this height would become infinitely small.

The ridges so often thought to be due to coarse feed are due to the cutter being run out of true, *i. e.*, eccentric. This action is caused by a number of things such as untrue spindles, sprung arbors, and cutters with holes too large for the arbor, or even by cutters ground on sprung arbors, etc. The common effect of all these causes is that the cutter mills deeper at one part of the revolution than another. The number of turns it makes in crossing a piece of work may be found by counting the ridges produced.

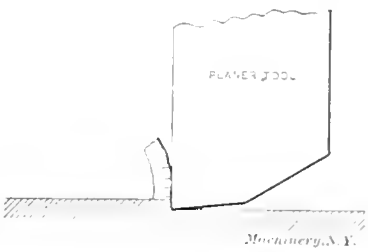

Fig. 4. Planer Tool without Front Rake

It is thought by many that a spiral tooth cutter will mill a flatter surface theoretically than a straight tooth cutter. This is only true practically, because the spiral action prevents vibration. Theoretically, the only difference would be that the ridges produced by one would be parallel to the spindle while the other would be diagonal.

Chattering.

Chattering is due to variations of pressure between the cutter and the work. When a corner of the work advances toward a cutter, as in Fig. 5, point A, the first tooth to strike it springs back as it cuts. As it passes the corner it jumps forward. This action is repeated by each tooth and it sets up a vibration of the cutter and arbor which continues until the cut is well under way, as at C, Fig. 5. If the cutter has excessive clearance, the vibration will cause it to feed deeper than necessary at the instant when the cutter vibrates toward the work. This action causes the formation of notches. These notches or grooves once formed are apt to follow clear through the cut and keep up the chattering.

The vibration is begun by the intermittent action of one tooth. Soon two teeth begin to cut part of the time (see position *B* in Fig. 5). Here the pressure variation becomes due to the difference between one tooth and two teeth. As soon as three teeth begin cutting part of the time, the pressure variation is between two and three teeth, and so on. The more teeth bearing on the work at one time, the less is the pressure variation.

We have assumed above the use of straight face cutters; but they are not always used. The best practice recommends cutters with a slight spiral. Then the initial shock is reduced and the first tooth takes an appreciable time to perform its cut. On wide cuts it is practical to have the second tooth begin cutting before the first finishes its cut. Still there exists a variable pressure which can cause vibration, though it is not so great as with a straight face cutter.

A given combination of cutter and arbor will have a definite period of vibration, just as a violin string of given length, thickness and tension will vibrate at a definite rate and produce a certain sound. Sometimes the spindle speed and cutter pitch are such that they cause chattering that matches closely to the period of vibration of the cutter and arbor. They may be said to be in tune, though the noise that results is frequently anything but music. This can happen with spiral cutters as well as with straight tooth cutters, though the action will not be so pronounced.

The remedy is twofold: Reduce the clearance, if excessive; change the spindle speed. A change of feed will have little effect except as it tends to make use of excessive clearance. Using a cutter of different diameter will frequently help, beause it breaks up the noisy combination.

Number of Teeth.

The considerations that govern the number of teeth in a cutter are as follows:

(*a*). Degree of finish required.
(*b*). Depth of cut.
(*c*). Amount of metal removed per revolution.
(*d*). Kind of material being cut.

There are other considerations that depend more or less on these, and these four depend a great deal on each other.

(*a*). A fine tooth cutter will produce a better finish for a given speed and feed than a coarse tooth cutter. Since finishing cuts are light, the use of a coarse tooth cutter would cause chattering because of the variation of pressure due to the probable action of one or two teeth intermittently, as before noted; hence finer tooth cutters are better for finishing.

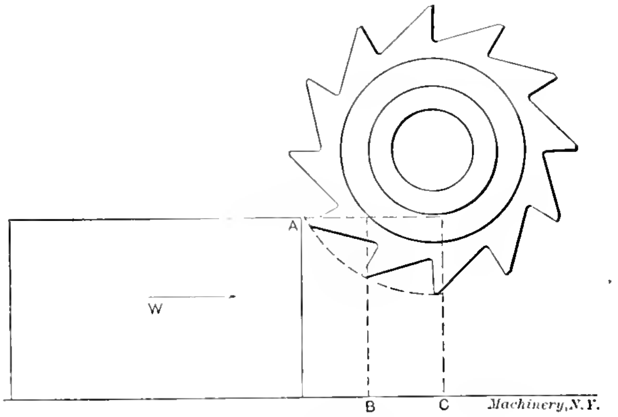

Fig. 5 Action of Cutter, just Starting to Cut.

(*b*). The deeper the cut the more teeth of a given cutter will be in action at one time. There is no object in having this number too large. In fact, it is a distinct disadvantage, because the feed has to force all the teeth into the work.

(*c*). The amount of metal removed per revolution depends on the rigidty of the work, *i. e.*, the method of holding it, and its capacity to withstand the pressure of the cut. The space between two cutter teeth has to carry the metal removed by one tooth during its cut. The area of this space varies as the square of the pitch of the teeth. Hence the relative ability of the space to carry away metal becomes greater as the pitch increases. Coarse teeth are therefore best fitted for rapid cutting. It might seem that coarse feeds require extra power in proportion as they are increased. This is not so, because the top rake or wedge-like action of the teeth makes it easier for them to enter the work. As the feed is increased the top rake is increased, hence the resistance increases at a slower rate. It might be mentioned that the top rake is equal to the theoretical clearance required at the point under consideration. This is true when the face of the tooth is radial.

(*d*). The kind of material to be milled affects the pitch of the teeth in general, as follows: The harder the metal, the fewer the teeth or coarser the pitch; the softer the metal, the finer the pitch, because the cutter must have some support at its cutting edges or it will enter the work too eagerly. For soft metals, such as brass, the additional precaution is taken of making the teeth faces slant ahead of the axis of the cutter instead of radial. This reduces the top rake. The spiral of cutters is more rapid on cutters for soft metals, because of the greater danger from chatter.

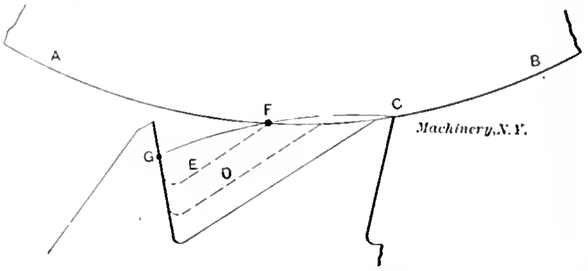

Fig. 6. Effect on Clearance caused by repeated Grinding of Cutter Teeth.

Diameter of Cutter.

For a given feed per tooth and a given pitch, a reduction of the diameter of the cutter has the effect of increasing the necessary clearance and the resulting top rake. It also decreases the torsional strain on the arbor, the shearing stress in the cutter key, and the frictional force in the spindle taper. It reduces also the strain thrown on the driving gears of the spindle, and a saving of metal in the cutter is affected, but since the number of teeth are fewer, they are used oftener and wear out more quickly. Experience seems to prove the advisability of using cutters as small as possible without reducing too much the rigidity, or the reasonable allowance for recutting.

Grinding Cutters.

Consider a given cutter running always at the same feed per tooth. In Fig. 6 two teeth are drawn with the cutting curve *C F G* between them. The arc *A B* represents the position of the grinding wheel when grinding the clearance which was necessary when the cutter was new. The dotted lines *D* and *E* represent the flank of the tooth at two stages of its life before recutting. When regrinding has brought the flank to *E*, the heel of the tooth *F* will lie on the cutting curve. To lower this point below the cutting curve requires a smaller wheel. But this has the effect of weakening the cutting edge at *C* by reducing the angle of the point. This makes overheating more likely to occur.

Cutters should seldom be ground away so much as shown here because the space between the teeth is reduced so much that it will not carry the chips away properly. When the distance *F C* becomes half the pitch, the chip space becomes nearly one-fourth what it was originally.

The previous discussion seems to suggest the necessity of having some means of modifying the clearance ground on a cutter so that its performance will be uniform after successive grindings. In this way the maximum results would become more nearly possible, because another of the uncertainties in the use of milling cutters would be eliminated.

* * *

"Alas!" confessed the penitent man, "in a moment of weakness I stole a carload of brass fittings."

"In a moment of weakness!" exclaimed the Judge. "Goodness, man! what would you have taken if you had yielded in a moment when you felt strong?"—*Exchange.*

MAKING SAWS.

ETHAN VIALL *

Owing to the fact that many of the machines used in saw manufacturing are designed and made by each firm for its own use, and also to the fact that many of the processes in saw making have been developed along independent lines, there are many things in a saw factory which are not generally known, and the processes are often regarded as trade secrets. However fallacious this policy of secrecy may be, it is followed by nearly all saw manufacturers; yet it is safe to say that not one firm is in ignorance of the important processes and methods used by its competitors.

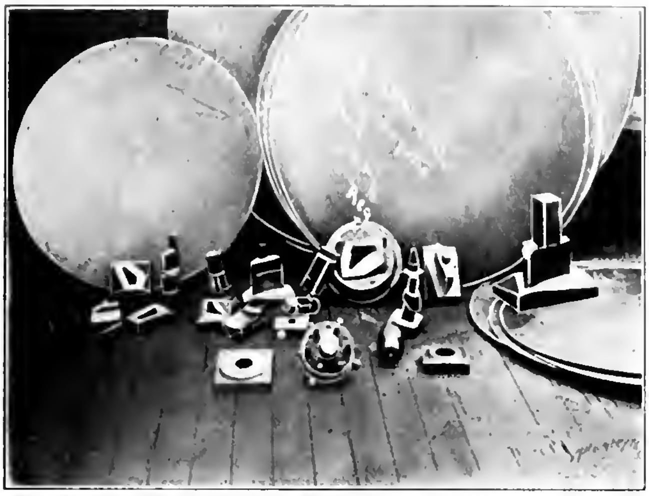

Fig. 1. Steel Disks for Circular Saws, and Punches and Dies for Center Holes and Teeth.

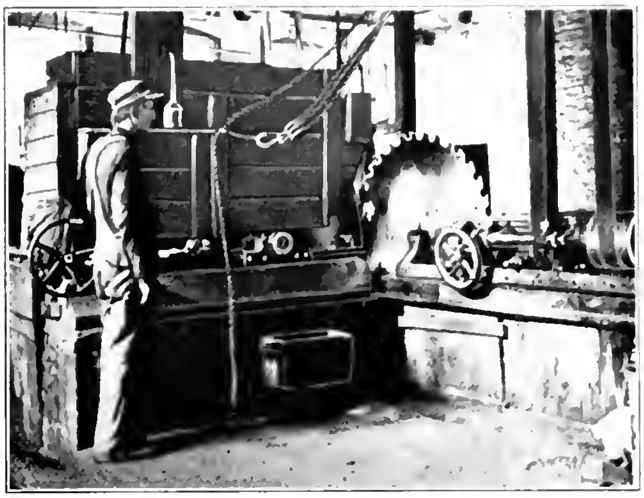

Fig. 2. Machine for Grinding the Sides of Circular Saws

Fig. 3. Hammering and Tensioning a Circular Saw.

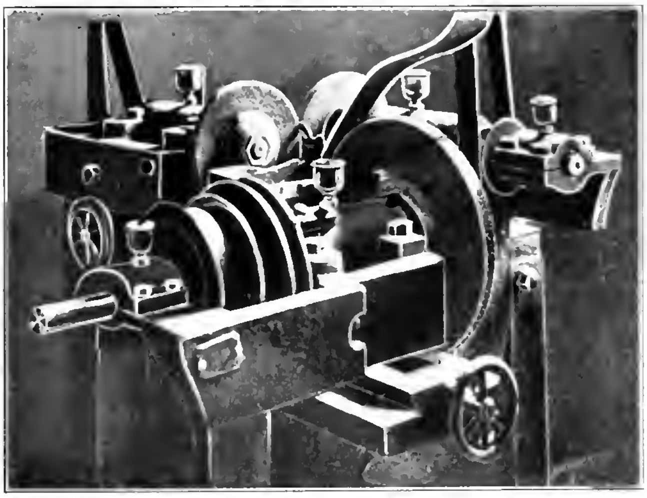

Fig. 4. Special Three-wheel Grinder for Grinding the Teeth of Inserted Tooth Saws.

E. C. Atkins & Co., of Indianapolis, Ind., is one of the few saw manufacturers realizing the futility of trying to keep their machines and processes secret. This firm, which is one of the largest and oldest manufacturers of saws in the United States, through the courtesy of Mr. Atkins, the superintendent, gave the writer the opportunity of taking a number of photographs, and obtaining the information necessary to give the readers of MACHINERY an idea of how the Atkins saws are made. This company turns out thousands of band saws, but the main product is large circular and large band saws. The circular saws are of two general types, the solid and the inserted tooth.

The steel for the saws, which is made especially for the firm, comes in circular disks or in long strips or bands of the proper size and standard gage for the various standard circular and band saws made. A number of the steel disks from which the circular saws are made, are shown in Fig. 1. Several center hole and tooth forming punches and dies are also shown in this engraving.

In working up the steel disks into saws, the center hole is first punched in a punching press, and in the next operation the teeth are cut. The operator selects a tooth-forming punch and die corresponding to the number of teeth required. These are set up in the press and an indexing disk of the same number of teeth as required in the saw is placed on a stud, as shown at A in Fig. 5. The saw blank is then placed over this indexing disk and securely clamped by means of a nut on the stud. The carriage holding the blank is then moved in or out, and the entire fixture moved to the right or left, until the disk is in the correct position for the punch to cut the teeth at the proper angle and depth. The teeth are then rapidly cut, the spacing being obtained by the indexing plate. All of the circular and inserted tooth saws are cut out by using this kind of punch press jig.

When hardening the saws, they are laid flat in a special gas furnace, and heated slowly. When evenly heated, the saw is drawn out and placed on the lower plate of a grated clamp, as large or larger than the saw, and a similar grated plate is lowered from above. The saw is thus kept flat, and prevented from warping, and is quickly lowered into a large tank of oil. When the saws are taken out of the hardening bath, they are placed in the machine shown in Fig. 2, where the sides are ground. This machine is provided with a large grindstone, which is fed in or out by means of a hand-wheel, shown just back of the operator. The saw is placed on an arbor mounted on a carriage which automatically feeds it across the face of the grindstone. The grinding begins at the outer edge of the saw, and as the operation proceeds, and the grindstone is gradually fed in toward the center, the saw is made thinner in the center than at the edge. This method provides a free-cutting saw with little tendency to bind.

While grinding, the saw revolves in the same direction as the grindstone, but more slowly, as belt-driven rolls, one on each side of the saw, act as brakes, and thus make grinding possible. The practice of running the saw in an opposite direction from that of the wheel, usually followed in grinding small milling saws, would be practically impossible in this case, owing to the leverage caused by the size of the

---

* Associate Editor of MACHINERY.

saw and the width of the grinding wheel. Besides, it is doubtful if there be any advantage in running the saw and wheel in opposite directions.

During the grinding process, water pours down between the saw and the stone, and only a few minutes are required to grind the sides of the largest saws, with no danger of drawing the temper. After grinding the sides of the saw, it is placed on an arbor in another machine, and while revolving rapidly, is polished by holding a polishing pad with a wooden handle against the side and feeding it back and forth on the top of the rest, as shown in Fig. 6. Flour of emery is used on the pad for polishing. Then the teeth are touched up on a special grinding machine, as shown in Fig. 7.

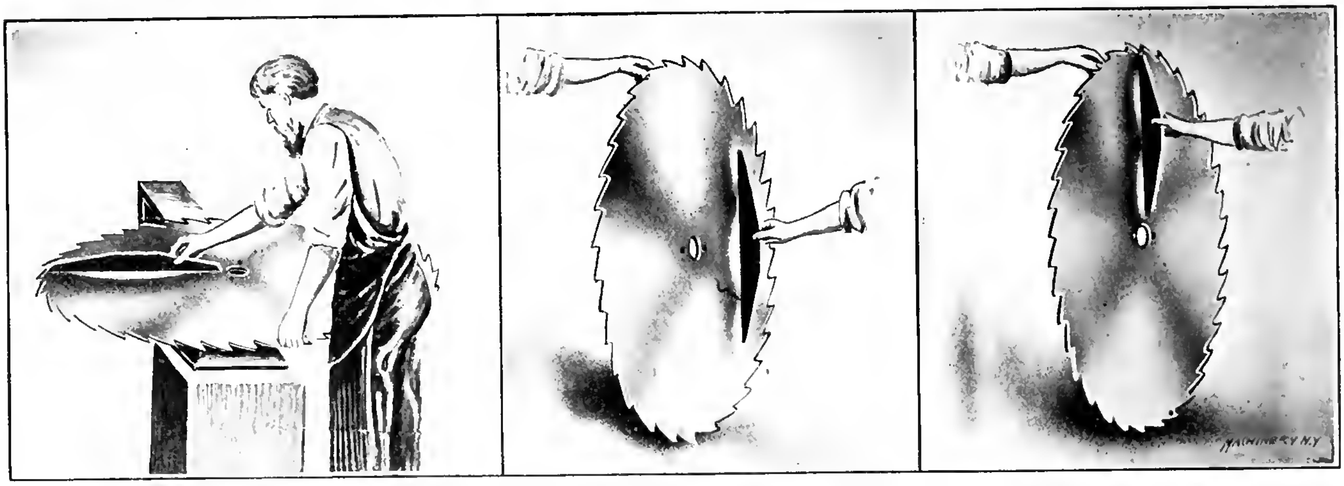

Figs. 8, 9 and 10 Testing the Sides of a Circular Saw to Determine the need of Hammering and Tensioning.

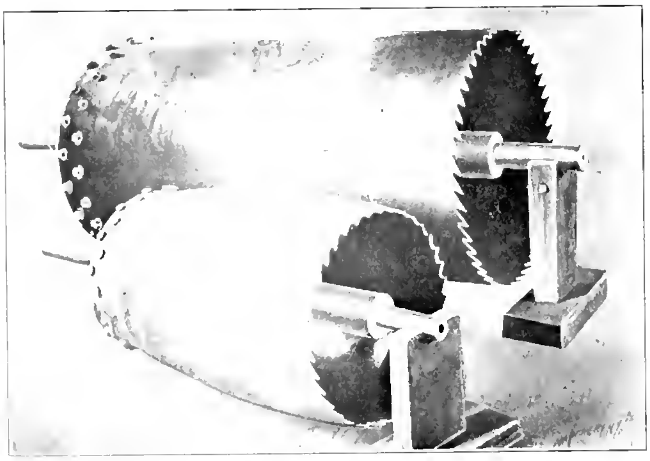

Fig 11 Barrel Saws.

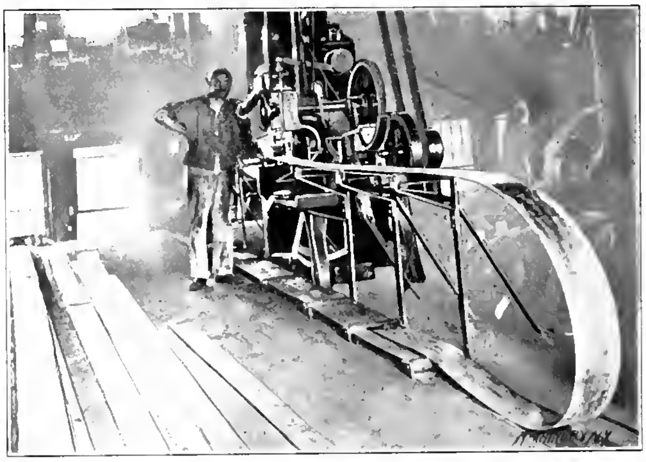

Fig. 12. Punching the Teeth in Band Saws.

One of the most important operations on the saw is the hammering and tensioning. This work is tedious—or at least it looks so—and it takes long practice to become an expert. Twenty-five or thirty men are employed in this department, and a large majority of them are well past middle age, and have been doing this work for years. Fig. 3 shows the shape of hammers and the anvil used for hammering the large circular saws. As few mechanics outside of saw-mill men know what "tensioning the saw" means, the following is quoted from a pamphlet of instructions issued by E. C. Atkins & Co. for their customers.

"For the benefit of our patrons and sawyers using our saws, we take pleasure in explaining the general principles involved in the hammering and tensioning of circular saws. The practice taught by masters of the art thirty years ago, when only saws of small diameter were used, was that a circular saw, to do proper work, should be left firm between the center and the

rim, and open as to its whole diameter, whereas experience has shown that it is best to open out the body of the saw between the center and the rim to the extent required for the speed the saw is to run.

"Very high speed and thin saws require that the saw be opened out until it takes a strong push or pull to throw the center either way when the saw is standing upon the floor. When the saw is in proper tension and is shaken, the body only of the saw should vibrate, while the rim should be nearly or quite steady.

"Gumming a circular saw, or alternate heating and cooling of the rim, will permanently expand a saw at the rim, and in consequence it will become too stiff in the center or body, and run 'snaky.' A few strokes of a round-faced hammer on both sides of the saw at the proper place will restore the tension. In Fig. 17, the portion of the saw to be hammered is indicated by the dotted lines. The same treatment is required if the saw is put up for too low speed. The rule is that it must be more open or 'limber' in the body of the saw for fast speed than for slow; for hard than for soft wood.

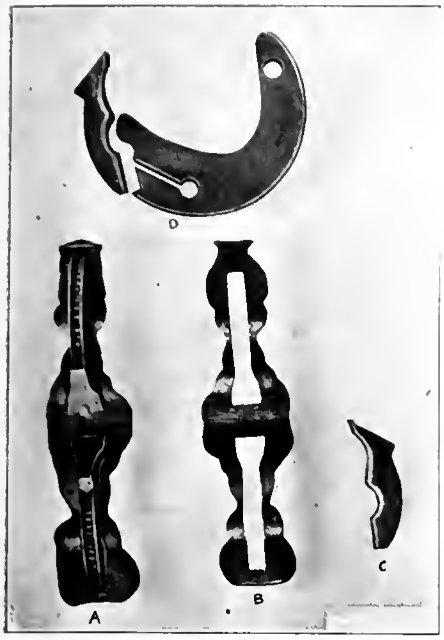

Fig. 13. Forging for Tooth and Holder for Inserted Tooth Saws.

"When the saw is standing on the floor and shaken with the hand and the center and rim both vibrate, it requires more hammering on the line next to the rim. When opening out the body of the saw, do not hammer within 6 inches to 10 inches of the center.

"Observe the motion of the saw when on the mandrel and running up to full speed; if it runs wavy on the rim, it needs opening out on the dotted lines. If it runs steady and true out of the log, it is the fault of the hanging, lining, fitting or management if it does not run steady and true in the log.

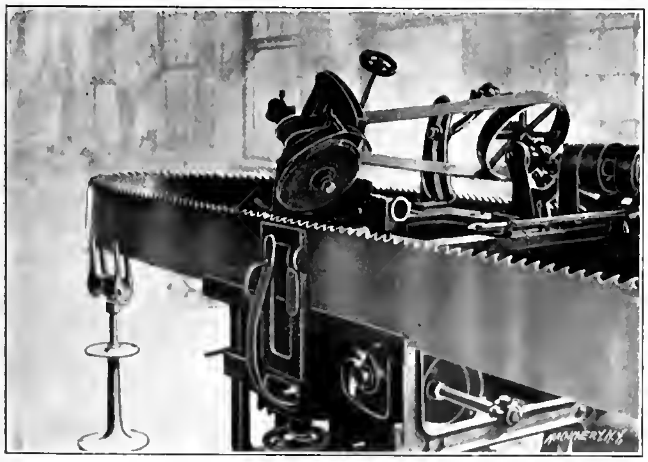

Fig. 14. Large Grinding Machine for Band Saws.

"Fig. 8 illustrates the examination of the saw with the straight-edge in adjusting tension: the center of the saw resting on the anvil, the rim back of the anvil supported on a narrow bench extending from the anvil to the wall, and the opposite point raised with the hand, the straight-edge extending from the center toward the rim of the saw. If the saw is properly opened in the body, the portions indicated by the dotted lines in Fig. 17 will drop away from the straight-edge equally all around the saw.

"To equalize the tension, the parts that drop least require hammering until the tension is even and all parts indicated by the dotted lines drop equally all around the saw, the center line dropping a little more than the others.

"Hammering to take out lumps should always be done on the high side or on that side which touches the straight-edge. Lumps or ridges upon or near the rim may be found with the straight-edge by examining that part of the saw, with the center of the saw resting on the anvil, but lumps or ridges in the body should be found with the saw standing perfectly perpendicular upon the floor, Figs. 9 and 10. Mark the high spots with chalk, and hammer where marked, on an anvil.

"Allowance must be made for change in tension produced by the blow of the hammer, as every blow stretches and opens the saw at the point struck.

"Lumps usually run in ridges and should be hammered out with a cross peen hammer, the peen following the ridge in the direction in which it runs as discovered by the straight-edge. Round lumps may be hammered down with the round face hammer, or with a cross peen hammer, by changing the position of each blow so that the strokes cross each other. The strokes should be directly on the lump or ridge."

Fig. 15. Inserting the Teeth.

The foregoing extract will not only give a good idea of what hammering and tensioning means, but it will also give a fair idea of how it is done.

In the inserted tooth circular saws, the cutting teeth are forged in pairs, as shown in Fig. 13, where *A* is the forging untrimmed, *B* the part trimmed off, and *C* the tooth. At *D* is shown the tooth and holder ready to be put into the saw.

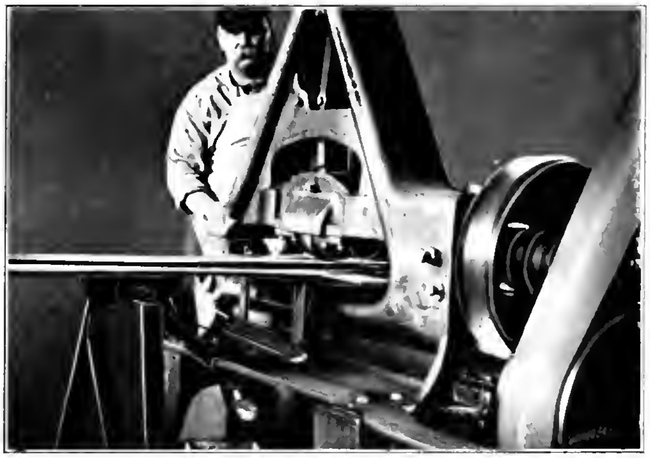

Fig. 16. Tensioning a Band Saw by Rolling.

The teeth are ground on both sides and on the cutting edge at one operation, on a special three-wheel grinder, shown in Fig. 4. The manner in which the tooth-holder or "shank" is inserted is shown in Fig. 15, one tooth being already in place at *E* and another just being put in with a wrench at *F*. The saw is held in position by a stud which passes through the center hole and by a clamp, operated by a hand-wheel, which grips the rim.

A special form of saw called the barrel saw, which is used

for sawing out barrel staves, is shown in Fig. 11. In these saws only a narrow strip at the edge is made of saw steel, the body being made of a cheaper material, to which the saws are riveted. The cutting blades are made in the same way as a band saw, with the ends lapped and brazed.

In making band saws, the teeth are cut in a punch press, as shown in Fig. 12, the teeth being set against a stop the right distance from the punch, and the feeding being done by hand. These saws are hardened by fastening them to a "dummy" strip, which is slowly drawn through a gas furnace and into an oil tank. The whole operation is continuous and practically automatic. After hardening, the band saws are ground by feeding them under a large grindstone. The table is tilted so as to grind the saws thinner at the back.

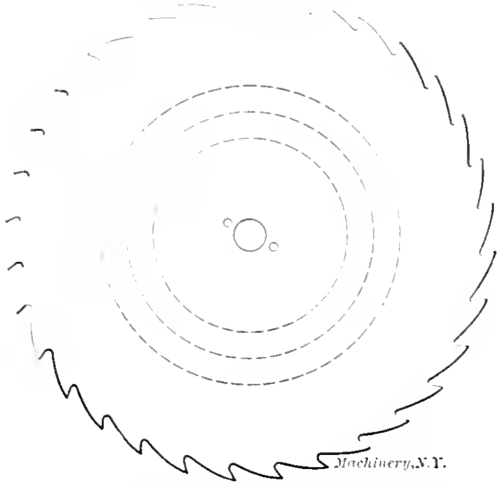

Fig 17. Diagram Indicating the Lines along which a Circular Saw is Tensioned

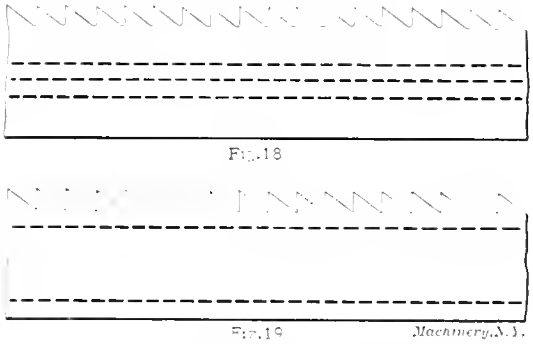
An automatic band saw tooth grinder is shown in Fig. 14. This grinder will take saws of any size and length; for small saws of similar type, smaller machines of the same design are used. These smaller machines are common in wood-working shops.

The manner in which band saws are rolled to give them the proper tension is shown in Fig. 16. To run properly, a band saw must be open in the middle, and it is rolled as shown by the lines in Fig. 18. If it is too open, it is rolled as shown in Fig. 19.

Hand saws and cross-cut saws are both ground thin on the back, the same as the band saws, and in the same way. They are heated and held in long clamps while being dipped in the hardening oil bath. The teeth on the hand saws are set with a light hammer. The men engaged in this work, the setters, use their hammers as steady as the ticks of the clock and never miss a tooth.



Figs. 18 and 19. Lines along which a Band Saw is Tensioned.

* * *

The length of new railways opened in the United States last year was 3,214 miles, showing a decrease of 1,998 miles, or 38 per cent, as compared with 1907. The largest new construction on the part of any one company was 790 miles of track involved in the Chicago, Milwaukee and St. Paul Railroad's Pacific Coast extension. The railway network of Canada was increased last year by 1,250 miles, and that of Mexico 435 miles.

JIGS AND FIXTURES—12.

BORING, REAMING AND FACING TOOLS.

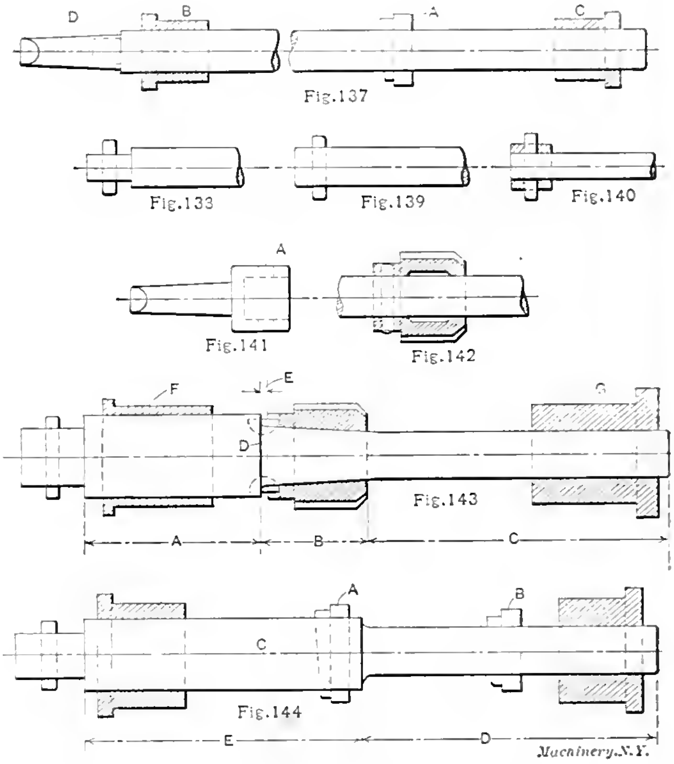
EINAR MORIN *

More or less elaborate tools or sets of tools are required for the various boring operations performed with or without boring jigs. These tools comprise boring, reaming and facing bars, boring and facing cutters, solid or shell reamers, boring and facing heads, bushings, stops, drills, collets, and knuckle or universal joints.

Boring Bars.

The general requirements of a boring bar are that it must be as heavy and rigid as possible, straight, and ground concentric, and a good running fit in the bushings. When the bar has been turned and once ground to the right size, it should never be put in a lathe and filed, or emery cloth used on it. Boring bars are made from machine steel and are not hardened. Sometimes small bars are made from tool steel and hardened, in order to give them additional stiffness. Shanks for reamers, and facing bars, should be made in the same way as boring bars, but if possible, should be even stiffer.

The most common type of boring bar is shown in Fig. 137, the cutter *A* being located at about the middle of the bar, and the bar being guided at both ends by bushings *B* and *C*. The bar is provided with a taper shank at *D*, fitting the spindle of the machine or a collet connected with a knuckle joint. It is quite common practice to turn down the end of the bar, as shown in Fig. 138, to fit the knuckle joint or collet shown in Fig. 141. Sometimes, of course, the bar can be left full size, as shown in Fig. 139, and sometimes the end is even made larger than the bar, by forcing on a collar, as shown in Fig. 140, in order that the end may fit the driving collet. A key is passed through the end of the bar for driving it; this key fits in the slot *A* in the collet shown in Fig. 141.



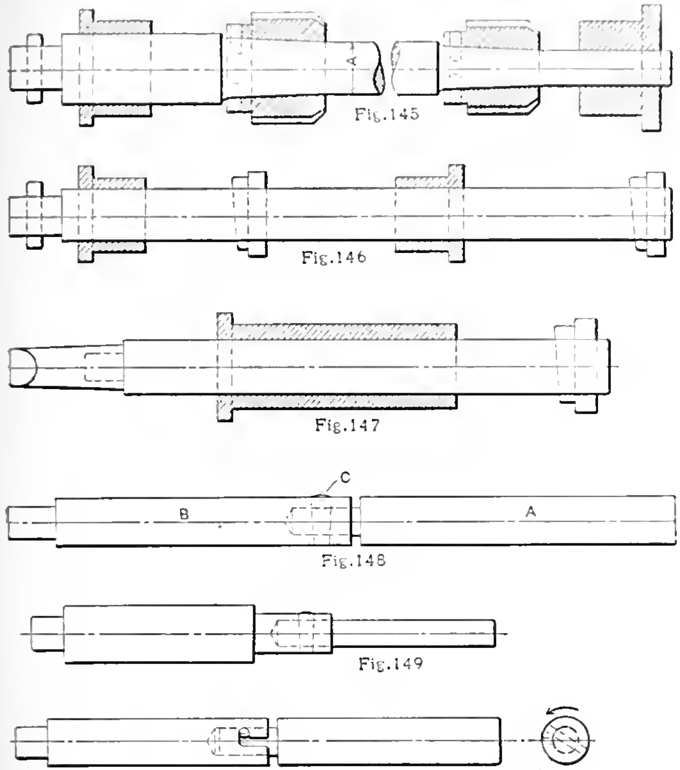
Figs. 137-144. Boring Bars of Different Types.

The bar shown in Fig. 137 can also be used for facing purposes, the cutter *A* being taken out, and a facing cutter inserted. The same bar can also be used for a special shell reamer, when this has a straight hole, the reamer being held to the bar by a taper pin, as shown in Fig. 142. Standard shell reamers have a taper hole, and for these, the bar must be turned with a taper part, as shown in Fig. 143, where the part *A* is turned up to the largest size possible (generally 1/32 or 1/16 inch under the diameter of the reamer); part *B*,

---

* Address: Borlänge, Sweden.

being turned to fit the taper hole in the shell reamer, is left long enough to permit the reamer being pressed up tightly without touching the shoulder *D*. As a rule, the taper part is so dimensioned that ⅛ inch will be left at *E*, between the shoulder of the bar and the back of the shell reamer, when this is forced up as far as possible. The reamer is driven by keys or pins entering in a slot cut across the end of the reamer. The part *C* of the bar is turned down to some standard size, just below the size of the small end of the taper hole in the reamer. The bushings *F* and *G* may be made with the same outside diameter, fitting the same size lining bushings in the jig, their inside bearings being made to fit the large and small diameters of the bar.



Figs. 145-150. Other Designs of Boring Bars.

A boring bar used for boring out two holes of different size may be made as shown in Fig. 144; *A* and *B* are the cutters for the two holes, and part of the bar *C* is turned down for a length, *D*, to suit the small hole. The part *E* can then be made of as large diameter as permissible for boring out the hole for which the tool *A* is used. By making the bar in this way, a more rigid construction is possible than if the part *E* were turned down to the smaller diameter required by the hole bored by cutter *B*. There may be more than two holes of different sizes in succession, and then the bars may have a greater number of steps; if there is but a slight difference in the sizes of the holes to be bored out, it hardly pays to turn down steps on the bar. The stepped bar may also be used for facing bars. While these small matters may seem unimportant and elementary, they must be taken into consideration when designing a set of expensive tools for boring jigs which are to be in constant use.

Reamer bars used for reaming out two or more holes simultaneously may be made as shown in Fig. 145, providing the diameter *A* is large enough for turning the taper portion for another shell reamer of smaller size. Should the diameter be too small to permit this, an extension can be provided, or a separate bar used for the smaller reamer. The principle of stepped bars can be applied also where the cutters are placed as illustrated in Fig. 146, where one boring cutter or facing tool is placed at one end, the bar still being guided by two bushings.

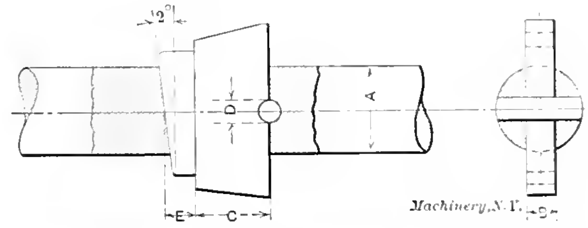
A boring, facing, and reamer bar used almost as commonly as the one already described, is illustrated in Fig. 147. The principal features of this bar are that the cutting tool is always located at the end of the bar, opposite to where it is driven, and that there is but one bushing for guiding. This bushing should be as long as possible to give a good bearing, and prevent the bar from wobbling. Sometimes, as illustrated in Fig. 121, January issue, the jig is made with two bearings which, however, are on the same side of the cutter, and a comparatively short distance apart.

Sometimes a bar must be made in two parts. The reason may be that one solid bar would be too long to permit of its being pushed into the jig from one side. Another reason may be that the cutting tools are too large to pass through some intermediate hole. The two parts of the bar may be connected with a taper pin, as shown in Fig. 148, the end of bar *A* being a sliding or driving fit in the hole in section *B*. This bar should be ground after the two parts are assembled, so that they will run exactly true with each other. A stepped bar made up of two sections as shown is Fig. 149. In Fig. 150, another method of connecting the two sections is shown; when this method is used the two bars can be put together and taken apart very rapidly. This method can also be used to connect two bars by a separate piece, as shown in Fig. 151, the two sections being bored out to fit the intermediate piece, which has two pins *A* and *B*, driven into it, and transmitting the motion from one section of the bar to the other, as indicated. It is evident that two bearings would hardly be sufficient for this class of boring bars. When these bars are used, three or more bearings should be provided. This type of bar, however, is not used to a very great extent.

Cutters for Boring Bars.

The cutters used in boring bars vary widely. The cutter *A*, Fig. 152, is commonly used. It cuts with both ends, and is centered by the two flats *B*, milled or filed on the bar; a slot is provided in the cutter, which fits these flats of the bar. After the cutter has been put in place, it is tightened by the key *C*. and is turned to the correct diameter required, and then hardened. A more modern arrangement is shown in Fig. 153. The cutter here is a plain rectangular piece of steel, cutting with both ends. It is centered by the pin *A*, which is driven into a hole drilled so that one-half of it passes through the slot in the cutter. As in the former case, the cutter is turned down to the right diameter when in place. It is tightened down by the key *B*. This way of locating the cutter centrally has proved very satisfactory. In Table X are given dimensions of cutters for different bar diameters.

TABLE X. BORING AND FACING CUTTERS.

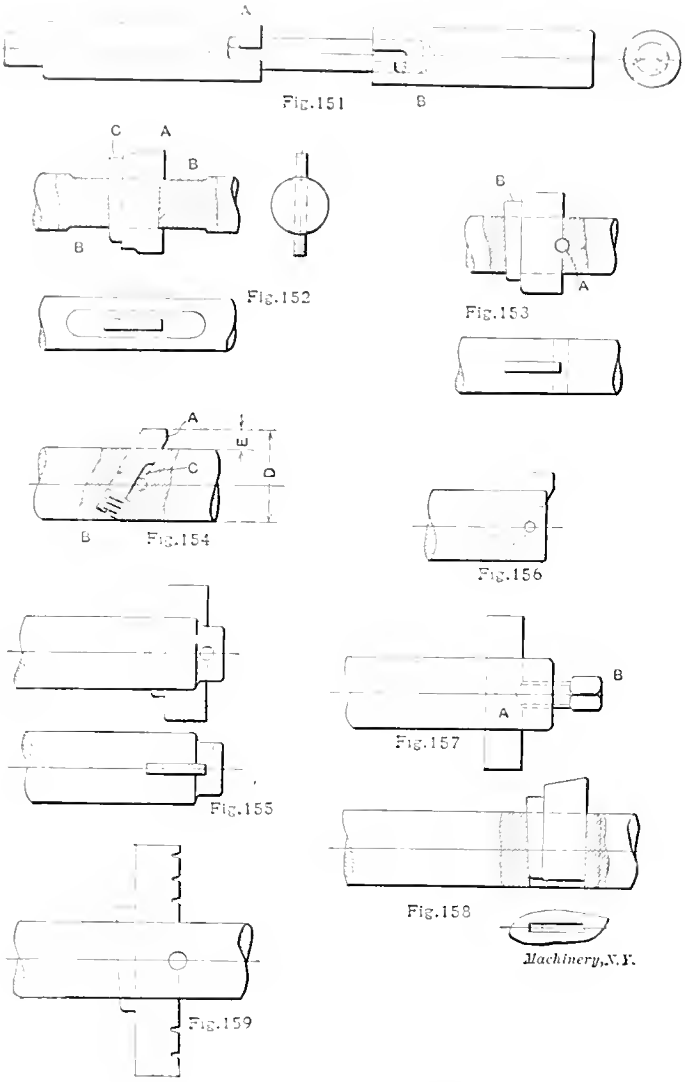


A	B	C	D	E
¾ to 15/16	¼	¾	3/16	¼
1 to 1 ⅜	5/16	¾	3/16	¼
1½ to 2 ⅜	⅜	⅞	¼	¼
2½ to 3	½	1	¼	5/16
3½ and larger	⅝	1¼	5/16	⅜

Facing cutters may be located and held in place in the same way. They are longer than boring cutters, being intended to finish a boss or seat around a hole, but otherwise they are made to about the same dimensions.

Single-ended boring cutters, as shown in Fig. 154, are used to a great extent, and it is claimed that they give a more perfect hole. The illustration shows a common way of securing the tool; the cutter *A*, which is made of drill rod or other round tool steel stock, fits a hole bored at an angle of sixty degrees with the axis of the bar, and is adjusted by the headless set-screw *B*. When adjusted, the cutter is held rigidly in place by the pin *C* provided on one side with a flat tapering portion, which fits against the flatted side of the cutter, as shown in the engraving. This cutter is very easily set by taking a measurement *D* with a

micrometer. Subtract from the dimension *D* the diameter of the bar, thereby obtaining dimension *E*. Now add *E* to *D*, thereby obtaining the diameter of the hole which will be cut. The screw may have to be adjusted a few times, to obtain the desired result. Table XI gives dimension for this kind of cutter, and also for screws and pins used with them. The two kinds of cutters referred to may also be used on the ends of the bars, as shown in Figs. 155 and 156. The cutter of the type shown in Fig. 153 may be held in either of the two ways shown in Fig. 155 and Fig. 157. In the latter case, the cutter is spotted at *A*, and held by a pointed screw *B*. This method, however, does not always insure very accurate results. The simplest kind of single-ended cutter, and the manner in which it is held is shown in Fig. 158. It may be used in any kind of bar, and, with ordinary care, good results may be obtained even with this simple tool. The variations possible are many, and the examples shown simply indicate the most common practice.



Figs. 151-159 Different Types of Cutters and Methods of Fastening.

Facing cutters may be made similar to boring tools, or they may be made with teeth, like end milling cutters, as illustrated in Fig. 161. In this engraving, one of the cutters *A* cuts with both sides, while the cutter *B* cuts with one side only. The bar is provided with a slot and with notches for locating and holding in place the various cutters, as shown at *C*. A pin *D* is driven into the cutter, and enters the notch, thus driving the tool. The cutters can also be held on the bar by taper pins, but the putting in place and the removal of the cutters would then be much slower.

Different cutters are commonly used for roughing and finishing. To make it easier to remove the metal with the roughing cutter, it may be made with every other tooth beveled in opposite directions, as shown in Fig. 160, where *A* is one tooth beveled towards the center, and *B* the next tooth beveled outwards. Using a cutter of this kind will produce a surface as indicated at *C*, which must be faced square by a finishing cutter.

In order to face the work to correct dimensions, stops are sometimes provided which strike against some finished surface on the jig which stands in a given relation to the finished surface on the work and the cutting edge of the facing cutter. Such a stop may be made as shown at *E* in Fig. 161, and be held and located in the same way as the facing cutter. The stops are made of machine steel, case-hardened, and ground on the bearing surface. When facing up a wide surface with an inserted blade facing tool, it is often the practice to cut small notches in the blade, as shown in Fig. 159, the cutting edges on the one end overlapping the notches on the other. Very often the holes to be bored are too large to permit of cutters, such as previously described, being used, and then it is necessary to provide the boring bars with a boring head. A simple boring head is illustrated in Fig. 162, where *A* is the head held on the bar by a taper pin; *B* is a boring tool which fits in a slot in the head, and which can be adjusted out and in by the screw *C*, which passes through the shoe *D*, which also fits the slot, and against which the cutter is located, as illustrated. The cutter and shoe are held by the bolt *E*. The bolt is milled flat on one side so that a hook is formed for binding the cutter and shoe. Two or more cutters may be used in these boring heads. At *F*, in Fig. 162 is shown a facing tool used in the same head as the boring tool. No adjusting shoe is necessary in this case, as the facing cutter bears directly against the bottom of the slot in the head, and against the boring bar, and is held by a bolt *G*, milled with a tapering flat on one side, which wedges the cutter into its seat. More complicated boring heads are provided with a small slide for adjust-

ing the tools, and some are made similar to the box tools used in turret lathes.

The reamers most commonly used in connection with the boring jigs are shell reamers of standard make. Many concerns have been in the habit of making their own shell reamers with inserted blades, designed about as shown in Fig. 163; *A* is a machine steel body, and *B* a tool steel blade, which is made tapered as shown, and driven into place. When the blades are inserted in the body, the reamer is ground. The reamer can be re-ground when dull, and kept to standard size, by forcing up the blades along the taper. The bodies of very large inserted-blade reamers are made of cast iron.

Bushing for Boring Jig.

Lining bushings for boring jigs are made of machine steel, case-hardened and ground, and the loose bushings are often also made of machine steel. They may, however, be made with equal success from cast iron, which wears well, and has less tendency to stick to the steel bar. The bushings for boring jigs may be made with facilities for removal, similar to those described in the May, 1908, installment of this series. In Fig. 164 is shown a bushing having two pins driven into the head, to facilitate removal, and the pin *A* over which the half-round slot in the edge of the head fits, prevents the bushing from turning. Slots, as shown at *B* are sometimes provided to permit cutting tools to pass through.

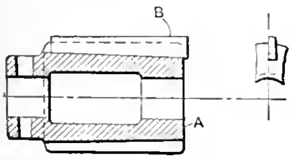

Fig.163

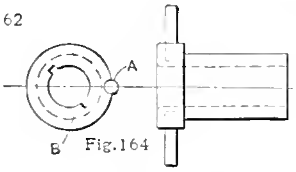

Fig.164

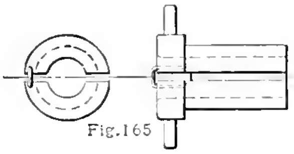

Fig.165

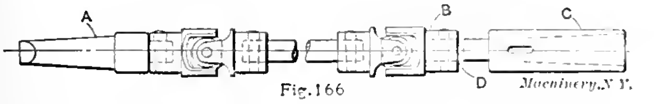

Fig.166

Figs. 160-166. Facing Tools, Boring Heads, Boring Jig Bushings, and Universal Joints for Driving Boring Bars.

In places where it is impossible to put in bushings before the bar is put in, or over the end of the bar after it is put in, a bushing made in two halves can be used, as illustrated in Fig. 165. The writer has seen this kind of a bushing in use in the Pratt & Whitney Co.'s shops, where it probably was originated, and it worked very well. The two halves are held together by a wire passing through the head flanges at one side as indicated. A bushing of this type can be put right over the bar at any place, and pushed into the lining bushing.

Knuckle Joints.

When boring bars are provided with a standard taper shank, this may be put directly into the spindle of the machine, but in that case the jig must be lined up very accurately with the spindle, and this sometimes takes more time than is permissible. It is better to use knuckle or universal joints for connecting the live spindle with the boring bar. These are constructed as indicated in Fig. 166, and are made in different sizes, for the different sized bars for which they are used. The shank *A* fits into the machine spindle. The end of the knuckle joint *B* is provided with a hole *D* into which fits the end of the collet *C*, which, in turn, takes the shank of the boring bar. The hole *D* may also take the end of the boring bars directly. The method of driving the bar from the knuckle joint may be either by a taper pin as shown in Fig. 166, or by the means shown in the engraving in Table XII, where dimensions are given for a coupling of good construction, connecting boring bar and knuckle joint.

* * *

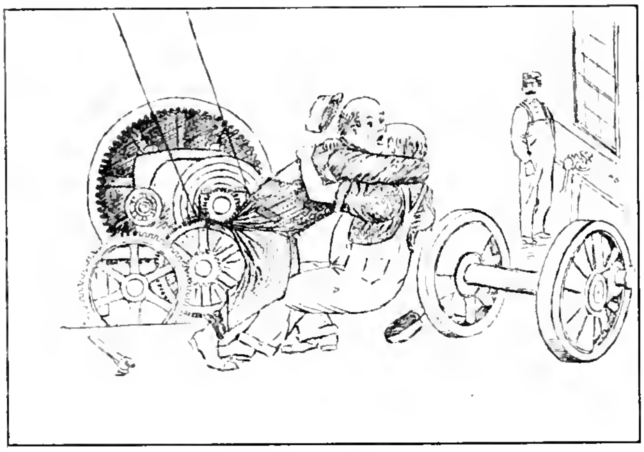
Constant improvements are being made in machines used for aerial navigation. Wilbur Wright, since the breaking of the driving chain of one of his propellers while in flight, has made an arrangement by which both propellers are connected by a chain so that if either of the driving chains should break both propellers will still continue to revolve, and there will be no danger of accident from the gyroscopic action. The superiority of the Wright brothers' machines is attributed by Sir Hiram Maxim, whose pioneer work in aeronautics has attracted wide attention, to the fact that the Wright machine uses two propellers turning in opposite directions, whereas Farman's and Delagrange's machines are equipped with a single propeller run at a very high speed. When these latter machines are turned sideways the gyroscopic action tends to make the machine turn over about a transverse axis. This accounts for the difficulties which these inventors have had in properly navigating in circles and curves. It is reported that the Russian government is negotiating with the Wright brothers for the purchase of some of their aeroplanes. The Russian government requires a three hours test flight, but the inventors consider this unnecessary, as a one-hour test flight would demonstrate the practicability of the machine equally well, provided sufficient fuel was carried for the machine to remain in the air for three hours.

SHOP SCRAPS.

PEACEMAKER

"Scrap" is a very general and common term around the shop, but usually the sense in which it is used makes its meaning clear. Everyone familiar with shop work is more or less familiar with the shop "scrap," as it is commonly called, and can, no doubt, recall instances of such "monkey work," or may even remember of having themselves taken part in one of these star performances. It was, of course, the other fellow's fault, but it is poor business, at best, as experience has proven a great many times. The scrap habit is not prevalent in every shop, but there are some shops in which it is continually prevalent among a certain class of men, when the foreman's back is turned. This foolishness not only takes the time of the parties engaged in the scrap, but it distracts the attention of other workmen, and as a consequence much time is lost, which, as we know, is not to the advantage of the company.

Discipline in a shop usually depends as much on the man in charge as it does on the men themselves. It is not necessary for a foreman or superintendent to knock a man down with a piece of two-inch pipe in order to assert his authority, as I have seen done in a large tube mill. The best disciplined shop that I have ever seen, and in which a shop scrap of any kind was almost unknown, was one in which the "boss" made himself one of the boys, yet he had very little to say except on business. He never tried to appear in the least way above his workmen, and he had always the respect and admiration of every man and boy in the shop.



"Help! Help! Pull, Gus, pull!"

Although shop scraps are not at all necessary, we have them nevertheless, but they do not all come to and end so suddenly or in such Sunday-school story-book fashion as did a shop scrap which recently caused considerable amusement as well as a little excitement. Pat Hagerty, who ran the big driving-wheel lathe, never had much love for his shop neighbor, Gus Goodheinz, since the time he was accused of setting an alarm clock behind Gus when the latter had fallen asleep over his job on the boring-mill. If these men were on speaking terms at all, they were usually engaged in a wordy scrap whenever the foreman's back was turned, and this of course furnished much amusement for some of the boys in the immediate neighborhood. Occasionally Gus or Pat would get an apple core on the head, or possibly a rotten tomato in the back of the neck, which had no other effect than to make the surrounding air blue for a while and to renew the scrap with more vigor than ever. It happened that these scraps had never come to blows as it seemed that Providence had moved in a mysterious way His wonders to perform, and the foreman always put in an appearance just as the boys expected to see one or the other ready for the hospital.

Not only did Gus and Pat differ in opinion as to what a man's nationality should be, but they also disagreed on political matters. Although these men had not been on speaking terms for some time, each had been making sarcastic and slurring remarks within hearing of the other about the chief candidate he was supporting for the fall election. This of course caused considerable ill feeling, but nothing had been said strong enough to cause them to break their long spell of silence until the morning after election. The dark gray dawn of the morning after found Pat in an irritable mood, as he had lost the greater part of his night's sleep watching election returns only to see his hero defeated. On the other hand, Gus was in the best of spirits and was on the job fifteen minutes early with his overalls on, his sleeves rolled up and all ready for business. In order to avoid as much "kidding" as possible, Pat did not care to put in an appearance at the shop that morning until it was absolutely necessary, and entered the shop door just as the whistle blew. Neither looking to the right nor the left, he made a bee-line for his machine, and giving it a few hurried glances to see that things were all right, grabbed the starting lever and threw it over with a bang. Gus, who was standing nearby with a broad smile on his moon face, could hold in no longer. Calling across to Joe on the 10-foot planer, he shouted "Hey, Joe! It 'pears to me that it is about time some of these fellers around here were startin' on their journey up Salt River this mornin' after gettin' walloped the way they did yesterday."

This was too much for Pat, who, of course, overheard the remark. He looked about and the foreman was not in sight. Turning on Gus like a shot out of a gun, he "ripped" off some remarks that would not look well in print, and in an instant Gus's happy smile had faded. There was all indications of a lively scrap as he stepped over in front of Pat at the end of the latter's lathe, but Providence again seemed to interfere and in an instant Pat felt a tug at his rear, and before he realized what was going on, he was being pulled into the gears of his lathe. With a wild and desperate effort he threw his arms about his opponent's neck, and Gus waking up to the situation at the same time, threw his arms about Pat and began pulling like a bull-dog with a death grip, while Pat was yelling at the top of his voice, "Help! Help!! Pull, Gus, pull!!" After a frantic struggle Gus succeeded in pulling his victim from the tenacious grip of the gears in such a condition that he was hardly presentable to the large audience which was rapidly gathering to see what all the noise was about.

It is needless to say that this ended the scrap and that the boys gave Pat the laugh when they had learned the trouble and saw that he was not seriously hurt. Pat, with a sickly grin on his face, was backed up against a post for self-protection, and was so badly scared that he could hardly speak, while Gus in an excited and gesticulating manner was trying to tell the curious crowd how it all came about and how he saved his victim from an "awful death."

Pat was badly in need of a few "glad rags," and would probably have had the disgrace of going home in a barrel had it not been for kind-hearted Gus, who willingly consented to loan his unfortunate neighbor a pair of overalls which he happened to have in his tool-box.

The foreman who was on the scene shortly thought the whole thing a good joke, and when he explained the cause and effect to the superintendent he said he guessed their experience was reprimand enough, and a mild lecture would not only be unnecessary but would be entirely out of place after the practical lesson the boys had had.

That night after work, for the first time in a year, Gus and Pat walked home together. No one has yet learned what was said in the confidential talk that took place that evening, but Pat and Gus are now good friends, and every evening they are seen strolling peacefully home together.

* * *

An example of the effect of superheated steam on cast iron pipe fitting is mentioned in the *Engineering Record.* A twenty-inch tee recently removed from a main steam line in an electric railway plant in Baltimore, which had been in service three years carrying steam of 160 pounds pressure, with a superheat of about 500 degrees F., was found to have grown nearly three-fourths inch in length, and was fully one inch larger in diameter than when installed. The outer surface of the fitting was covered with fine cracks, some of which had opened up in places to one-eighth inch, and steam had begun to leak through the larger of these cracks.

METHOD OF MAKING MASTER TOOLS FOR EYELET SETS.

WARREN E. THOMPSON.*

The manufacture of tools or "sets" used in special machines called "eyeletters" for putting eyelets in shoes, corsets, pocketbooks, and other like products, is, in a way, a business in itself, as special machines and fixtures, as well as men who are specialists, are required. The method is one of the master tool methods of making forming tools and manufacturing tools that may be duplicated at any time. The processes described may be applied to the making of formed cutters by designing machines for the work embodying some of the principles shown.

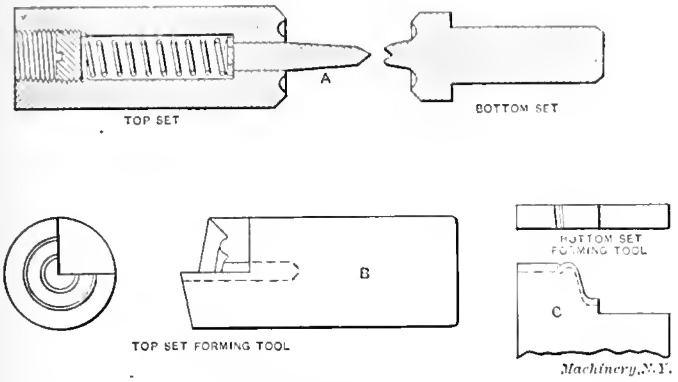


Fig. 1. Tools or Sets for Round Eyelets, and Forming Tools by which they are Formed.

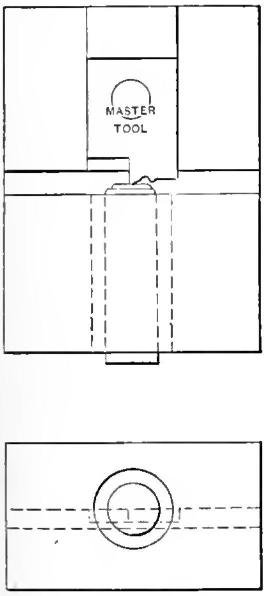
Eyelets are made by special machinery in an endless variety of sizes and styles. The round eyelet is the most common and the oval is used to a much smaller extent, but enough to make it important as far as the manufacture of the tools is concerned.

Stock used for Sets.

Tool steel drill rod is used in most cases to make all sets except the oval bottom set; drill rod is used because it needs no sizing and stands severe usage. The oval bottom sets are made of both tool and low carbon steel; 35-point carbon steel, pack-hardened in new bone, is used to the largest extent, as the dies are not damaged or worn as fast as when using tool steel, and the sets thus made have given satisfaction wherever used. All stock is cut off and finished on the screw machine, ready to have the end formed.



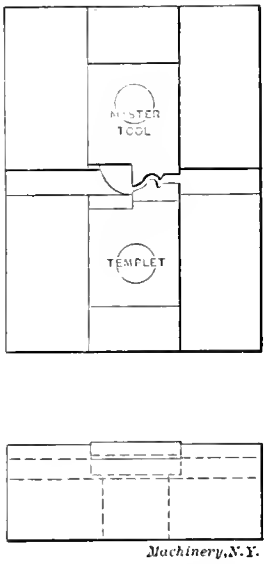


Fig. 2. Filing Jig for Templets and Master Tools, with Arbor for Holding the Eyelet. Fig. 3. Filing Jig for Master Tools.

Master Tools for Round Sets.

In Fig. 1, *A* is a section of a pair of sets for rolling the round eyelet. The top set is threaded at the back end to take a spring tension screw and to hold it in the machine. The pilot is made a few thousandths larger than the inside of the eyelet on its largest diameter; this enables it to take an eyelet from the raceway used on the eyeletter and hold it until the work is slipped into position. When the machine is in operation, the spring pilot is pushed back into the set and on the return leaves the work on the bottom set. Both sets must be made to conform to the eyelet used, and a slight change from the forms found correct will produce defective work.

Usually the tool-maker is furnished with a number of eyelets from which it is easy to select one that is perfect. This eyelet is mounted in an arbor as shown in Fig. 2. If necessary, beeswax may be used to hold it firmly in place, but in all cases the eyelet must be central with the arbor. This arbor fits a jig as shown, and its axis is exactly central with the slot or groove guiding the tool. The tool is then filed, as shown, to fit the head of the eyelet. This fit is made as close as possible, using a double eye glass to test with. The tool is then hardened and the face ground smooth, after which the form is stoned if necessary to a fine fit on the eyelet.

Often the top set for an eyelet is furnished to the tool-maker, and in this case a templet is made first. The same jig is used, and the templet made a perfect fit to the set. Templet stock of the same thickness as the tool stock should be kept at hand. It is milled away so as to leave only 1/32 inch to file.

The master tool for the bottom set is filed in a jig, Fig. 2, in the same way as the top set. The making of the first bottom set requires considerable experience. A blank is prepared and turned to what is judged to be about the correct form. It is then tested in a bench machine and the roll it makes on the eyelet is noted. The form is corrected until a perfect roll is obtained, and the master set is then hardened and polished.

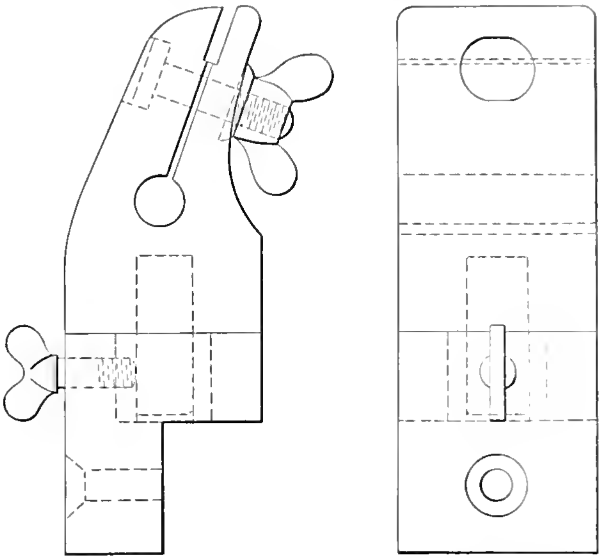

Fig. 4. Vise for Holding Templets and Master Tools when Filing.

In case a templet for the top set has been made, the jig shown in Fig. 3 is used to produce a master tool. This jig is simply a block of steel having two slots or grooves in line and in such relation to each other that the bottom of the top slot is about 0.005 inch below the face of a tool in the lower slot. The tool is filed and stoned to a perfect fit, and a tool having the same contour as the required set is thus produced. All tools are drilled in a plain jig with a standard hole.

The bench fixture or vise, Fig. 4, is provided for the convenience of the tool-maker when filing. It is made of hard wood and swivels in any position on a steel rod which is driven into the vise, and which rolls in a steel bushing having a thumb-screw for locking purposes.

Circular Forming Tools.

A top set forming tool is illustrated in Fig. 1, at *B*. The stock for these tools is first cut off and milled and a small hole drilled in the front end. The machine for making the tools is shown in Fig. 5. This machine consists of a cast

---

* Address: 39 High St., Lynn, Mass.

iron base planed and bored to take a tool slide and spindle. A spring chuck with draw-bar is fitted into the spindle, and a cam is held to it by screws. This cam is held against its mate by the spring shown, and the hand wheel is keyed and held by a lock nut. The cam used has a rise of 5/32 inch.

The tool in the tool slide is quickly adjusted by loosening a lock nut, and is then slowly fed into the work by the feed screw. The tool set in position has its face in a line with the axis of the spindle, and hence produces a form exactly the same as that of the eyelet. The first circular tool produced with each master is used to produce another circular tool of the same contour as the master, and this circular master is then used to produce all manufacturing tools. A cam having a throw of 3/32 inch is used in the duplication of the master in another machine of the same type.

Flat Forming Tools.

On account of the teat on the bottom set and the consequent difficulties encountered in making circular tools, flat tools are used. These tools are planed in the machine illustrated by Fig. 6. This machine has a cast iron base planed and bored to take two tool slides and the spindle. The spindle carries two cams, one of which operates the planing head and the other the tool relief. The tool slots are in alignment and the stationary tool is moved by the feed screw. The ram has a uniform downward motion for three-quarters of a revolution, and the other quarter returns it to the starting point. The two cams are so arranged that the tools are separated just before the return and are in position again before the down-stroke commences. The tools have 20 degrees end clearance and 4 degrees side clearance and the slots are planed at these angles.

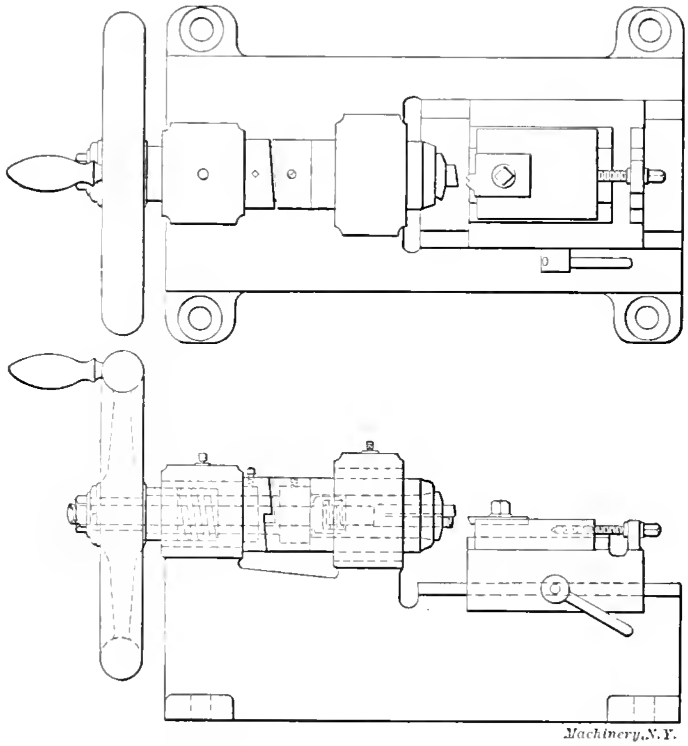

Fig. 5. Machine for Making Circular Tools Formed on the End.

The master tool previously fitted to the set is bolted to the ram, and a blank, roughed near to shape, bolted into the carrier. After the form is planed smooth all over, it is hardened and stoned. This tool is then used as a master for making the manufacturing tools, the first master being used but once, except in case of breakage.

The master tools should be kept in covered trays carefully separated, as the slightest nick or imperfection on the cutting edge destroys their value. The manufacturing tools are used in small bench lathes in special holders.

Oval Sets.

Oval sets, on account of their shape, are much more expensive to make than the round ones, and it requires considerable experience to construct the tools properly.

Oval top and bottom sets are shown in Fig. 7. As the oval eyelets do not break as evenly as the round eyelets when rolling, the bottom set has six or eight cutting edges in the form. These sets are stamped under a 100-pound drop hammer. The top sets have the form milled and the pilot hole broached.

The machine illustrated in Fig. 9 is used for making all of the plain oval forms in the top sets, trial bottom sets, "hubs," and other trial tools. It consists of a cast iron bed planed to take two slides, one for the cutter bushing carrier and the other for the work and feed mechanism. The work is driven by a worm and worm-wheel, and its position is regulated by a cam working on a roll set into the bed. This cam is held against the roll by a helical spring. The position of the cutter guiding bushing may be regulated by the set-screws shown, and its position determines the size of the oval form produced. The cutter is held in a drill press.

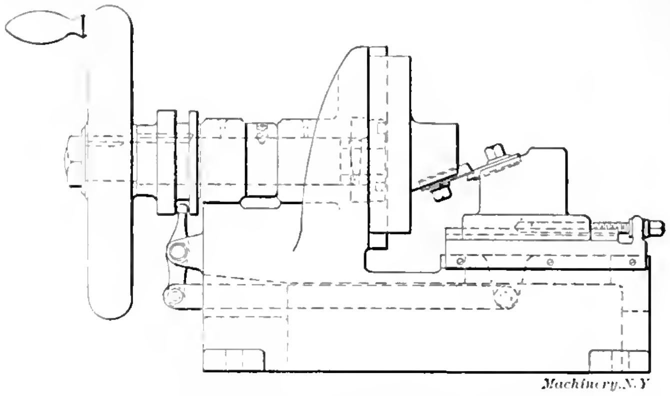

Fig. 6. Machine for Planing Flat Formed Tools.

Oval Master Dies.

A cam is first made of the same outline as the eyelet. This is placed in the machine and a cutter of about the correct form for the bottom set put in the drill press. A trial set is then milled and tested, using the device in Fig. 9. The cutter and setting of the bushing is corrected until a satisfactory set is produced. A piece of tool steel is now put in the machine and milled. It is of the same form as the trial set, and is hardened. This piece is called a "hub," and is used to produce a master form. The teat of the hub is made 1/16 inch longer than the set to provide clearance in the die. The ends of the stamped sets are finished after stamping.

The master form is made of $1\frac{1}{4}$ inch tool steel. This is held in a block by set-screws and the block is held in the stamp with the master blank aligned with the center of the "hub" holder. After setting, the master blank is heated to a good red heat on the formed end. It is then quickly clamped in a fixture and struck one good blow with the hub. This is usually sufficient to get a perfect impression, but in cases where it is not, the master has 1/64 inch turned from the face and is struck another blow cold. This impression must now be polished and the requisite number of grooves cut in it to form the splitting edges on the set. The divisions are made with dividers, as accurately as possible, and the cuts made with fine files. The master is then hardened and polished. Another hub is struck from this master and the manufacturing dies made from this hub.

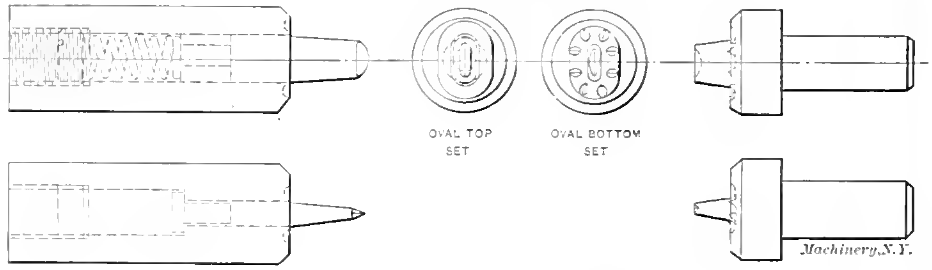

Fig. 7. Top and Bottom Set for Oval Eyelets

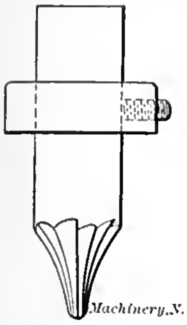
The fixture shown at Fig. 10 is used in stamping the sets. The rack and pinion are made 8 pitch with a long hand lever for operating. The hole and counterbore are ground and afterward lapped large on the top end. The die is held in a cast iron body by large case-hardened taper pins. Plenty of oil is used when stamping as this prevents excessive sticking of the set after stamping.



Machinery,N.Y.

Fig. 8. Cover for Oval Eyelet Tools.

A cutter for use in making a hub is shown at Fig. 8. The cutter for blanks to go under the stamp is made nearly flat at the point.

Oval Top Sets.

The jig shown in Fig. 11 is used for making the oval pilot holes. The work is held between V-blocks, one of which is movable in the leaf and tightened on the work by a screw. Three bushings are used, one with an eccentric hole, one central, and one for the broaches. The holes are first drilled with the eccentric bushing guided by the keys in opposite slots in the bushing head. The center is then cut out with a small end mill using the concentric bushing. The hole is then broached with the broach shown, using oil. After the hole is finished, the groove is milled in the machine Fig. 9. The depth of the groove is governed by the collar on the cutter. The spring pilots are turned and milled close to size and file finished.

The sets, after hardening, are polished with a lap running at high speed, using fine emery. A templet is made for every correct cutter for purposes of duplication. All tools should be stamped with the necessary data regarding their use and purpose.

* * *

A painting by Max Lievermann pictures a group of peasant spinners at work and incidentally shows one of the great fundamental differences between a primitive people and American and other peoples that have risen to commanding positions in the industrial world. It appears that the type of spinning wheel shown requires two people to operate it—one to turn the wheel and the other to spin. Our American grandmothers were not so prodigal with labor, their wheels being so made that the spinner both drove the wheel and did the spinning. The uneconomical use of labor is a trait which distinguishes a primitive, unprogressive race from people who, through economical use of labor, increase and develop productive capacity. If two persons are required to spin, it is only by unceasing labor for weeks that the family is able to produce clothing enough to clothe it for a year, because the other members must produce food to support the spinners while at work. The American spinning wheel, driven by one person, was only one step in the great advance that we have made in productive capacity. The prodigality of the primitive people in the employment of labor means everlasting poverty, while on the other hand, the increase of productive capacity through the development of modern machinery means that wealth is constantly accumulated, inasmuch as each worker produces much more than he consumes. In the primitive life the family is barely able to produce what the members require for a poor living, with all members of the family working who are able. Such a people will never develop a commerce of importance, neither will literature, art, or the other evidences of civilization become highly developed.

NOTES ON THE ECONOMICAL WORKING OF THE BLACKSMITH SHOP.*

JAMES CRAN †

In [illegible] machinery for the blacksmith shop, a practical blacksmith who has had experience on the class of work for which the machines are intended, should be consulted, so that the equipment selected would be in proportion to the work to be done. It is not uncommon to find blacksmith shops equipped with hammers out of proportion to the work to be done, either too small or too large. In either case, it is evident that the working of the blacksmith shop is uneconomical. It is poor economy, in equipping a blacksmith shop, to provide it with too few steam hammers in proportion to the number of forges, as it requires the smiths to wait for their turn, and the time thus wasted will in the long run be worth a great deal more than the interest on the original investment in one or more additional steam hammers. Not only is this waiting for the use of tools uneconomical in regard to the time wasted, but the steel is, in many cases, injured by having to wait too long in the fire after it is hot enough for working. If steel is thus left in the fire, it may get a pitty and rough appearance when the forging is completed, and in the case of tool steel, the surface will be decarbonized to a certain extent, and the tool will not give as good service when used for a cutting tool.

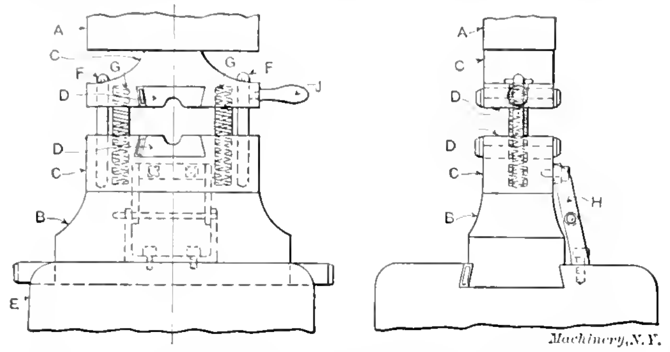

Fig. 1. Special Dies used for Economical Forging in the Steam Hammer.

The economy of the blacksmith shop is also largely affected by the condition of the material supplied to the shop. If the blacksmith shop is supplied with material in long bars, these can be cut into the right lengths for the required forgings, and there will not be any waste, excepting, perhaps a small piece on the end of each bar. If, on the other hand, the material is supplied to the smith in short lengths or in odd pieces, there will most likely be a small portion of each of these pieces wasted, and weight for weight, a great deal more material will apparently be used for completing the same number of forgings, when using short stock than when using long bars.

It should not be forgotten that in most cases forging to shape is cheaper than machining to shape. Since high-speed steel became commonly used, the forging of spindles and similar work has been largely done away with, except in cases where large collars are formed on the spindle, for the reason that, using high-speed steel tools, the excess material can be removed so quickly that it is supposed to be simpler to turn these parts directly from the bar. However, even when using high-speed steel tools, it is seldom that work of this character can be machined from the bar as quickly and economically as it can be forged to the approximate shape, providing the blacksmith shop equipment is up to date. Not only is there a great deal of material wasted when turning off a large amount from the bar in order to form a shoulder or a collar, but the wear and tear on the machines where the work is performed and the time consumed outbalance, in many cases, the cost of rough-forging. Often a single blow from a steam hammer, when an inexpensive former or die is used, will do more to put the piece of iron or steel in the approximate shape required than could be done by an hour of machining.

If the blacksmith shop equipment is adapted to carrying out the forging of more or less complicated shapes, the scrap pile can generally be turned to good use, and considerable economy can be exercised in the use of new stock. Old pieces of machinery, which may be useless for the purpose for which they were originally made, may still contain good material, which can be used to make other forgings, of smaller dimensions, and may even save considerable work in the re-working as compared with the use of new stock. Lathe and planer tools, when too short for service, are quite often consigned to the scrap pile, when they could just as well be turned over to the blacksmith to be drawn down to smaller sizes and used for smaller work. Even the smallest sizes of tools, when worn down too short, can be drawn out and used in toolholders or for boring bar cutters. Considering that high-speed steel costs anywhere from 60 to 80 cents a pound, and that a blacksmith can draw down to smaller sizes from 150 pounds to 300 pounds in a day, this would indicate a considerable saving in the steel tools. Of course, the scrap is always worth money, but the difference between the price of scrap and of new steel is too great to permit disregarding economy of this kind.

In order to help increase the efficiency, and to improve the quality and reduce the cost of work done in shops that are provided with only one steam hammer, the writer designed the steam hammer attachment shown in Fig. 1, which can be used for drop forging, swaging, forming collars, etc. This tool can also be fitted with shear jaws and used for cutting up material for forgings; or punches and dies can be fitted to it, and the tool used as a punch press. Being attached to the die chair of the hammer with jointed straps *H*, it can be used without removing the ordinary plain dies which can be used at any time by folding the attachment back in the open space between the hammer frame and the dies. This attachment can be used for all purposes that spring swages and other spring tools are used for, and will do superior work, because its being attached to the hammer prevents it from wobbling around while being used, as spring tools do. In making quantities of duplicate forgings, the attachment is a decided advantage over ordinary methods, both in the amount and quality of the work done. The blacksmiths' helper, not being required around the hammer to hold tools, can devote the most of his time to heating and handing the hot pieces to the smith. Should another smith want to use the hammer while the attachment is in position it can be folded back out of the way until he has worked his heat, and be placed in position again immediately after he has left the hammer. In the device shown, *A* represents the top die and *B* the lower die of the hammer. The parts *C* are holders for the dies *D*; *E* is the die chair, and at *F* are shown guide pins keeping the holders *C* in alignment. The springs *G* hold the dies open when no pressure is applied on the top, and *J* is a handle by which the attachment can be turned back out of the way when the plain dies are to be used.

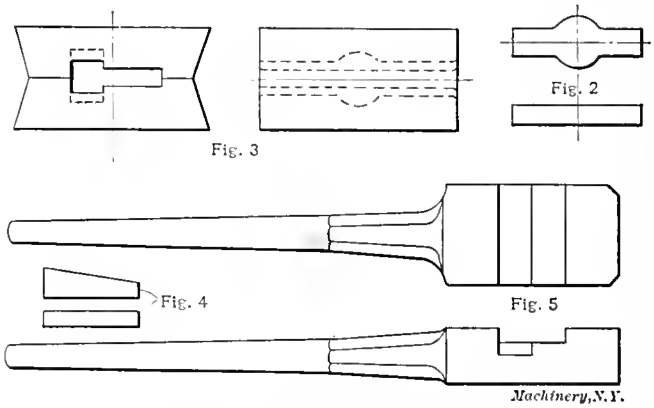

Fig. 2 Fig. 3 Fig. 4 Fig. 5

Figs. 2 to 5. Examples of Blacksmith Work and Simple Tools for Same.

The die holders *C* can be made either from steel castings or forged from machine steel. The lower dies *D* should be made from steel from 0.60 to 0.75 carbon and hardened. If the attachment is made so that the spiral springs *G* will keep the dies a couple of inches apart, a jet of compressed air or a small pipe connected with the air supply from the blower could be used to keep the impressions of the dies free from scale and would improve the appearance of the forgings.

---

* For previous articles on this subject, see "Welding," December, 1908, and articles there referred to.

† Address: 916 W. Third St., Plainfield, N. J.

Forgings of the style shown in Fig. 2 can be made in open dies, as shown in Fig. 3, which do not form any flash or fin, the only parts which need trimming being the ends of the forgings. The impressions are made wider than the forgings they are to shape, so that when a blow is struck by the hammer, the metal has room to spread. One impression shapes the forging edgewise, and the other brings it to the right thickness. When work of this kind is changed from one impression to the other at each alternate blow of the hammer, it can be completed in a very short time, and very close to size.

For forgings of the kind shown in Fig. 4 only one die or tool, as shown in Fig. 5, is necessary, the top die of the hammer being all that is required to form the top side of the forging.

The simple tools shown are used as examples to indicate how work can be done economically in the blacksmith shop. The economy of the blacksmith shop depends largely upon the tools and the general equipment, but, of course, it is also required that the tools be handled intelligently, and the economical working depends in the last instance upon the class of men employed. Any department in the shop, and not least the blacksmith shop, requires men who understand how to use the appliances furnished to the best advantage. It is a mistake to think that the cheapest help procurable is good enough for the blacksmith shop. On the contrary, the economical working of the blacksmith shop requires the very best class of men.

* * *

ARBORS FOR HOLDING WORK IN THE MILLING MACHINE.

A.

The arbors regularly used in milling machines for holding work between centers are invariably too long for certain classes of work, or in other words, they permit of too many pieces being held between the collar at one end and the nut on the other. The longer the arbor, the more it will spring when the nut on the end is tightened, and when under the pressure of the cut. No matter how true each separate piece placed on the arbor may be, if several of them are put together, they will invariably be "out of true," and the amount of "out of true" will increase with the number of pieces held. This spring in the arbors is very serious in some cases, especially when the pieces milled are to be finish-turned or ground after milling.

An example which may be cited is that of screw slotting cutters. The teeth are generally very fine and of very shallow depth. Suppose that a number of these had been milled on an arbor which springs out of true when the cutters are tightened in place. When we now come to grind the outside of these cutters true with the hole, we will find that when the teeth are properly ground on one side, they are almost entirely ground away on the other side, or, in other words, the width of the land on the one side is out of all proportion to the width of the land on the other side, as shown exaggerated in Fig. 1. In this illustration the dimension *A* indicates the diameter of the blank, turned true before milling. *B* shows the condition of the cutter after having been milled on the arbor sprung out of true. As it is milled so that the top of the teeth present a sharp edge, the teeth will all appear of the same depth, but the cutter runs out of true a dimension equal to *E*. When grinding the cutter true with the hole after hardening, the lowest teeth are, of course, just cleared as shown at *G*, getting the proper shape, but on the other side an amount equal to the amount that the saw runs out must be ground away, leaving hardly any teeth at all, as shown at *H*. The loss in diameter, equal to two times the amount *E*, which the cutter runs out in the first place, should also be noted.

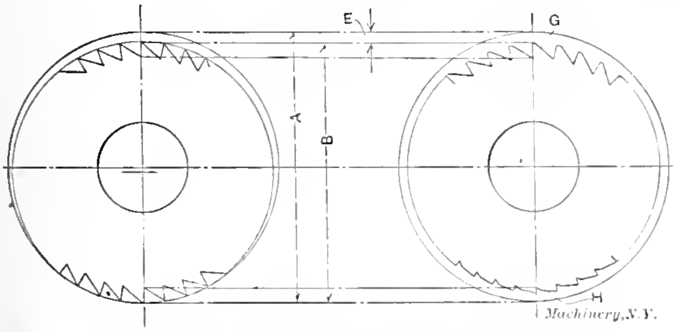

Fig. 1. Effect of Milling Screw Slotting Cutters on Arbors which are sprung out of true, owing to Excessive Length.

In order to avoid the difficulties mentioned arbors should be made rather short and stiff. The accompanying table gives well proportioned arbors for accurate work. These arbors may be considered too short, where work simply "good enough" is produced, but for the purpose for which they are intended, they will be found superior to arbors of ordinary length. On the other hand, the length has been made great enough, so as to answer all reasonable practical manufacturing requirements. They are more especially designed for turning and milling screw slotting cutters. This will account for the large diameter of the collar or shoulder *B*, at the end of the arbor, as well as the large diameter of the collar on the nut. These diameters are, of course, arbitrarily selected, and may be made to suit any requirements, but screw slotting cutters, being very thin, require all the support that can be provided sidewise. These arbors should be made of tool steel, hardened, and ground as indicated in the illustration accompanying the table. The nuts may be properly made of machine steel, casehardened, and ground on the face coming next to the work.

* * *

In a consular report, Consul Albert Halstead of Birmingham, refers to the primitive methods of chain manufacture still in vogue in the so-called "black district" in England. The chains are forged by individuals in or at their own homes. Those engaged in the trade are not organized in any unions, but each works for himself individually. They purchase iron rods of the required size, from the iron merchants, bring them home on a wheelbarrow or carry them home on their shoulders; and on a little forge at the back of the house, the links of the chains are made from these rods. The forged chain is then carried, thrown across the shoulders, to the merchants, who pay for it by weight. The makers of the chains are entirely at the mercy of these middle-men merchants. The tools used in making the chain are not many. The chain is made wholly by hammer and without finishing tools. Of course, the chain is not high grade, the links vary in shape, the weld is apt to be imperfect, and the chain is not tested. Small-sized chain from 3/16 to 1 inch in diameter is made chiefly by women, girls and boys, and by old men whose vigor is so much lessened that they are unable to do the heavier work. The women working on chain making earn from thirty to forty per cent of what the men earn making the same sizes. In some cases, the percentage is as low as twenty-five per cent.

THE NEW YORK CENTRAL LINES APPRENTICESHIP SYSTEM.

It is gratifying to note that the leading railroads of the country have realized the necessity of apprentice systems in the railroad shops. The New York Central Lines have a well-organized system for educating apprentices, and in an address before the Pittsburg Railroad Club, the superintendent of the apprentice school of this road, Mr. C. W. Cross, gave an interesting account of the results obtained, and the effect of the training of apprentices in the company's shops.

The one most noticeable from the installation of the new apprentice system has been the increased efficiency of the apprentices. This is largely due to the addition of the shop instructor, although the benefit of the class-room work is also apparent. Under the old system the foreman was expected to see that the boys received proper instruction concerning their work, and that they performed it properly. Ordinarily the foreman is too busy to give the boy anything like the required amount of attention. With the addition of the shop instructor, who has the duty of looking after the boys, the efficiency of the apprentice has very greatly increased, with a resulting improvement both in the amount of output and the quality of the work done. There is no question but that the work accomplished by the shop instructors has more than paid for their salaries. The shop foremen, relieved of the care of the boys, can give their time to the more important details of the work. Reports from the ten shops where apprentice schools have been established show that in every case the boys are not only turning out a better grade of work than ever before, but that they are working on machines, or doing bench work, that formerly it was not thought possible to entrust to apprentice boys.

Another important advance is that the apprentice, after he has had a few months of class-room instruction, can read simple working drawings, and the third and fourth year apprentices are able to read the most difficult drawings. When one stops to consider the comparatively small number of so-called mechanics in the average railway shop who can read working drawings readily, and the necessity of being able to do this, its importance can be realized. Not only this, but the boys are able to make sketches, or drawings, of shop devices or of broken parts, which it is oftentimes advisable to have for record at the local shop or for transmission to the mechanical engineer's office. During the past year the apprentices of the New York Central Lines made 1,344 drawings, which have been placed in the files of the New York Central Lines drawing rooms for use and record.

The criticism may be made that this work will unfit the boys for remaining in the shop. A certain percentage of the boys will, of course, wish to be transferred to the drawing room, but anyone who is familiar with the difficulty of securing satisfactory draftsmen for a railroad drafting room, who have had the necessary shop experience to handle the work required of them to advantage, will realize that it is very desirable to have a few of the boys graduate from the shop to the drawing room.

It is often desirable to conduct tests of tools or devices, or to determine the efficiency of various kinds of machines or other apparatus. The training which the boys have received in the class room has enabled a number of them to be used to great advantage during the past year in assisting on or conducting such tests. The benefit to the apprentice and the company is mutual. Another effect of the new system is the better discipline over the boys and the effect which this has had on the shop as a whole. At several of the shops the boys have organized apprentice or debating clubs. It is the practice to prepare papers on different topics and to discuss them. The class-room training helps the boys to take part in these meetings and has been the means of developing them to a considerable extent.

At several shops where it was formerly hard to obtain enough apprentices or to get a good grade of boys, little difficulty is now experienced, as the boys are assured of being given a thorough training in the trade and of having greater opportunities of advancement than formerly. It has been the practice for apprentices to occasionally make visits to neighboring shops of other roads or to some of the other shops on the system. Several of the boys obtained ideas which they put into use at once. One boy who was working on a boring mill changed to the method of fastening the tires on the table to correspond to the method he had seen at Schenectady. He did this without waiting for definite directions from the instructor, and soon found that he was able to gain one tire in his day's work. The impression made on the minds of the boys by observing the methods of experienced workmen prove much more lasting than when these same methods are explained ever so clearly by their instructors. It is a paying proposition to the company to allow either boys or men to visit other shops where work of a similar kind is being carried on. The boys, after the above-mentioned trips, were asked to write letters to the shop foreman as to their observations and what they had learned. These demonstrated the benefits which were gained.

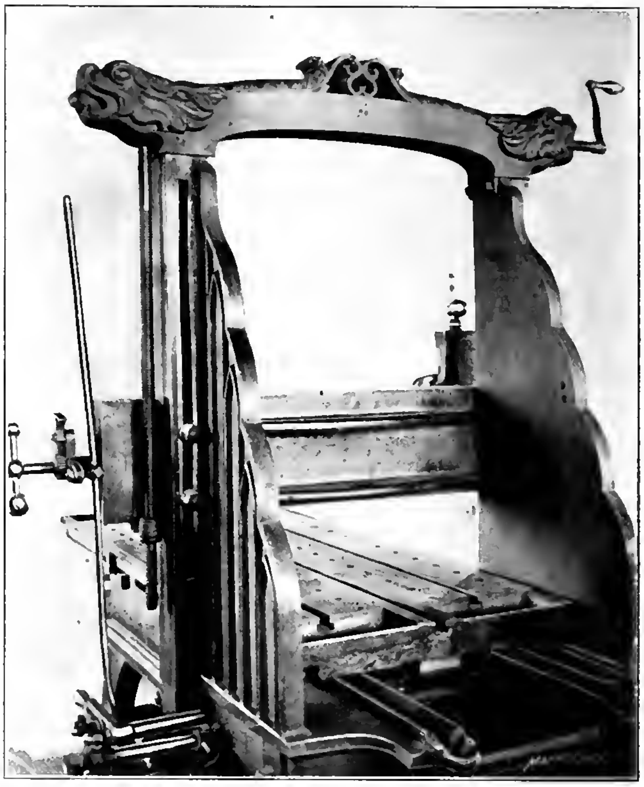
PLANER WITH ELABORATE ORNAMENTATION.

H. P. FAIRFIELD.

Highly ornamented machinery has, of course, gone out of style, but at one time there must have been considerable rivalry between the builders of machines, as to who could get out the most artistic machine patterns. The accompanying illustration, which shows an old planer that has been in service since about 1855 and is yet a "planer," is an excellent example of the vast amount of unnecessary artistic pattern work formerly done by some machine tool builders. As will be seen, the ornamentation of the sides of the housings is after the pointed or Gothic style of architecture, while the ends of the elaborately carved tie-piece across the top, represent gargoyles. This planer was built by the Thayer-Houghton Co. of Worcester, Mass., afterward the New York Engine Co.



Example of Artistic Pattern Work as practiced in the Early Days of the Machine Tool Industry.

* * *

The utilization of the water power available in Switzerland has now been placed under the direct supervision of the state, which will take the necessary steps to safe-guard the interests of the public. The transmission to foreign countries of power generated in Switzerland is subject to the approval of the state, and the royalties will be paid by private users of water power, to the Government. This development is one more step towards the recognition of the right of the whole people to natural resources exploited by private enterprise.

ITEMS OF MECHANICAL INTEREST.

INTERESTING FEATURES OF AN ELECTRIC COAL-PUNCHER.

One of the difficulties encountered in producing an electric coal-puncher, except in the solenoid types, has been in the conversion of the rotation of the motor into reciprocating motion for the drill. Where the blow is directly dependent on the motor, the latter gives trouble because it is not able to stand the vibrations and strains incident to the powerful blow of the pick, and if springs play an important part in obtaining this blow, there are other troubles because of breakage and unreliability. Types with separate motors and flexible shaft connections have also been tried in order to obviate some of these difficulties, but complications were introduced which at least partially off-set the benefits derived. A reciprocating drill or coal-puncher is made by the Pnuemelectric Machine Co., Syracuse, N. Y., which uses both compressed air and electricity. The latter is the actuating power and the compressed air gives the blow. As the connection between the driving motor and the striking pick is not a rigid one, the vibrations are cushioned. The mechanical means by which the rotation of the motor armature is changed to a reciprocating motion to drive the air compressing piston, and the way in which a single air cylinder, with practically no valves, compresses the air which impels the pick-carrying piston, will be explained in the following:

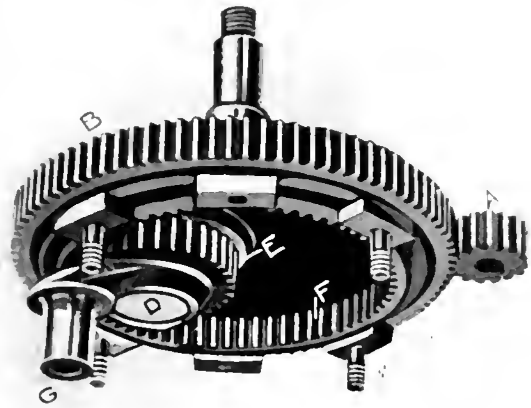


Fig. 1. General View of the Mechanism illustrated in Fig 3.

The small pinion *A* (Fig. 1) is attached to the shaft of the motor armature, and engages the main driving gear *B*, which has a solid web carrying the stud *D*, which, in turn, carries a crank pinion *E* having 33 teeth. Internal gear *F* (Figs. 1 and 3), which is rigidly fastened to the frame of the machine, is concentric with the main driving gear *B*, and the crank pinion *E* engages with this gear as shown in the illustrations. The pitch diameter of this crank pinion is just one-half that of the internal gear which has 66 teeth. The crank-pin *G* which is attached to the pinion *E* engages with the cross-head *H* to which the rear piston-rod *I* (see Figs. 2 and 3) is attached. When the main driving gear *B* is revolved by the armature pinion, the crank pinion stud *D* describes a circle in the direction indicated by the arrow, and the pinion *E* revolves on the stud and around the internal gear. When the pin *D* has moved one-quarter of a revolution, it will be in the position shown at *b*, and the pin *G*, attached to the cross-head *H*, will be in the center of the internal gear. At the completion of one-half a revolution, the pin *G* will have moved rectilinearly a distance equal to the pitch diameter of the internal gear and will be in the position shown at *c*. Similarly, at three-quarters of a revolution, the pin will be again in the center of the internal gear as shown at *d*, and at the completion of a full revolution, it will be at the point of starting as at *a*. In this way the crank pinion, as it revolves around the internal gear, gives the pin and attached cross-head *H* a rectilinear forward and backward movement.

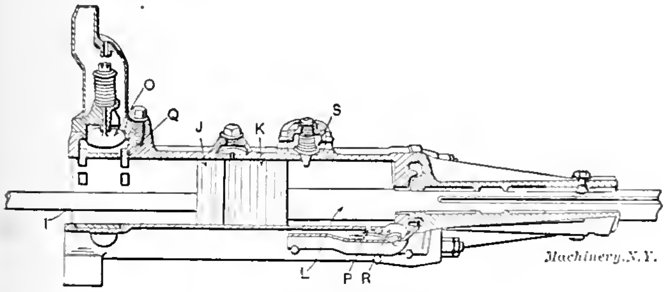

Fig. 2. Air Cylinder in which the Air is compressed and used to impel the Pick-carrying Piston.

The way in which the air is compressed and utilized to impel the pick-carrying piston forward, all in one cylinder, constitutes the most interesting and novel feature of the machine. Fig. 2 shows the cylinder, front head, and the two pistons and rods. The rear piston *J* is attached to the cross-head *H* in Fig. 3. The front piston *K* has no connection with *J*, but it is connected with the drill or pick socket by the rod *L*. The first stroke of the pick is purely mechanical. The rear piston *J* moves forward, pushing the front piston *K*. During this stroke, air is drawn into the cylinder behind the piston *J*, through the main inlet valve *O*. On the return stroke, this air is compressed and at the same time the front piston *K* is drawn back by the partial vacuum created by the piston *J*, air being admitted in front of *K* through a port *P*. When the return stroke is completed, the rear piston has passed the by-pass opening *Q* in the cylinder, which opening is between the two pistons at the time. This allows the compressed air to force the front piston forward, exactly as in any compressed air drill. In this way the first real stroke of the machine is made; that is, the mechanical stroke mentioned above is made only once or when starting from rest. On the forward stroke of the piston *K* the air in front escapes through the port *P*, but after the piston has passed and therefore closed this port, a sufficient amount of air remains to cushion the blow and prevent damage to the front cylinder head. This cushion air may leak somewhat, and to prevent an insufficient supply remaining which would have the effect of creating a partial vacuum in this space and holding the piston on the return stroke, a small inlet valve *R* is placed in the forward part of the cylinder. This allows air to flow in under these conditions before the open port is passed. When the front piston *K* has made its forward stroke, the rear piston follows, mechanically driven as before, and would compress the air which has just made the stroke of the front piston, were it not for the so-called vacuum valve *S*, which allows all air between the pistons above a certain pressure to escape to the atmosphere. The action of this prevents the two piston faces from coming together.

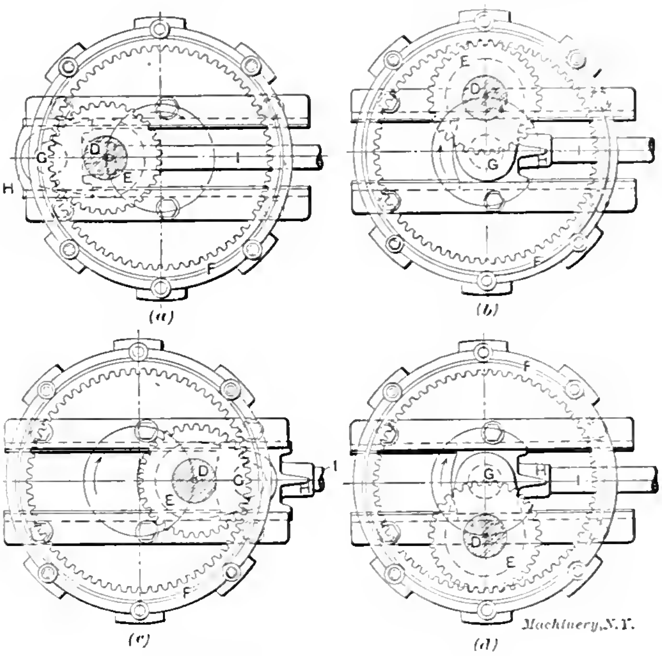

Fig. 3. Method of changing the Rotary Motion of the Motor to a Reciprocating Movement.

Entered at the Post Office in New York City as Second-Class Mail Matter.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

MARCH, 1909.

PAID CIRCULATION FOR FEBRUARY, 1909, 21,037 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

SOME DEFECTS IN OUR TARIFF REGULATIONS.

The practical workings of some of the tariff regulations applying to the return of American machinery to this country for repairs, and the importation of gages, samples and other parts which are of no value to the American manufacturer except for purposes of measurement and comparison, were brought out at the recent hearings before the Committee on Ways-and-Means.

The Gisholt Machine Co. of Madison, Wisconsin, in a communication to the committee, stated that it received from a foreign customer a number of gages which were to be used for testing the tools being made for him, on which he had placed a value of $450, doubtless for insurance purposes. These gages, of course, were of no value to the Gisholt Machine Co. and it refused to pay the $200 duty demanded by the Custom House, as there was no possibility of the amount being refunded when the gages were returned to the owner, and the Gisholt Co. preferred to take its chances on getting the standards correct from drawings furnished by the customer. Another well-known tool builder, in a letter to MACHINERY, calls attention to a Custom House regulation, of a peculiarly aggravating character, applying to the return of broken parts sent for repairs. Our correspondent states that if a machine is broken in transit abroad, and the buyer asks to have the part repaired, the American manufacturer cannot have the broken parts returned to him without paying 45 per cent duty on them, although they are necessarily a part of the original machine and are of no value until the repairs are made. Another manufacturer also calls attention to the custom of charging duty on gages and tools, referred to by the Gisholt Machine Co., stating that he was obliged to pay $25 on a reamer sent by a foreign customer for finishing certain holes to the required standard. The reamer was of no use to any one except the owner, as it could only be used for finishing certain holes on special machines to an odd shape and size, and, consequently, it was returned with the shipment.

In the general revision of the tariff which is now taking place, the attention of our law makers should be called to unnecessary and irritating regulations of this character, which serve no purpose except to delay and increase the cost of repairs and construction of machines for foreign shipment.

* * *

WHEN A TRUST MADE GOOD.

We have all been taught that the unwieldy organization and the enormous capitalization prevents the average trust from manufacturing as cheaply as can a concern having all its activities directed by one concentrated management. We are prone to believe that trusts are bad, and that their capitalization of wind and water places a burden on labor and on the public out of all proportion to the benefits derived. Granted that these statements are true, in general, there is nevertheless another side to the shield, surprising in aspect in one case at least.

Some years ago an important manufacturing industry was "trustified," with the exception of one large concern having an annual productive capacity nearly equal to all the plants that went into the trust. The capitalization of the latter consisted of the usual amount of water, while that of its competitor represented actual values. For a number of years both the trust and the independent concern did a big business, but the common belief was that the trust would not make as good a showing as the single plant when hard times came. The independent plant is highly concentrated and organized in an old-fashioned way, while the trust comprises a large number of individual plants scattered over the eastern part of the United States; the equipment of many of which *was* very indifferent. However, the men responsible for results early in the game began a reorganization which utilized the great improvements in machine tools, methods, and steels, that have been developed in recent years; and the trust is producing machines today with a labor cost of approximately two-thirds that of the independent concern, being able to build machines for $1,000 apiece less than its competitor, and still make a good profit.

It is needless to say that the independent company referred to is a horrible example of misapplied methods. New machines, new steels, handling appliances, etc., are used; but the plant as a whole has not been reorganized systematically, nor the advanced modern methods made an integral part thereof. Present day improvements have been grafted onto old methods in a way that has resulted in no marked increase of productive capacity per unit of labor employed, and the modern engineering ideas which have been usually so potent a force in cost reduction have not been advantageously employed by the independent concern.

This seems to be a case where the necessity for earning dividends on watered stock has resulted in reducing the cost of a product to the user; but it should be understood that the machines referred to are not protected by patents and that the industry is one that cannot be monopolized.

* * *

As has been previously stated in these columns, the new British Patents Act requires that all patents granted in Great Britain be worked in that country. If they are not worked in Great Britain, the patents may be revoked upon application of parties who would themselves enter upon the manufacturing of the patented products. Ten applications for revocation of patents have so far been filed with the Patent Office, and two revocations have already resulted. These, of course, are subject to appeal before the courts. It appears that a great many manufacturers of patented articles both in the United States and on the European continent do not intend to manufacture their goods in the United Kingdom, but will depend upon their manufacturing facilities in the home countries to make it possible for them to compete with English manufacturers who would eventually take up the manufacture of their goods in Great Britain. Except in some special instances, it is evident that the British manufacturer who undertakes to manufacture foreign patented articles would place himself in an untenable position, because he would have to depend upon the British home market entirely for his sales; it would not be possible for him to obtain any foreign markets as long as the article is patented in other countries.

A CHANGE IN RED TAPE DESIRABLE.

Our reference last month to the lack of mechanical experience which frequently impairs the purchasing agent's value, is emphasized by a recent letter from a mechanic employed in one of the government departments, in which he speaks in strong terms of the difficulty of turning out work with the files supplied by Uncle Sam, which he says are "crooked, warped, not cut to edges, corners or ends. They glaze over, and in many cases are re-cut files, some of them having broken tangs. No doubt they are files rejected by the maker's inspector, but are good enough to unload on Uncle Sam."

A certain amount of departmental red tap is always necessary in connection with government purchases; but why not let it be applied by the operating instead of the purchasing department, in the case of small tools as well as large ones? If all bids for small tools were accompanied by samples to be tested, and the contracts awarded with due regard to quality as well as price, the government would undoubtedly be the gainer, and the industry represented would be benefited instead of being injured by the award of contracts to the lowest bidder for the lowest quality of goods; for that is what it virtually amounts to in many cases when the purchasing agent has absolute control.

* * *

A PROFIT SHARING EXPERIMENT.

In the December number, engineering edition, we referred to the interesting offer to employes of the Middletown Shipbuilding Yard, England, made by Sir Christopher Furness of that company. The company sustained heavy losses during the past year, largely due to labor troubles, and Sir Christopher offered the men preferred stock, payable in installments of 5 per cent of their wages, to be deducted weekly; these shares carrying a fixed interest rate of 4 per cent, and to participate equally with the common stock in a pro rata distribution of any surplus profits over 5 per cent for the common. The various trade unions concerned have agreed to the arrangement, which is to be given a year's trial before final determination.

This proposition has been described as a profit sharing scheme, which is hardly accurate. The men pay full value for their stock, in weekly installments, receiving only 4 per cent on their investment until, as stated, the regular stockholders are paid 5 per cent. As a matter of fact, they share in the profits as the investors or shareholders in any company share in its dividends. Nevertheless, this arrangement will benefit the men indirectly, as it benefits the firm directly. Each employe will now have a stockholder's interest in the welfare of the enterprise with his desire for profits undiminished by losses incurred in labor disputes. This should ensure peace to the company and greater permanency of employment to its employes; and the habit of saving to which the men are committed under this arrangement will be of permanent benefit to a great many, who will learn, perhaps for the first time, that a small amount regularly laid by provides in due time a substantial savings account. The exercise of self-control and self-denial, the building up of character, the cultivation of thrifty habits in the individual are possibilities of the greatest importance inherent in this English experiment. It is necessary to regard the proposition from this point of view in order to appreciate it, for as a case of actual sharing in the profits resulting from their own productiveness, the proposition is rather weak from the standpoint of the worker.

* * *

THAT INDUSTRIAL DEMOCRACY.

Referring to the editorial in the January issue of MACHINERY, entitled "An Industrial Democracy," the writer feels prompted to say that not everyone who has studied industrial conditions in Germany agrees with Captain Carden as to the competition of Germany with America in the manufacture of machine tools. "The man behind the gun" is not here. Both general and industrial education here, compared with that in America, bear the same relation to each other that the savage's ceremonial suit of a silk hat and a breech-clout does to a "derby" and a plain business suit. The superior education of the employers and managers is here; but the workman is repressed industrially and socially; he has no inducement, no opportunity to come forward. Few or none start at the ash-pit and reach the manager's office.

The writer's first visit to Germany was in 1878-9; and since then, while the percentage of improvement in methods and finish is greater here than in America, because the basis of calculation is smaller, the actual progress in America is much greater; and at the present percentage rate of progress in the two cases it will take more than one generation before the two nations come together. Since January, 1894, the writer has lived, with the exception of one year in America and one in France, continuously in Germany; and has been uninterruptedly in communication with German engineers and manufacturers; has visited considerably more shops than the average American has, reorganized some, and ordered work from several; to say nothing of countless orders from individual workmen:—carpenters, locksmiths, model makers, blacksmiths, tinsmiths, plumbers, masons, etc. With the exception of about twenty shops, where the work is done on American machines, or on German imitations or modifications thereof, the German establishment is not on a level with ours in design or execution. In many of these twenty there are American or English foremen, or German foremen instructed by them. In one of the three very best German shops the leading spirit spent months in an American shop and brought back American machines as models. The work is now good enough, and original enough, for anybody; but after bringing over one special American machine he was obliged to send over for the foremen of the Philadelphia shop that built it, before he could make it work, after which he built others like it. What is considered the model German machine shop in amount, range, and quality of work, was built after an expert had visited over sixty American shops and culled the best features from each; and at first it had seven American foremen.

As regards the average German workman who is not a machine-tender—he has too many thumbs. The writer has never seen so much inexact work as is turned out by him. Captain Carden evidently never stepped into a German hardware store and compared, piece by piece, American and German tools, locks, etc.

Where Germany has the advantage of America is, among other points: 1. In low wages. 2. In granting long time on sales. Try to sell a machine tool in Germany under three months, in Austria under six, in Russia under twelve, and see "where you are at." Germans do it on the long-time basis. 3. In government ownership of railways, etc., shutting out American and other foreign competition in the matter of locomotives, cars, rails, etc. 4. In the difference of the banking institutions. Here the banks, as such, are directly stock-holders in machine shops, and indirectly interested in other manufacturing establishments; so that the latter get good credits from the banks, conditional on their buying their machinery, etc., from the bank-owned shops. These banks have branches in foreign countries, making collections more sure, and also discounting notes on condition of purchases being made where they indicate. 5. In short hauls of freight. 6. In an immense fleet of merchant vessels, sailing directly to all important foreign ports. 7. In reduced railway freights on exported goods. 8. In the love of work, as such, inherent in the German. 9. In the knowledge and use of foreign languages and business methods, enabling direct dealing with many nations. 10. In the willingness to make what the customer demands, instead of what the manufacturer thinks he ought to call for. 11. In the use of the metric system, enabling him to work in the standards of a great part of his customers, without extra trouble and expense. 12. In the neglect of Americans to patent their inventions in Germany. The writer has been offered, for example, "Trimo" wrenches bearing either the name of the German manufacturer, or the customer's, or the American trade-mark. Further willingness to oblige would be superfluous. 13. In packing goods decently for export. 14. In the absolute necessity to get trade abroad. The German is in the condition of the boy who was digging in a bank for a gopher. "Think you'll get him?" asked a passer-by. "Git 'im? Bound to git 'im. We're out o' meat!"

X.

NOTES AND COMMENT.

A consular report from Germany states that the Siemens-Schuckert Electrical Company contemplates the erection of a separate plant for the manufacturing of airships and aeroplanes.

It has been stated officially by President McCrea that the Manhattan terminal of the Pennsylvania Railroad will be able to handle traffic by May 1, 1909, and that one thousand trains a day will then be taken care of. The tubes under the rivers are practically finished with the exception of track-laying.

According to a German source the number of locomotives provided with superheaters in October, 1908, was 3,455. The Prussian State railways lead in the use of superheated steam locomotives, there being 1,789 locomotives of this type in use or in process of construction on the Prussian government railroads.

One of the speakers at the recent Conference on Natural Resources stated that the total power at present produced by prime movers in the United States is nearly 30,000,000 horse-power, of which 26,000,000 horse-power is produced by steam engines, 3,000,000 horse-power by water motors, and 800,000 horse-power by gas and oil engines.

The subway and elevated lines of the Interborough Rapid Transit Co., New York City, on Monday, December 21, carried 1,800,000 passengers, which is about 200,000 more than the maximum number for a single day last year. There was a slight diminution in the traffic on the Elevated lines for 1908, but in the Subway the volume of traffic increased 30 per cent.

A section 6,110 feet long of Boston's subway system was opened November 23. This section together with that previously constructed makes a total of 20,196 feet or nearly four miles. The section just completed cost $10,000,000 with its approaches and equipment, and has been leased to the Boston Elevated Railway Co. for a term of twenty-five years.

In a report made by Senator Flint of California to the National Conservation Commission it was stated that half the natural gas now coming out of the earth, equal to about 1,000,000,000 cubic feet per day, or more than enough to light all the cities of the United States having more than 100,000 population, is wasted by being allowed to escape into the atmosphere.

Prof. Charnock in a lecture, "Invention as a Science," delivered before the Bradford Technical College, England, called attention to the interesting difference between men and animals as regards mechanical instinct. Animals have no rotative movement, the very essential for mechanism. The fact that man can turn a crank and thus produce a rotary motion may be one reason for his ability to conceive and build mechanism.

The report of the Bureau of Railway Statistics states that the gross earnings for the fiscal year ending June 30, 1908, decreased $139,000,000. The gross earnings were $2,450,000,000 or $10,652 per mile, as against $11,383 a mile for the previous year. The operating expenses for 1908 will approximate $1,729,000,000 which is about $20,000,000 below those of 1907, so that the official returns for the year show a loss of $120,000,000 in net earnings, as compared with 1907.

The number of patents applied for in Great Britain decreased somewhat during 1908, as compared with the figures for 1907. This is ascribed to the fact that the new British Patent Act has discouraged foreign inventors from patenting their inventions in Great Britain, if they be not in a position to manufacture in that country. Of the patents issued, 1,100 relate to gas engines, between 800 and 900 to bicycles, 800 to the automobile industries, and 350 to aerial navigation. The total number of inventors was 3,586, of which 40 were women. It is a curious fact that a patent obtained by a woman, related to the cyanide process of treating ores, and apparatus for this purpose.

A subway system for transporting the mails between the various post-offices is to be established in Berlin. Two lines are projected, one of which will form a belt line in the central part of the city and will connect the main post-offices with the principal railroad stations. The second line will run between the various offices. The subways will be of small section, only 6 feet wide and 3 feet high, double tracked, the traffic being maintained by small electric cars run by an automatic system without a motorman. Between the two tracks in the subway there will be a depression which will serve as a footpath for those who need to pass through the tunnel for inspection and repair purposes. The speed of the cars will be twenty-five miles an hour.

The galvanized wire suspender ropes which are to support the main span of the new Manhattan bridge, were recently tested under the direction of the bridge department of the city of New York at the works of John A. Roebling's Sons Co., where these ropes were made. The suspended span will be attached to the ropes, which are 1¾ inch in diameter, by means of steel castings socketed to the rope ends and threaded on the outside for 5¼ inch nuts. Three pieces of the rope were broken during the test, and in each instance the socket proved stronger than the ropes, which broke at 287,000, 288,600, and 290,000 pounds respectively. The greatest load to which one of the suspender ropes can be subjected is 50,000 pounds, so there is a factor of safety of over 5 for the suspenders and sockets.

In more than one instance in American railroad history can be found records of fatal wrecks caused by the burning of a bridge in a wild or lonely district where such a conflagration would rarely be discovered in time. The Canadian Pacific Railroad has provided against the possibility of such accidents by the adoption of automatic alarms designed to stop trains in case a bridge should burn. Semaphore signals are fixed about 3,500 feet from the bridges, each way, and at each signal is attached a wire which runs to a pulley on the bridge. These wires are connected with a rope which extends beneath the bridge for its entire length. The semaphore arms are heavily weighted so that if the rope should part, as would be the case if the bridge should burn or be destroyed by a flood, the signals would fly to the danger position.

The development of the underground rapid transit system of London has been very rapid. There is in that city, at the present time, eightly miles of subway built like the rapid transit system in New York, just below the street surface, and in addition to this, there is about one hundred miles of underground tube railways which are built at a depth of from 50 to 180 feet under the surface. During the rush hours, trains are run in some of these underground railways at an interval of a minute and a half; in the New York subway, due to the fact of impractical construction of the cars, it is not possible to run trains at closer intervals than about two minutes. As regards the handling of the passenger traffic with rapidity on both urban and regular railroads, there is no question but that England sets a pace well worth following.

A bulletin on comparative tests of briquetted and ordinary coal on locomotives has recently been issued by the Technologic Branch of the United States Geological Survey. The results of the test are summarized in the following conclusions: The evaporation per pound of fuel is greater for briquetted coal than for the same coal in its natural state; the capacity of the boiler is increased by the use of briquetted coal; briquettes have little effect in reducing the quantity of cinders and sparks, but the calorific value of these is not as high in the briquettes as in the natural fuel; the density of smoke is much less than with natural coal; the expense of briquetting, under the conditions of the experiments, added about $1 per ton to the present price of the fuel, an amount which does not seem to be warranted by the resulting increase in evaporative efficiency. In terminals, however, the briquettes can be used to considerably decrease the amount of smoke.

The Forest Service of the United States Department of Agriculture has of late issued several statements regarding the waste of our lumber resources, and it has appeared from many of them as if the lumber supply of the country could not possibly be expected in the future to meet the demand. Recently, however, a report has been issued on the present condition of the country's forest resources which indicates that, under proper management, our forests may be made to yield all the lumber required in our industries and trades, and that still the forests cover one-fourth of the area of the whole country. Methods of saving, which are, in particular, emphasized are the reduction of waste in the woods during lumbering, and in the mills, preventative treatment of wood exposed to water and dampness, steps for preventing forest fires, and especially proper legislative enactments, looking towards continual replanting of the forests.

In a recent issue of the *Iron Trade Review*, some applications of vanadium steel are indicated. It is stated that locomotive springs have been made from this material with excellent results. In ship-building work, the duty of the riveting dies of pneumatic hammers is very severe, and the average life of such dies is only about ten hours. Expensive brands of steel were tried by the New York Ship Building Co., but the results were not satisfactory until vanadium steel was used. The first cost of this steel was not only less, but it is inferred from the article mentioned that the dies can be used for months without breakage. It is also mentioned that in the yards of the same company, three hundred sleeves entering in the design of certain pneumatic machines had been broken in two or three months. In March, 1908, vanadium steel sleeves were adopted, and no breakages have since occurred.

In the *Zentralblatt der Bauverwaltung* an interesting reference is made to the wear of bridge pins. An early German pin-connected railway bridge, built in 1863, was taken apart recently for the purpose of replacing it with a bridge of larger capacity. The bridge was of the Pratt truss construction, 102-foot span, and 12 feet 7 inches depth of truss at center. The pins were two inches in diameter and made of carbon steel. They were measured at the center of the seat in the chord eye-bars, and the wear was found to be surprisingly small; only three pins in the entire bridge showed greater wear than 0.004 inch, and in the three cases where the wear was greater than this, it did not exceed 0.040. This is a good indication of the permanency of a steel bridge properly designed and erected and constructed of good material. Being still in good shape, this bridge will be re-erected as a foot-bridge.

The Cunard liner *Mauretania* has recently undergone extensive repairs, and the propellers have been re-arranged, so that it is expected to be able to increase the speed at least one-half knot, and at the same time reduce the vibration of the vessel. The change consists in fitting four-bladed solid propellers, each weighing 18 tons, to the two forward shafts, while the propellers on the two after shafts still retain three blades. What it means to overhaul a large ocean vessel may perhaps be best understood by reference to the fact that the *Mauretania* was in dry dock for about nine weeks, during which time nearly 2,000 men were employed in the work of overhauling and repairing the ship. The damaged shaft, which was broken some time ago during a trip across the ocean, has been renewed, and the forward port bracket—a forging weighing twenty-six tons—has been replaced. It is stated that the cost of this work amounted to $250,000, a rather large sum considering that the vessel is practically only one year old.

It is stated in the *Scientific American* that the question of supplying ties for American railroads has become so serious that the Santa Fé system recently sent its manager of the timber and tie department to Europe and the Orient to make a study of conditions. Among other things learned during this trip of investigation, was the fact that the Japanese government began to conserve its forests three hundred years ago, and that as a result of this foresight, Japan is now in a position to sell ties to railroads in this country. There is a duty of 20 per cent of the value on ties imported to the United States. The working of the higher political mind is certainly wonderful; on the one hand there is an outcry about the excessive use of our forests, and on the other hand an attempt is made to prevent the importation of lumber from other countries by a restrictive tariff, although such importation undoubtedly would tend to save some of the timber supply in this country.

At the structural shops of Milliken Bros., Inc., on Staten Island, New York City, in the latter part of December, 1908, 143 tons of plates were punched in one day (8 hours, 47 minutes) on one machine. The plates were 13-inch flange plates for girders, ⅝ inch and 11/16 inch thick, and averaged about 32 feet in length. The average number of 15/16-inch holes was about 96 to each plate, staggered except at the ends. There were three sizes of plates and varieties of spacing; 52 of one kind, 168 of the second and 96 of the third. The total length of plate handled was 10,036 feet; weight 285,850 pounds, and total number of holes 30,384. This work was done on a multiple punch, four plates being passed through at a time. A few days previous to this, one man punched 12,740 9/16-inch holes, one at a time, in 10 hours. This was on light transmission line tower angles, on a light single stroke, quick-acting punch. These performances are believed to be records in the line of rapid punching in the bridge shop.

"There are other ways of killing a cat besides choking it to death with butter," and the conventional drill press and twist drill of the machine shop are not the only "pebbles on the beach" when it comes to the matter of putting a hole through iron. The Western plainsman uses his Winchester to perforate the wagon tire for a new bolt hole, and the blacksmith heats it and drives a punch through with three or four vigorous blows with his hammer. The boiler-maker scorns a ratchet and drill when he needs to set a stud in a boiler shell—if he is in a hurry. A hammer, cape chisel and drift in his hands are made to perforate a ⅜-inch shell and produce a smooth round hole in the time that a machinist would take to set up an "old man" and ratchet drill. The up-to-date engineer might use the oxy-acetylene torch if he had to perforate an armor plate quickly and without annealing. There are other ways too but none perhaps quite as novel as that proposed in the *Youth's Companion*: "Shape a stick of sulphur to the required dimensions of the hole, then heat the iron white-hot at the place where it is to be bored, and press the sulphur against it: sulphuret of iron is formed, and the stick passes through the metal."

Several times we have alluded in this column to the importance of the moving picture industry in America and Europe. Not only is it important as an amusement enterprise but it is acquiring much educational value and undoubtedly will become a very useful factor for improving industrial education as well as imparting general knowledge of processes difficult to describe without the visual expression. As a matter of amusement, for example, the people in Northern cities are acquainted with the life and local color of Southern cities, and *vice versa*. One series of pictures shown to a Northern audience recently illustrates the gathering, preparation and marketing of cotton. The field hands are shown on the scene gathering the snowy white product from the dark green plants. Then follows the loading of the cotton onto wagons, its transfer to the cotton gins and pressing into bales. From the gin the transfer to the wharves and loading into steamers follows, and then the scene changes to the cotton mill, the picking, carding, spinning, winding and weaving machines being illustrated in full operation. Thus in an interval of, say, fifteen minutes, an audience of ordinary individuals is shown as much and is taught as much of the cotton industry as an individual might acquire in a week or two of traveling—and all for the sum of five cents.

MODERN SWEDISH MACHINE TOOLS.

OSKAR KYLIN *

In the writer's letter from Sweden in the September, 1908, issue of MACHINERY, reference was made to some of the more prominent Swedish machine tool works, and a general review given of the present state of the machine tool industry in that country. It is the writer's intention in the present article to describe and show a few representative types of modern Swedish machine tool design.

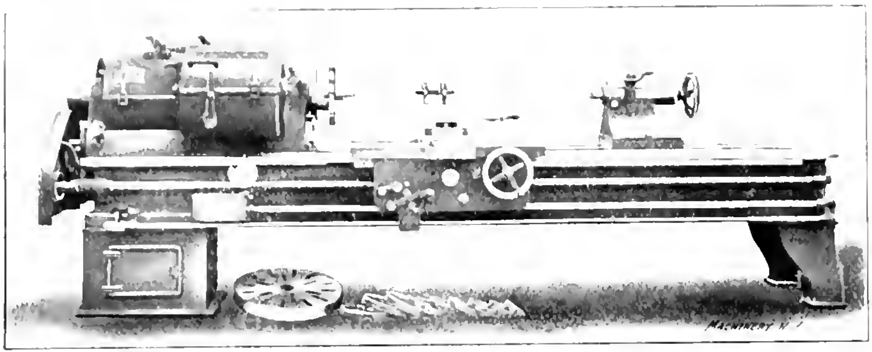

Fig. 1. Geared-head Lathe built by Lidkopings Mekaniska Verkstad, Lidkoping, Sweden.

Figs. 1, 2, and 4 illustrate machines designed and manufactured by Aktiebolaget Lidköpings Mekaniska Verkstad, Lidköping. This firm has been established for more than thirty years, but did not take up the building of machine tools until about ten years ago; at the present time, however, the works specialize on a general line of machine tools, lathes being the most prominent feature.

In Fig. 1 is shown a twenty-four-inch geared-head lathe manufactured by this company. The design is along powerful lines, in order to permit advantage to be taken of the full capacity of high-speed steel. The single pulley geared head-stock is designed with twelve spindle speeds, the largest change gears being placed on the front side in order to obtain a steady drive. The bed is made according to the American practice with V-slides, the shape of the slides thus differing from the common German practice which employs perfectly flat ways. The power feed of the machine is friction driven and the lead-screw together with its driving gears is running only when the lathe is used for thread cutting. The power feed is stopped, reversed and varied in amount by means of a knob conveniently placed for the operator. The action of the lead-screw is controlled by means of a handle placed on the apron, and a quick return is provided for the carriage when cutting screws, which saves considerable time when cutting long threads. The feed rack, as well as all gearing in the apron, is made of steel.

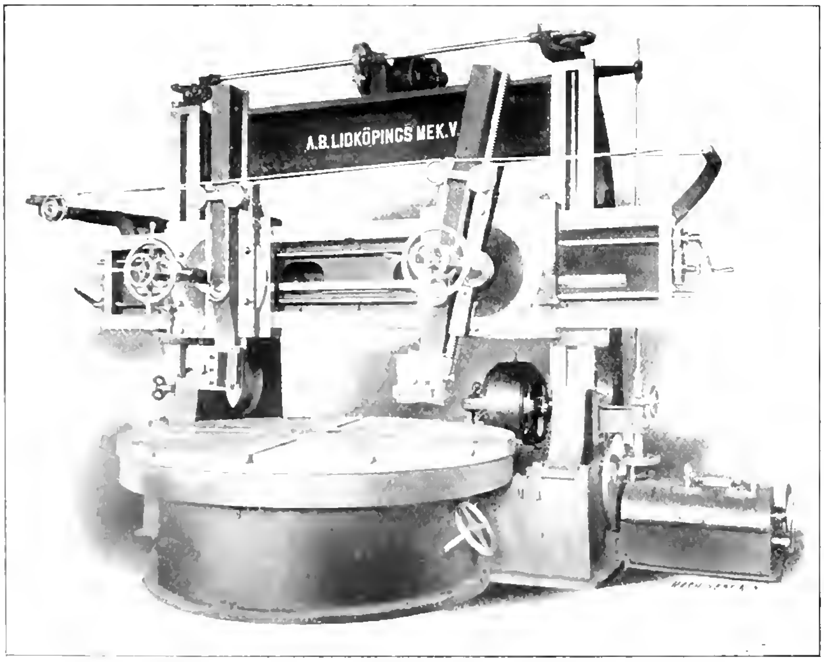

Fig. 2. Vertical Turning and Boring Mill of Swedish Manufacture.

A motor-driven vertical turning and boring mill of neat design is shown in Fig. 2. This machine is provided with a speed-changing mechanism furnishing sixteen changes of speed for the revolving table, and controlled by conveniently placed levers. The feed is friction driven, as shown on the right side of the machine and changes in feed can be made without stopping. The cross-rail of the machine is raised and lowered by means of an independent motor placed on the top of the machine as shown in the engraving. The vertical slides are balanced according to modern practice with two independent counterweights and can be set at any angle with the cross-rail required. The tool-holders are of special interest, as they permit of very accurate adjustment. They can be swiveled around a stud in the center, and have also a longitudinal slide adjustment. The machine is of very powerful design, intended to be able to stand heavy strains, and practically all gears are made of steel. This machine is also provided with cone pulley belt drive when required. In this case the cross-rail is operated from an independent counter-shaft and pulleys are placed on the top of the machine where now a motor is located.

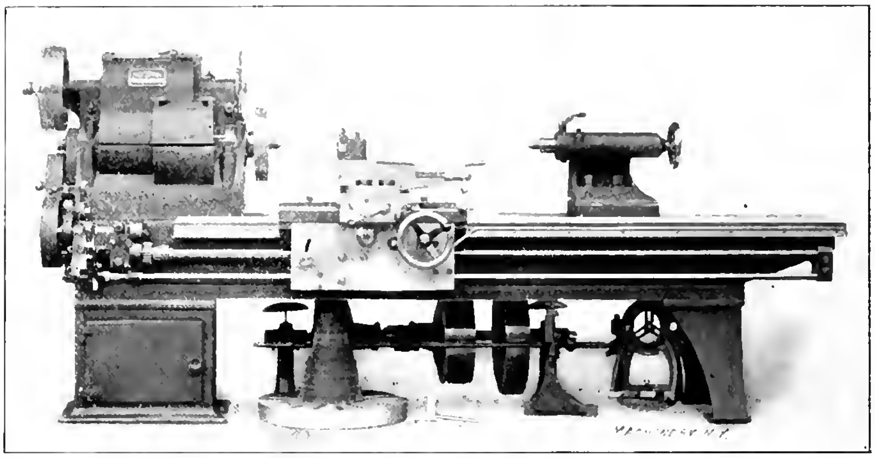

Fig. 3. Geared-head Lathe built by Kopings Mekaniska Verkstad, Koping, Sweden.

In Fig. 4 is shown a high-speed radial drill built by the same company. This machine is provided with a single pulley drive and a gear box; ten spindle speeds are obtained partly by changes in the speed box and partly by the back gearing in the spindle head. As indicated by the arrangement of the pulleys in the illustration, the power is transferred from the gear box to the spindle by means of belts. The drill spindle can be swung to any angle within an arc of slightly more than one-hundred-eighty degrees, and the auxiliary table shown mounted on the main part of the machine can be tilted to angular positions for drilling holes at angles with the base of the work.

Figs. 3 and 5 to 9 illustrate a number of machines built by Köpings Mekaniska Verkstad, Köping, the foremost machine tool building firm in Sweden. The reputation of this firm is due fully as much to the high class of workmanship exhibited in its machines as to the modern and up-to-date design. It may be said in general as regards design of Swedish machine

---

* Address: Hornsgatan 45, Stockholm, Sweden.

tools that they do not embody all the special labor-saving features of American machines, which may be of great importance in certain special lines of manufacture, but which are often of small value for general lines of work; and the aim sought by leading Swedish firms is to design machine tools without too many complicated features, making them easy to operate and of a rigid design and good workmanship. Köpings Mekaniska Verkstad is largely specializing in the lathe line, but as will be seen in the accompanying illustrations, the firm is also making several other kinds of machine tools mainly in order to keep fully employed even when the demand in the lathe business is less heavy.

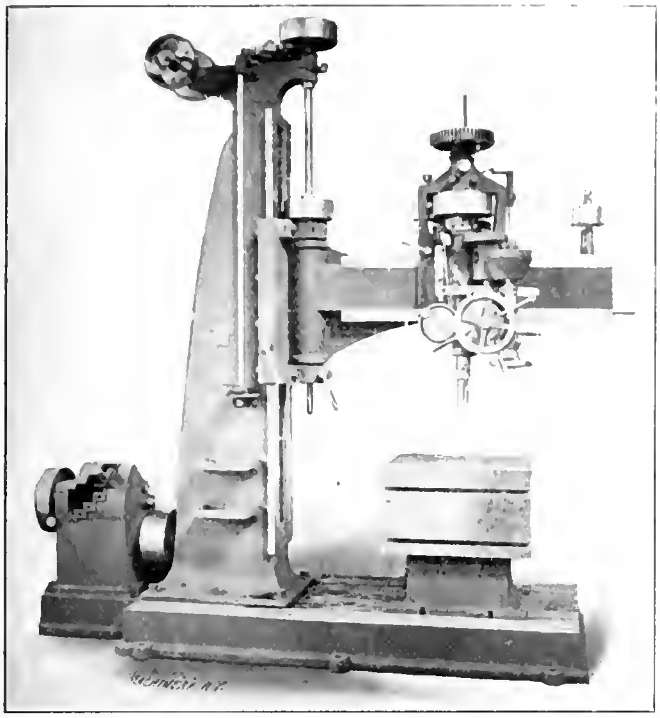

Fig. 4. Lidkoping High-speed Radial Drill.

Fig. 3 shows a high-speed geared-head lathe provided with all the ordinary features of up-to-date lathe designs. The number of spindle speeds obtainable through the change gears in the head is nine. The longitudinal and cross power feeds for the carriage and tool slide are obtained through a friction clutch arrangement. The feed is positive and gear-driven and can be easily changed while the machine is running. The lead-screw is independent of the feed for ordinary turning, the same as in all modern lathe designs, thus preventing unnecessary wear of the threads when not used for thread cutting.

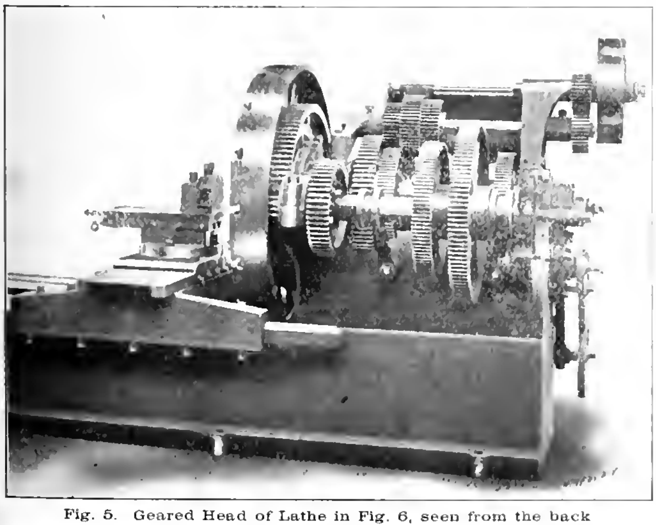

Fig. 5. Geared Head of Lathe in Fig. 6, seen from the back of the Machine.

A large, heavy duty engine lathe is shown in Fig. 6. Fig. 5 shows a back view of the same machine with the guards over the geared head mechanism removed so as to show the arrangement of the gears very plainly. In regard to guards for gearing and moving parts on machine tools, it may be remarked here that the careful covering of all gearing which is so plainly in evidence in all German machine tools is not quite so prominent in Swedish tools. In this respect the Swedish tools possess practically the same features as did until lately, the general run of American machines, where only the most important and more dangerous combinations of gearing were covered. It is to be hoped, however, that the German practice of covering all gearing with guards forming as nearly as possible an integral, or at least a homogeneous, part of the machine will become a common practice everywhere. The geared head in the machine illustrated permits fifteen speed changes for the spindle, the arrangement of gears through which these changes are obtained being plainly indicated. The feed is gear driven and consequently is positive. A novel arrangement for obtaining four different feed changes at the apron in addition to the usual changes, is introduced. This makes the changing of the feed while the machine is running very convenient to the operator. The kind of tool-post employed on the Köping lathes differs from the usual form, and is especially adapted for heavy, square lathe tools.

A machine embodying some rather interesting features is shown in Fig. 7. This side planing machine, also known as the Richard planer, is particularly valuable in cases where large castings are handled, which are often difficult to plane on the ordinary types of planers. The carriage which is provided with an exceptionally long slide is driven by a square-threaded screw engaging two adjustable nuts. The screw is driven by means of a belt on a tight and loose pulley. The reversing mechanism is provided with a bevel gear clutch reversing arrangement, a feature which has been introduced recently, and replaces the old method of reversing by means of shifting the belt from the forward to the return pulley. The small sizes of these side planers are provided with one work-table placed on a slide on the side of the machine, and the larger sizes are provided with two or more of these as shown in the illustration. This table can be easily removed when it is required to plane very large castings. A large pit is usually provided in the front of the machine so as to give ample space for large pieces to be machined. An extension for the tool-carrying arm is also provided in order to make it possible to plane surfaces which are out of reach of the ordinary arm. While the machine is substantially constructed, it is evident that on account of its peculiar design it does not permit of very heavy chips to be taken, as compared with the possibilities of the ordinary planer.

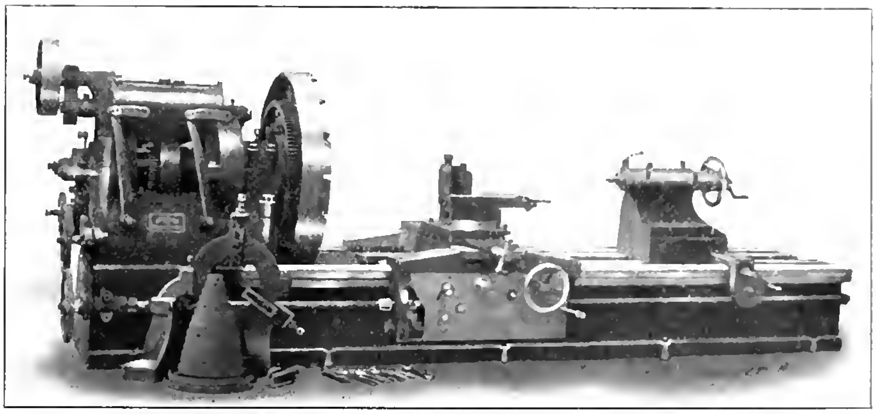

Fig. 6. Koping Heavy-duty Engine Lathe.

The universal milling machine shown in Fig. 8 is an interesting example of a high-class machine tool embodying in its design a combination of American, German and Swedish features, the first mentioned being most prominent. The machine is provided with power feed in three directions, the number of different feeds obtainable in each direction being twelve. The speed-changing mechanism permits of sixteen different spindle speeds. Automatic stops are provided for

the feeds in all directions It will be noticed that the telescopic feed-driving shaft commonly used on American designs is not employed.

In Fig. 9 is shown a high-speed upright drill press. In this machine six different spindle speeds are obtainable; of these three are obtained by means of a gear box and these are multiplied by two by the back gears. The feed is positive, three speed changes being provided for each spindle speed. The circular work-table can be swung out of the way whenever it is required to use the base plate for large work.

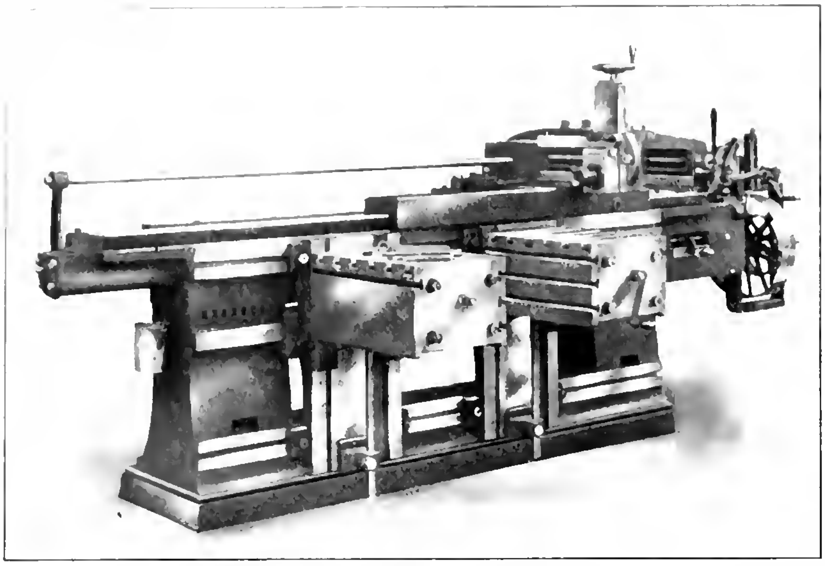

Fig. 7. Richard Type of Side Planing Machine.

The accompanying examples of Swedish machine tools indicate in a general manner the present state of the art in that country, and indicate the present development. While it is evident from the illustrations that the designs largely follow along the lines of American and German built machines, the high class of workmanship put into these machines should be emphasized. This has been one of the strong claims of the Swedish machine tools in the past and has enabled the Swedish machine tool builders to hold their own in competition with foreign-made tools.

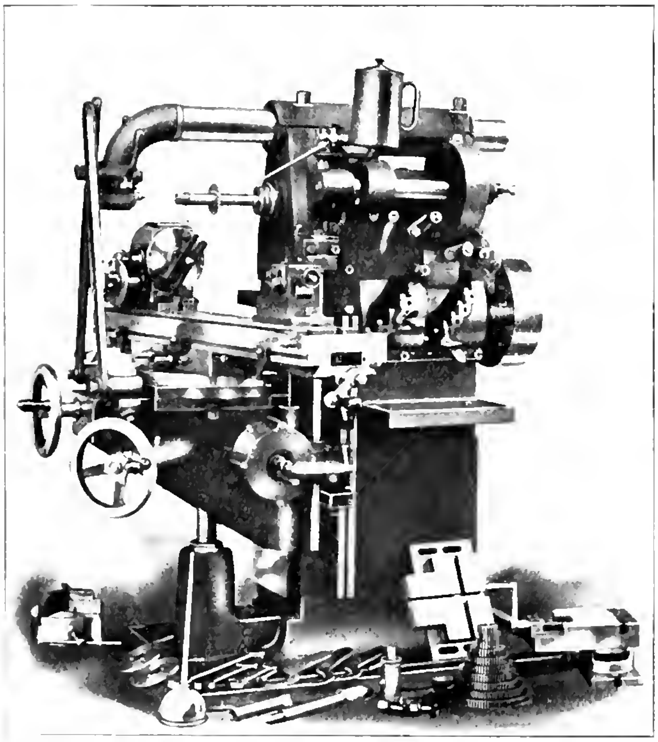

Fig. 8 Milling Machine, combining in its design American, Swedish and German Features.

The lawyer reasons by precedent; the engineer by cause and effect.—*Common Sense.*

STEAM PIPE SIZES.*

CHARLES L. HUBBARD †

The problem of determining the size required for steam pipes under varying conditions is one which often confronts the engineer, and the difficulty of obtaining reliable data is well known. In order to facilitate work of this character, the tables given in the current Supplement have been computed. Tables I, II and III (Plates I and II) are computed from D'Arcy's formulas for flow of steam in pipes, which are given in the Supplement in connection with Table IV, which gives the value of constants used in these formulas for various diameters of pipe.

Table I gives the flow of steam in pounds per minute through pipes 100 feet in length, for initial pressures of ¼ to 5 pounds, assuming that the pressure in each case drops to zero. That is, the drop in pressure equals the initial pressure. It is seen from the table, for example, that a 2-inch pipe will discharge 2.9 pounds of steam per minute under a pressure of ¼ pound per square inch, or 14.9 pounds under a pressure of 5 pounds, the terminal pressure dropping to zero in each case. The table is sufficiently accurate for any initial pressure less than 10 pounds for the drops in pressure noted at the heads of the columns, regardless of whether the pressure falls to zero or not. For example, a 4-inch pipe, 100 feet long, will discharge approximately 18.1 pounds of steam per minute with a drop in pressure of ¼ pound, or 91.9 pounds with a drop of 5 pounds, for any initial pressure up to 10 pounds.

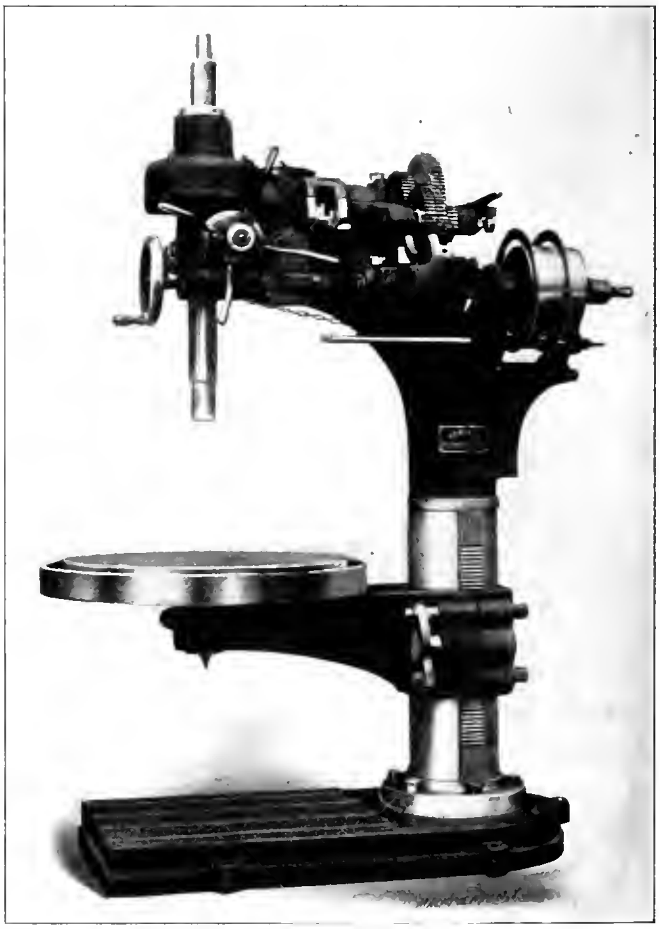

Fig. 9. Koping High-speed Upright Drill.

As the initial pressure increases, the quantity of steam discharged for a given drop in pressure becomes greater than given in Table I. Table II gives correction factors for higher initial pressures. For example: The factor for a drop of 5 pounds at an initial pressure of 80 pounds is 2.09, so that

---

* With Data Sheet Supplement.
† Address: 283 Central St., Auburndale, Mass.

under these conditions a 4-inch pipe will discharge 91.9 × 2.09 = 192 pounds of steam per minute, the value 91.9 having been obtained from Table I.

The figures given in Table I are for pipe runs of 100 feet only. For different lengths, the results should be corrected by the factors given in Table III. For example: A 4-inch pipe, 100 feet in length, will discharge 91.9 pounds of steam per minute with a drop in pressure of 5 pounds at the discharge end; if the pipe is only 50 feet in length, it will discharge 91.9 × 1.41 = 129.5 pounds, or if it is 500 feet in length, it will discharge 91.9 × 0.45 = 41.4 pounds.

Examples in the Use of Tables.

What weight of steam will be discharged per minute through a 3½-inch pipe, 100 feet long, with an initial pressure of 40 pounds, and a drop of 3 pounds?

$$47.8 \times 1.70 = 81.3 \text{ pounds.}$$

What size of pipe will be required to deliver 51.3 pounds of steam a distance of 100 feet, with an initial pressure of 60 pounds, and a drop of 2 pounds?

The factor for 60 pounds initial pressure and 2 pounds drop is 2.02, and $\dfrac{51.3}{2.02} = 25.4$, which in Table I corresponds to a 3-inch pipe.

What weight of steam will be discharged per minute through a 5-inch pipe, 600 feet long, with an initial pressure of 5 pounds, and a drop of ½ pound?

$$45.7 \times 0.40 = 18.3 \text{ pounds.}$$

The tables given may be applied to either power or heating work, or to any conditions where the quantity of steam used can be reduced to pounds per minute.

Engine Connections.

Steam pipes for engine connections are commonly based on a velocity of 6,000 and 8,000 feet per minute for the steam and exhaust pipes respectively, assuming the entire cylinder to be filled with steam at each stroke. This gives approximately 0.14 square inches internal area per H. P. for the steam pipe and 0.20 square inches for the exhaust. For example, a 100 H. P. engine would require

100 × 0.14 = 14 square inches, or a 4-inch steam pipe.
100 × 0.20 = 20 square inches, or a 5-inch exhaust pipe.

Tables V, VI, and VII, finally, give the diameters of pipe required for heating purposes.

* * *

THE DISTURBING EFFECT OF CENTRIFUGAL FORCE ON HIGH-SPEED CUTTERS.

The manufacturers of wood-working machinery have found the effect of centrifugal force a very troublesome factor in high grade wood planers. It has been found practically impossible to build a planer cutter head that will stay so well balanced that it will not run out at speeds of say 4,000 revolutions per minute sufficiently to leave distinct cutter marks on the lumber planed. The slight eccentricity due to lack of perfect balance causes one knife to cut deeper than the other three. The result is irregular work that will not pass inspection where the product is employed for fine furniture. A circular issued by the S. A. Woods Machine Co. of Boston, Mass., is devoted to this matter, and describes an attachment for truing up planer cutter heads at full speed. The circular in pointing out the nature of the difficulty, states that the effect of centrifugal force is far greater than is ordinarily supposed. One pound of metal revolving at 4,000 revolutions per minute, in a circle of six inches diameter, exerts a radial force of over 1,700 pounds. On the same basis a 7-inch cutter head, which is an ounce out of balance, would have to stand a strain of 125 pounds, tending to throw a knife edge out of perfect concentricity with the others. So it follows that even if cutter heads were in perfect balance when built, they could not remain so because of slight inequalities developed by grinding and wear; hence the practical necessity for truing these knives up when running at speed and thus elminating the effect of the disturbing influence. The truing device is in the nature of a lathe turning tool, guided by a straight bar, an emery stick held in a suitable holder and traversing along the cutter head when at speed being employed to remove a small amount of metal from the blade projecting beyond the others.

APPROXIMATE FORMULAS FOR SIZES OF BEAMS AND GIRDERS.

C. R. WHITTIER*

In determining the size of a beam to carry a uniformly distributed load, it is customary to use the tables in the various steel companies hand-books as follows: The total load and span are given. The size is tentatively found by selection from the load tables; the weight of the beam thus provisionally determined is calculated and added to the load; and then a second reference is made to the tables to see that the total capacity is not exceeded.

A more rapid, and closely approximate method for determination without tables is developed below. It is founded on the well-known fact that I-beams and plate girders resemble open beams or trusses. In the ordinary truss with uniformly distributed load, the horizontal stress at the center of either chord is approximately the total weight times the span, divided by 8 times the height—all in inch pounds. Applying this to an I-beam flange, we have for 16,000 pounds fiber stress:

$$\frac{Wl}{8\,h} = 16{,}000 \times \text{area of flange.}$$

As the area of the flange is practically one-third the area of the cross-section of the beam:

$$\frac{Wl}{8} = \frac{A}{3} \times 16{,}000\,h.$$

Transforming the left-hand member of this equation to inch-pounds, we have:

$$\frac{2{,}000\,W \times 12\,l}{8} = \frac{A \times 16{,}000\,h}{3}$$

[The assumption that the area of the flange is one-third the area of the cross-section of the beam is only approximately correct. The area of the flange varies in proportion to the total area of the beam from 0.26 for the larger sizes of standard I-beams to 0.37 for the smaller sizes. It should also be remarked at the outset that the approximate formulas in the following apply only to the minimum or standard sizes of I-beams.—EDITOR.]

In I-beams it is found, closely enough for our present calculations, that $A = h - 2$.

[More accurately A varies between $h - 0.68$ and $h - 2.74$ for different sizes of I-beams.—EDITOR.]

Introducing this value of A, reducing, and solving for h, we have:

$$h = \sqrt{0.56\,W\,l + 1} + 1$$

The quantity 1 under the vinculum is so small as to be negligible.

The coefficient 0.56 needs further modification to allow for the average weight of the beam itself, which value is taken as equivalent to $3.5\,h - 10$ per foot; also a correction for using h as the distance between extreme fibers instead of the distance between the center of gravity of the flanges, and an allowance for the strength of the web. This changes the coefficient to 0.6, giving as a final formula:

$$h = \sqrt{0.6\,Wl} + 1$$

This is so simple that it can be solved mentally. Thus h may be determined without reference to the tables for all preliminary work. A trial in comparison with the tables will be convincing proof of its accuracy. It applies *only to the minimum sections*, as these are always used if possible.

Similar formulas have been deduced for minimum sections of channels, Z-bars, angles with equal legs, and tees with stem and flange equal; also for plate girders of the ordinary dimensions tabulated in Carnegie Steel Co.'s hand-book, as shown on the following page.

The formulas reduce to this simple form because the relation between weights and areas of beams, if plotted, closely approximates a straight line.

Incidentally, it may be stated that a closer approximation is given by the following formulas:

Weight per foot of I-beams, minimum section $= 0.07\,h^2 + 1.7\,h$ pounds.

---

* Address: 204 West 111th St., New York City.

Area of I-beams, minimum section $= 1.1\,h - 3$ square inches.

The average weight per foot of plate girders of standard dimensions (Carnegie Steel Co.) in pounds, is

$$\text{weight} = 0.1\,h^2 + 2\,h.$$

Memorizing the formulas which are most useful to the work in hand enables one to make mental calculations without reference to tables.

Another handy approximate rule, *good for all standard weights* of I-beams, and depending on l in feet, W in tons, and w (weight of beam per foot) in pounds being known, comes from the following well-known relation: When depth of beam in inches equals span in feet, then, weight of beam per foot in pounds equals load in thousands of pounds; other loads vary inversely as their lengths.

BEAMS OF MINIMUM SECTION.

h = height in inches, l = span in feet, W = load in tons.

Shape	Maximum Fiber Stress	For Uniformly Distributed Load	For Center Load.
I-beam	16,000	$h = \sqrt{0.6\,lW + 1}$	$h = \sqrt{1.2\,lW + 1}$
Channel	16,000	$h = \sqrt{lW + 1}$	$h = \sqrt{2\,lW + 1}$
Z bar	16,000	$h = \sqrt{lW}$	$h = \sqrt{2\,lW}$
L (equal legs)	16,000	$h = \sqrt{lW + 1.3}$	$h = \sqrt{2\,lW + 1.3}$
T (equal legs)	16,000	$h = \sqrt{lW + 1}$	$h = \sqrt{2\,lW + 1}$
Plate girders	15,000	$h = \sqrt{0.5\,lW}$	$h = \sqrt{lW}$

Then, changing the load from pounds to tons, it follows that

$$\frac{w\,h}{2\,l} = W, \text{ and}$$

$$h\,w = 2\,l\,W$$

As w depends on h, a value of h must be selected by trial to balance the equation.

* * *

MECHANICAL IMITATION OF GRAVITAL FORCE.

An interesting account of experiments conducted by Prof. Arthur Korn in gravitation was recently published in the *Westminster Gazette*. Prof. Korn has constructed a machine which mechanically imitates the action of gravital force in a way visible to the eye. He apparently demonstrates that gravitation is a mode of motion, inasmuch as by rapid vibration he causes bodies to attract one another which are under the influence of the vibratory force with a force proportional to their mass.

Prof. Korn started with the assumption that gravitation is the result of the vibration of elastic bodies in an inelastic medium. All matter is in a state of eternal vibration. The vibration according to the professor, is analogous to the vibration of a violin string. The third string of a violin, for instance, rightly tuned, emits an A. In addition, however, to the ground tone A, there are the so-called over-tones in the relation of 1 to 2, 2 to 4, and so on. Of complex character are the vibrations of all particles of matter, and it is these vibrations which lead respectively not only to the attractive force of gravitation, but also to the repulsive force which, in the case of the heavenly bodies, is observed at the same time.

The machine constructed by the professor to produce this "artificial gravitation" is extremely simple. A metallic globe, fitted with a window for observation of what is going on inside it, is united by tubes with a cylinder, one end of which is closed only by a membrane. To this membrane is attached an electro-motor, which, by pushing and pulling the membrane alternately, makes rapid pulsations. The metal globe contains two air-filled india-rubber balls of different sizes. The larger one is fixed firmly to the inside wall of the globe; the smaller is free to move whither it likes. The whole apparatus is then filled with water, and the motor set to work. Each time the membrane is pressed in, the increased water pressure causes the rubber balls to contract, and each time the membrane returns to its original position the relaxed pressure of the water causes the two balls to expand. The motor is set working so quickly that these pulsations become inconceivably rapid vibrations, and the contraction and expansion of the balls is invisible to the eye. As water is practically incompressible, Prof. Korn thus obtains the conditions he needs—he has two elastic bodies vibrating in an inelastic medium. Then the phenomenon looked for occurs. When the vibrations attain a certain speed, the smaller ball, impelled by a mysterious force, begins slowly to move through the water to the larger ball, and gradually increases its speed, exactly as the apple observed by Newton increased its speed as it fell nearer and nearer to the ground.

So far, this was merely a puzzling phenomenon; but that it was gravitation, and no other force, which drew the balls together was soon proved. Measurements showed that the bigger ball attracted the smaller exactly in accordance with Newton's law, or in inverse ratio to the square of the distances between them. It became, therefore, possible to construct an exact working model of the solar system in water, in which the planets should all move in their appointed paths without any visible support or externally-applied power.

Prof. Korn's researches do not end here. He had shown why matter attracts matter, but he had to solve the problem why matter also repels matter. Why is it, for instance, that comets, after rushing directly towards the sun from the depths of infinite space, never collide with it, and invariably return whence they came? To this problem the professor again applies the musical-vibration theory. Just as there are over-tones in the violin string, so in the vibrations of matter there are over-vibrations. These over-vibrations come into play when the attracted bodies come too near, and their effect is immediately repulsive. They are counter-gravitational in their effect, and operate in this way also only in an inelastic medium like water. In an elastic medium the vibrations of matter would have no attractive or repulsive effect; hence it follows that gravitation depends entirely upon the fact that all the heavenly bodies are surrounded by inelastic ether.

NEW COOPERATIVE TRADE SCHOOL.

A cooperative plan of shop and school instruction for boys has, according to the *Iron Age*, been instituted in Chicago, along lines similar to those in operation at the University of Cincinnati, and at the high school in Fitchburg, Mass. In Chicago, the manufacturers send their apprentices to the Lewis Institute one-half of the time, one week being spent in the shop, and the next week in the school. The course extends over two years, but it is not the intention either of the manufacturers or the instructors of the Lewis Institute to turn out a skilled workman in this time. The idea is simply that the boy will be able to develop intellectually, and grasp the principles of his trade more quickly, than he otherwise could. Each manufacturer is represented in the school by units of two boys, one boy working in the shop, while the other is in the school. The employer pays a tuition fee of $50 a year for each apprentice sent to the Institute, and pays the boy $5.00 a week for each week he works in the shop. Two weeks' vacation from the school instruction is given in the summer, but twenty-six weeks are spent in the shop.

The school instruction comprises eight hours a day for five days in the week. Instruction is given in the physical sciences and the principles of mechanics, mechanical drawing, mathematics, English and history, and in shop work, supplementing the productive work done by the boys in the metal working shops. A boy who has taken this course at the Institute and in the shop will still have to continue his apprenticeship in the shop, but it is expected that it may be possible to reduce the time of the apprenticeship as a result of the better education of the boy. The Lewis Institute has equipment for the instruction of sixty boys in this course.

British Machine Tool Trade.—In a note published in the November issue on the English machine tool trade in the London district, it was mentioned that the firm of Henry Pels & Co. had enough work on hand to keep several shifts busy for several months, and that it was contemplating considerable extensions. The idea conveyed was that the company has a plant in Great Britain, which is incorrect. All the tools sold by the company in Great Britain are imported from the Continent.

MANUFACTURING AIR-COOLED CYLINDERS.

F. J. HAYNES.*

The process of manufacturing air-cooled cylinders of the type used by the H. H. Franklin Mfg. Co., Syracuse, N. Y., on the Franklin automobiles, differs radically from the operations used in manufacturing water-cooled motor cylinders. The operations are of considerable general interest from the manufacturing standpoint, and in the following article a few processes are illustrated and briefly described.

The motor cylinder of the Franklin car is made from cast iron, and cast in a separate piece. On the exterior of the cylinder are mounted phosphor-bronze rings, which increase the radiating surface. After the casting has been made, it is first inspected; the things to be noted at this time are that the casting is sound in all respects, having no blow holes or other defects; that the cores are located centrally, and the dimensions of the core holes correct and that the bosses are in proper position. Then the casting is sand blasted to remove all core sand; this saves the cutting edges of the boring tools.

The cylinder is bored on a Gisholt turret lathe. The boring bar is guided in the spindle by a bushing, and the cylinder is bored within 0.015 inch of the finished dimension. The dome head is machined simultaneously with the boring of the cylinder, and the base is faced off at right angles to the bore, the proper distance from the base to the center of the auxiliary exhaust port being made the right dimension at the same time. In machining the dome head, considerable care must be taken to avoid forcing the forming tool to one side, as this would result in throwing the dome head off center. These operations are very severe on the tools; carbon steel cutters will last only a short time, and even high-speed steel tools must be carefully watched. The boring and the facing operations are illustrated in Fig. 3.

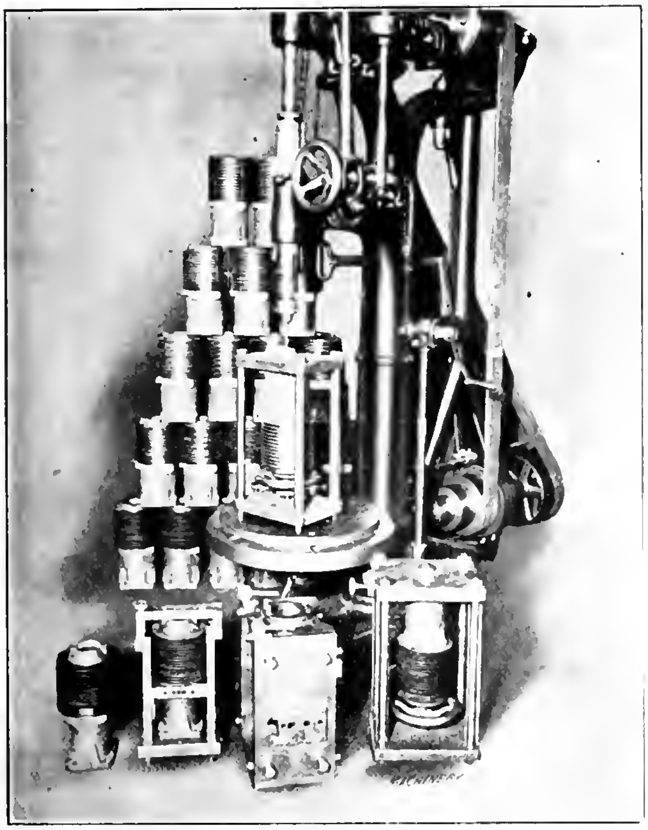

Fig. 1. Drilling the Cylinders, and Jigs for this Operation.

The cylinder is now submerged in water, and tested with compressed air of eighty pounds pressure. Any porous or unsound places will be revealed by the leakage of the air. Of course, if the cylinder shows leakage in this test, it is "scrapped" before any further operations on it are performed. If it passes the test, it goes to the next operation, consisting of rough turning and grinding. During the grinding operation, and also during the later operation of grinding the bore of the cylinder, it is flooded with water and kept at a temperature of 70 degrees F. It is necessary to keep the water at this temperature, by adding either cold or warm water, otherwise the micrometer measurements taken by the operator, and those taken by the inspector, will not agree. If the water is too cold, the dimension of the cylinder will be too large when the cylinder has acquired the temperature of the room; if the water is too hot, the cylinder will be too small when cooling down. When the cylinder has been accurately ground to the exact size outside, it is again tested by compressed air under water. If no leaks develop, it passes to the inspection room for checking of the outside diameter. When this is done, the phosphor-bronze rings are applied.

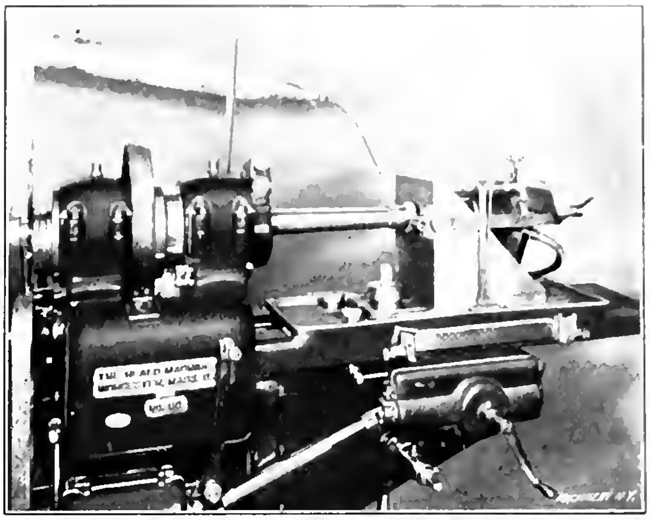

Fig. 2. Grinding the Cylinder Internally

These rings are punched in a combination die which produces a complete ring for every stroke of the press. Before being applied to the cylinder, they must be accurately bored for a shrink fit. The allowance for the shrink fit is carefully calculated, so as to be within the elastic limit of phosphor-bronze when the rings are shrunk in place. On the other hand, due consideration should be given to the fact that the rings must not work loose, due to their expansion caused by the heat of the cylinder when in use. After boring, the rings are heated in an oil bath to the exact temperature required, and are placed on the cylinder with split steel washers between the rings.

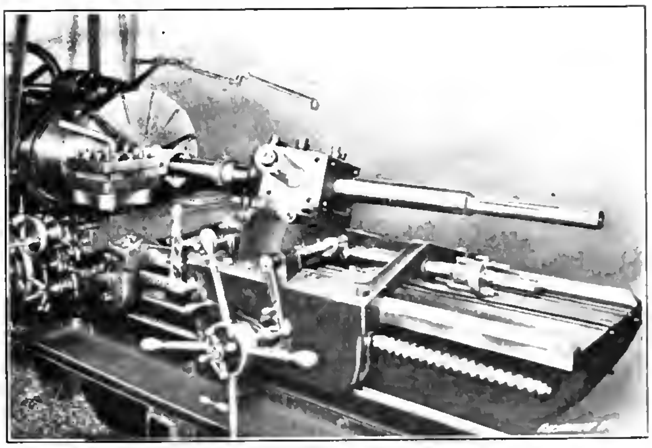

Fig. 3. Boring and Facing the Cylinder

The remaining work on the cylinder, such as facing the bosses, drilling and tapping the holes, etc., is now carried out with the exception that the concentric valve seat in the dome head is only roughed out to within a few thousandths of the correct size. The drilling and the tapping of the holes is done in jigs, as shown in Fig. 1. When these operations are performed, the cylinder is again inspected, and if found correct, it passes again into the grinding room to have the bore ground. The cylinder is placed in a cylinder grinder, by fastening it to a large angle plate provided with a hole of the same size as the bore. The grinding wheel enters

---

* Address: Superintendent, H. H. Franklin Mfg. Co., Syracuse N. Y.

through this hole, as shown in Fig. 2. The grinding machine is of the type where the grinding wheel has a planetary motion, besides its regular revolving motion, so that the work itself does not revolve. The finish grinding of the bore is performed last, in order that the pressure due to the shrinking on of the phosphor-bronze rings may have no effect on the final dimension of the bore.

When the grinding operation is completed, the cylinder passes to a large heavy lathe, fitted with a special face-plate and compound rest, as shown in Fig. 4, which is used only for finishing the concentric valve seat. As a roughing cut has already been taken on the valve seat the finishing cut merely insures that the angle of the valve seat is correct, and the surface round and true. The valve seat is tested for its accuracy with a hardened taper plug, ground to the exact shape and size of the finished seat, and smeared with Prussian blue. When this operation is finished, the cylinder passes through the final inspection, and is then delivered to the stock-room for finished work.

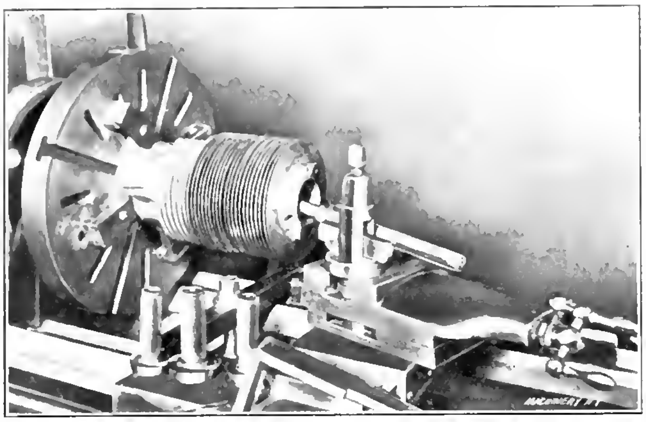

Fig. 4. Finishing Valve Seat Hole in Top of Cylinder.

The cylinder, some stages of the finishing of which are shown in the accompanying illustrations, is of 4½-inch bore, and is 11 9/32 inches long over all, and weighs 16 3/4 pounds when fitted with the phosphor-bronze rings. The wall of the finished cylinder is 3/16 inch thick. All of the inner surface and one-half of the outside surface is machined; thus there are no uneven thicknesses of metal, and the design enables a very light cylinder to be produced. It is interesting to note that, in all, the cylinder passes through thirty-two operations before completion.

* * *

Mr. Bethel, foreman of the manufacturing department of the Taft-Peirce Co., Woonsocket, R. I., has a blueprinted placard tacked on the shipper rod of each of his lathes. This placard reads as follows:

LATHEMEN—ATTENTION.

Be sure
That lathe is well oiled.
That lathe and work are kept orderly.
That live center runs true.
That tail center is smooth.
That tail center is hard.
That both centers are 60 degrees.
That center holes in work are clean.
That center holes in arbor are clean.
That arbor runs true.
That arbor is smooth and does not rough hole in work.
That wrenches are kept with lathe.
That you take your work to be inspected every two hours.
That you work to figures.
That at least one hour before your job is completed you notify your foreman.

This list of instructions, which somewhat resembles in positive form the "don'ts" we published some time ago, combines a number of points which are commonly understood, but are as commonly neglected. By placing this list where it is before the men constantly, and holding them responsible for following it, a noticeable improvement in the quality of the work was effected.

With an engineering education you know the relation of knowledge with its use.—*Common Sense.*

MACHINE SHOP PRACTICE.*

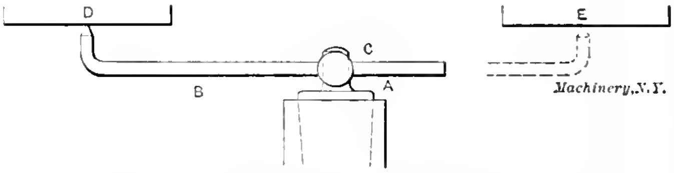
MACHINING A THREE-THROW BUILT-UP CRANK-SHAFT.

W. BURNS.[†]

As the machining and building-up operations on a crank-shaft of the built-up type, are usually done by the same men in the shop, one may be employed for considerable time without having the opportunity of obtaining experience on work of this class; and should one chance to be called upon to do such work when starting in a new shop, he might be quite at a loss to know how to proceed. A short description, therefore, covering some of the salient points in connection with this work, may be of interest.

The largest sizes of the three-throw shafts are usually made up of three separate cranks, each machined and built up separately, and then all connected in their relative positions to one another by means of solid forged couplings on each shaft. There are, however, a very large number of three-throw crank-shafts shrunk together into one solid shaft and then turned after the building-up operation. As it is a much easier proposition to machine a single crank and then connect it to other cranks by means of coupling bolts, than to machine, shrink together, and then turn a three-throw shaft, a brief description of the work involved in the latter will be given. Illustrations showing the construction of a built-up shaft will be found on the Shop Operation Sheet accompanying this issue.

The forgings for the different parts of the shaft and the crank-pins, should first be roughed out to within 3/16 or 1/4 inch of the finished size. It is not necessary to face the ends to the correct length and center anew, as it is not essential that the centers be left in the finished work, in this case, as is desirable for some shafts. When the different parts of the shaft are being roughed out, they should all be turned to the same diameter, as this uniformity makes it much easier for the erector to produce a true shaft when shrinking the parts together. This, however, does not apply to the crank-pins, as they are finished to fit the holes in the webs and turned to finish size on the body before being shrunk in place. When turning the coupling end, the inside face and the fillet should be roughed out first, as the forging is sometimes defective in this part, and should it chance to be condemned because of any defect, little machine work will be lost. Occasionally, a flaw in the metal may be discovered near the center of the shaft when facing the outside of the coupling. If such a defect appears, it should be examined carefully to determine, if possible, the distance it penetrates into the shaft.



Tool for Setting Lines Concentric with, or Surfaces at Right Angles to, the Axis of a Horizontal Boring Mill Spindle.

Before any of the cylindrical parts are machined, however, the webs are first finished as the crank-pins and the ends of the shaft proper are turned to a shrink fit for the holes in the web. These webs are usually forged solid, which means that a large amount of metal has to be removed in boring the shaft and crank-pin holes. Sometimes, however, small holes are punched for the crank-pins and shaft so as to reduce the time required for the boring operation. When machining the webs, the thickness and the distance between the shaft and crank-pin holes are the most important dimensions. It is also essential that the holes be bored out very true to the face of the webs, that is, at right angles, as no machining is done on them after the crank is shrunk together. The method of setting the angle-plates, described on the Shop Operation Sheet, will, as will be understood by referring to the Supplement, bring the faces of the angle-plates in line with the cross travel of the table. In a well-built machine this cross travel will be at right angles with the axis of the spindle, and, in that case,

---

* With Shop Operation Sheet Supplement.
[†] Address: 16 Golfview Terrace, Paisley Road West, Glasgow, Scotland.

the angle-plates will be correctly set. By the use of a special tool, such as the one here illustrated, the setting of the plates may be tested directly from the spindle, which is a desirable thing to do, as then any error in the machine table will not be reproduced in the work. This tool consists of a shank *A* which fits in the spindle, and has passing through its outer end a gage wire *B* which is adjusted in and out and held in position by a knurled thumb-screw *C*. The faces of the two angle-plates *D* and *E* may be tested by bringing this gage point into contact with one, and then revolving the spindle one-half of a revolution. This moves the gage to the position indicated by the dotted lines in the illustration, and obviously, if the plane in which the two faces of *D* and *E* lie, is at right angles with the axis of the spindle, the point of the gage will just touch the face of each plate. By the insertion of a wire *B* having a sharpened point, circles scribed on the work may also be accurately set concentric with the spindle, by revolving the spindle and gage and adjusting the work until the pointer follows the line on it.

The outside edges of the webs are machined after the sides have been planed and the holes bored. These edges are occasionally painted when in place on the engine, and, in that case, often they are only rough machined. When all cylindrical parts are turned to fit the webs, the shaft is ready to be shrunk together. This might seem like a rather complicated job, especially when doing it for the first time, but if one keeps cool (which is not an easy thing to do when two big bunsen burners are playing on the web) no trouble will be experienced. When the shaft is shrunk together it is placed in the lathe for the final turning operation and all the parts of the shaft proper, or the journals, are finished as described on Shop Operation Sheet No. 93, thus bringing them into alignment. Considerable care has to be exercised when performing this last operation to obtain a shaft which is round and not sprung to any appreciable extent. It is hardly practicable, however, to finish a large three-throw crank-shaft which will not show slightly out of true when being bedded in place in the bushings in the sole-plate.

* * *

TESTS ON CRANK SHAPERS.

Some interesting tests on crank shapers were recently undertaken by the Queen City Machine Tool Co., Cincinnati, Ohio, with the purpose of ascertaining the horse-power required for taking ordinary cuts on motor-driven crank shapers. The tests were made on the 16-inch and the 24-inch back-geared crank shapers manufactured by the company. A 5-horse-power constant-speed motor was used for driving the smaller machine, and a 20-horse-power motor for the 24-inch shaper; 220-volt current was used. A regular cone pulley drive was employed, the counter-shaft being driven by the motor. The required revolutions per minute of the counter-shaft were obtained by reduction through pulleys, so that the counter-shaft for the 16-inch shaper was running at 300 revolutions per minute, and the 24-inch shaper counter-shaft at 330 revolutions. The length of the stroke in the tests on both machines was 16 inches, which is the rated capacity of the smaller shaper. All the cuts were made with the back-gears thrown in, the 16-inch shaper being run to obtain an average cutting speed of 24 feet per minute, and the 24-inch to obtain a speed of 22 feet per minute.

TESTS ON 16-INCH CRANK SHAPER.

Depth of cut, ½-inch.

Feed.	Net Amperes.	Net Horse-power.	Feed.	Net Amperes.	Net Horse-power.
0 0125	2.5	0.75	0.075	14.	4.1
0.025	4.5	1.33	0.0875	16.5	4.87
0.0375	6.5	1.93	0.100	17.5	5.16
0.050	8.5	2.5	0.125	21.5	6.33
0.0625	11.5	3.4	......	....	....

The motor and counter-shaft were first run idle, and the power required for this was carefully noted. Then the machine belt was thrown in, and it was found that when running the machine idle, there was practically no increase in the power required for the 16-inch shaper, except at the point of reversal, when there was a rise of about one-half ampere. On the 24-inch shaper, one-half ampere or about one-seventh horse-power was required to run the ram on the forward stroke, and nearly two amperes at the moment of reversal. Readings were taken at the highest point reached by the needle of the meter on each stroke. In the accompanying tables, the results of the tests are given for cuts one-half inch deep made in cast iron. The net amperes and net horse-power given in the tables give the figures actually required for taking the cut. In the case of the 21-inch crank shaper, one-half ampere should be added to the net amperes to obtain the maximum amperes required for running the machine on the forward stroke.

It is rather surprising that so high a horse-power is required for driving the coarse-feed cuts, but considering the reciprocating motion of the machine, a somewhat smaller motor can be used than what would be indicated by the net horse-power, because first-class standard motors provide for a momentary over-load of 100 per cent. Besides, it is doubtful if many shops would attempt to take cuts with as coarse feed as that indicated by the last items in each table, although the shapers being tested are guaranteed to withstand cuts with this feed indefinitely, if properly cared for.

TESTS ON 24-INCH CRANK SHAPER.

Depth of cut, ½-inch.

Feed.	Net Amperes.	Net Horse-power.	Feed.	Net Amperes.	Net Horse-power.
0.025	5.5	1.6	0.150	22.5	6.6
0.050	8.5	2.5	0.175	25.0	7.4
0.075	11.5	3.4	0.200	26.5	7.8
0.100	15.0	4.4	0.250	31.0	9.1
0.125	20.0	6.0	...	....	...

Some of the interesting things noted from the two tables given are that the horse-power for any given cut is about the same on the two sizes of machines, and that the horse-power advances in nearly direct ratio to the feed. The first fact is interesting as indicating that shapers of different sizes, when properly built, will work with about the same efficiency within their respective capacities, and the latter fact is of interest because it indicates that there is little additional loss from binding action and friction, even on the heavy cuts, in shapers properly designed and rigidly built for the work for which they are intended. This is all the more remarkable, as the shaper is particularly subjected to severe twisting stresses, due to the great amount of over-hang inherent in its construction

MACHINERY SWINDLER IN THE SOUTH.

The swindler, "Eddie Ward," whose operations in the West were mentioned in the August, 1908, issue of MACHINERY, is now working in the South. He still represents himself as agent for J. J. McCabe, 30 Church Street, New York, and was last reported at West Point, Miss., and Talladega, Ala. At West Point he collected from Mr. F. A. Bentley of the West Point Machine Co., a deposit on a trade he proposed, which seemed very profitable to the concern. The Talladega Foundry & Machine Co. gave Ward a deposit on the purchase of a Hendey lathe, which was represented as belonging to McCabe, and as being ready for shipment from some point in Mississippi. Mr. McCabe informs us that he has no traveling men whatsoever at present in the South or West, as he is represented in these sections by prominent machinery dealers.

* * *

The last reports of the exports of machine tools from Great Britain indicate a healthy increase in trade. The exports during the month of December last year were the highest for any month during the year. The value of the exports of machine tools for this month amounted to about $575,-000, and the value of the imports during the same period, to about $40,000.

FORMULAS FOR MACHINE SCREW BUTTON OR SPLIT DIES.

THOMAS J. NORTON[*] AND DOUGLAS T. HAMILTON

Upon the adoption by the American Society of Mechanical Engineers of new standards for machine screws, it occurred to the authors to investigate a means of standardizing the proportions of button dies, so as to admit of a uniformity of manufacture and to eliminate all trial and error methods in the laying out of these dies. The method described has as its basis the maximum root diameter and outside diameter of the basic screw to be threaded. These are the only fixed quantities; all proportions of the die are derived from these two fundamental dimensions.

The dies are made with three cutting edges or teeth set slightly ahead or in advance of the center. The ratio of land to space has been taken as one to two. This relation has been found to work most satisfactorily in practice, especially in the present case for machine screw dies of small size. The advance ahead of the center, necessarily a small dimension to lay off, is taken care of by the general method employed.

Let D = outside diameter of basic screw,

d = maximum root diameter of basic screw,

A = distance of first clearance hole of diameter D from center of die blank.

Take any three axes G on the die blank at 120 degrees to one another. Lay off the center lines of the clearance holes to make angles of 55 degrees with these axes. The distance A of the centers of the clearance holes from the center of the die blank along these 55-degree lines is given by the formula

$$A = \frac{d}{2}\cos 40\text{ deg.} + \sqrt{\left(\frac{D}{2}\right)^2 - \left(\frac{d}{2}\sin 40\text{ deg.}\right)^2}$$

From these centers, by drawing circles of diameters equal to the outside diameters of the basic screw, the correct relation of land to space is immediately obtained, and the necessary advance ahead of the center assured. For the larger size dies with a single clearance hole, the die blank is now ready for drilling and tapping.

In the case of the smaller dies, where two clearance holes are necessary some difficulty was experienced in obtaining a general method, inasmuch as the outside diameter of the die blank is constant for several sizes. This must be so on account of the die holder.

The diameter C of the second clearance hole is given by the formula

$$C = \frac{H}{2} - \left\{A + \frac{D}{4} + F\right\}$$

where H = outside diameter of die blank,

F = width of metal between outside of die blank and edge of clearance hole.

The thickness F of the outer skin of the die may be taken to suit different practice; in the present case it was taken as 3-32 inch.

The distance B of the second clearance hole from the center of the die blank is given by the formula

$$B = \frac{H}{2} - \left\{\frac{C}{2} + F\right\}$$

It will be seen from the accompanying tables of proportions that B and C are given in nearly all cases. In many of these it is impossible to drill C without a jig, in which case the second clearance hole may be filed. These tables give all the proportions derived from the foregoing method for laying out button dies for the A. S. M. E. standard and special machine screws.

Universal Application of Formulas.

The formulas may be applied to any case whatsoever, regardless of the number of flutes and relation of land to space. For example, they may be used for dies with say six lands.

Let n = number of lands,

α = land ratio,

β = space ratio,

then the formula in its general application will be

$$A = \frac{d}{2}\cos x + \sqrt{\left(\frac{D}{2}\right)^2 - \left(\frac{d}{2}\sin x\right)^2}$$

$$\text{where } x = \frac{360}{n \times (\alpha + \beta)} \times \frac{\beta}{2} \text{ degrees}$$

For a case of four lands with a ratio of land to space of 2 to 3

$$x = \frac{360}{4(2+3)} \times \frac{3}{2} = 27 \text{ degrees.}$$

---

[*] Address: Northern Electric & Mfg. Co., Ltd., 814 Notre Dame St., West Montreal, Canada.

The angle that the clearance hole makes with the axis of the teeth would be x — 5 or 22 degrees. This gives the necessary advance ahead of the center. For a second clearance hole the method is the same as outlined above.

In order to insure a good cutting edge on the die, the first clearance hole is lapped after hardening. This proves very satisfactory.

HOB GRINDING ATTACHMENT FOR THE PLANER.

To avoid the necessity for the constant attendance of an operator in sharpening hobs, an automatic arrangement for this work has been rigged up by Mr. H. C. Gilman, shop superintendent of the Philadelphia Gear Works, Philadelphia, Pa. This attachment is mounted on an old 16-inch planer and employs a very simple arrangement of mechanism for the necessary movements, automatically indexing the hob and feeding the wheel. Fig. 1 shows the attachment at work, and Fig. 2 is a diagram showing the arrangement of the mechanism.

Special index centers are provided. Indexing spindle *A* carries two dials. One of these, *B*, has ratchet teeth for indexing the spindle, while the larger one, *C*, is provided with notches for locking the spindle after the indexing. A "tip-up" dog *D* with a taper face is mounted on a bracket *E* fastened to the rear side of the bed. This dog engages the rounded end of a bar *F*, which slides in guides in the front face of the head-stock casting *G*. As the table starts on the forward stroke, the rounded end of *F* runs up the inclined face of the dog *D* pushing *F* to the right. The locking bolt *H*, clamped to *F* by the support shown, is thus released from the notch in locking dial *C;* and a counter-weighted pawl *J*, also pivoted to *F*, indexes the spindle by its action on dial *B*. When the end of *F* drops over the face of the dog *D*, the bolt *H* flies into place in the locking disk, holding the spindle in position for the next stroke of the wheel, while pawl *J* is brought back into engagement with the next tooth of ratchet *B*. This retraction of bar *F* is effected by spring *K*. On the backward stroke, as shown at the right of Fig. 2, dog *D* tips up to the position indicated by the dotted lines, allowing *F* to pass in this direction without interference.

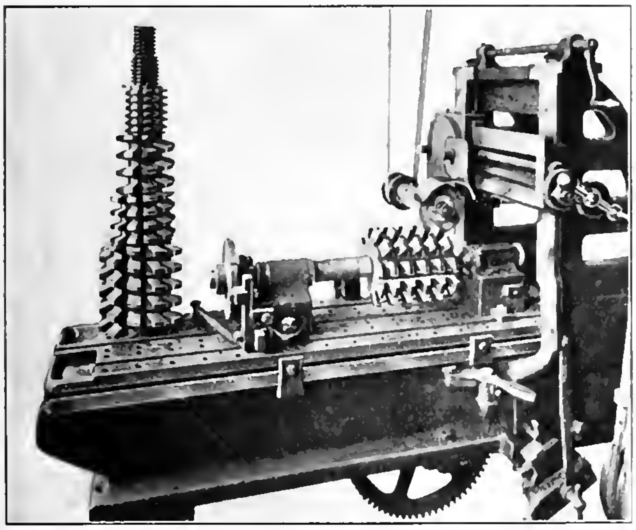

Fig. 1. Simple Planer Attachment for Sharpening Hobs.

The automatic feed arrangement is almost ridiculously simple. The feed-screw has an end movement of about 1/64 of an inch between its thrust collars. This end movement is taken up toward the right by a spring suitably placed at the left hand end. In setting up the machine for a grinding operation, the wheel is fed up against the face of the teeth until this slack is all taken up. When the machine is once started, it will continue to cut until 1/64 of an inch has been removed. On the first few cuts the end teeth are rounded, of course, but as the work progresses, the face is finished straight across. This machine has proved to be of such value that it is left permanently rigged as shown, and is constantly in demand.

CHECK SYSTEM FOR TOOL-ROOMS.

GEO. D. HADEN.

In order to determine the best system for keeping track of the tools lent to the workmen from the tool store-room, three methods, as outlined in the following, were tried in a well-known shop employing about five hundred hands.

With the first method, each man had a number of checks in his own keeping, and one of these was deposited with the store-keeper for each tool borrowed. This check was hung near the space previously occupied by the tool lent, in the usual manner.

As the foregoing method was somewhat unsatisfactory all checks were collected from the workmen, and kept on a board in charge of the store-keeper, from which they were removed and hung, as in the first case, when tools were borrowed.

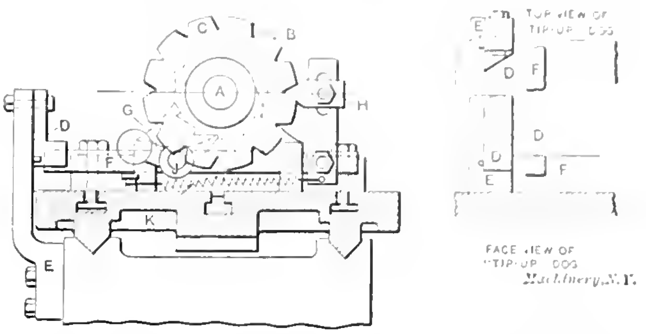

Fig. 2. Diagrammatical Sketch of the Mechanism shown in Fig. 1.

The second method also proved unsatisfactory and was abandoned. Loose printed slips of paper were then distributed in suitable boxes about the works, and each man was obliged to write on a slip his pay roll check number, what tool he required, the date, and his signature. This slip was then handed to the store-keeper in receipt for the tool borrowed, and the slips filed away in card cases, in numerical order, back of guide cards arranged to suit the various classes of tools, such as taps, reamers, cutters, etc. When the tool was returned, the slip was handed back to the man to be destroyed.

The first two methods are the ones commonly used where there is a tool store-room, some firms preferring one, and some the other. The first method was abandoned by the shop in question after a twelve months' trial, because the men could not, or would not, take care of their checks, and if one of these were lost, there was nothing to prevent its being used by another man, if he found it, for it was impossible for the store-boys to know whether every man handed in the proper check or not. Again, checks would occasionally get misplaced, causing considerable trouble. Various means were taken to prevent these troubles, but without success, and finally the second method was adopted. This was also given a twelve months' trial, and, if anything, proved rather worse than the first, as the store-boys misplaced the checks, omitted to replace them on the board when tools were returned, or, if there was more than one check on the hook, sometimes took off the wrong check. I do not think, however, that these boys were any worse than the average. No doubt some of the men contributed to the trouble by losing or mislaying a tool, and then claiming that it had been returned and that the boy had forgotten to replace the check on the board. The third method has now been in use about three months, and, so far, it has proved more successful than either of the other two. Of course, it takes longer to write out the slips, and there is a slight expense for paper, printing, etc., but this expenditure is more than offset by the satisfactory way in which the system works.

Perhaps some who read this may be inclined to say that the first system is the best, and greater firmness should have been exercised in order to keep it going. Possibly if I had not tried all three methods I should be inclined to say the same, but all will agree that with the same men, and under similar conditions, the system which causes the least trouble is the system to adopt, and this was done. Have any of your other readers had a similar experience?

VALVE GRINDING MACHINE.

J. F. MIRRIELEES *

A machine for grinding gas engine valves, designed to grind the particular style of valve shown in Fig. 1, is illustrated in Fig. 2. Previous to designing this machine, the best practice in valve grinding, in general, as applied to this style of valve, in particular, was thoroughly investigated; and from a series of experiments the following facts were established: The grinding speed should not be less than 50 feet per minute, nor more than 75 feet per minute; the valve must be rotated alternately in both directions, and one and a fractional part of a revolution each way is sufficient and even better than two or more revolutions; the valve must be raised clear of the seat and allowed to rotate freely; carborundum is the best abrasive for cutting, and emery flour the best for finishing.

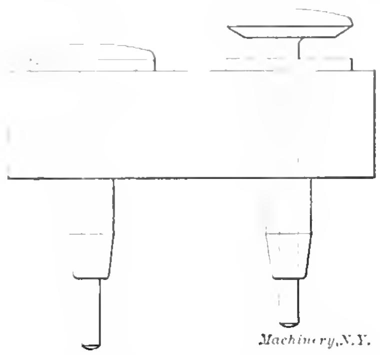

Fig. 1. Type of Valves for which the Machine shown in Fig. 2 was designed.

The necessity for reversing the motion and lifting the valve is much more pronounced when carborundum is used than when emery. The particles of the former seem to have a greater tendency to imbed themselves in the metal, and if this tendency is encouraged by rotating continuously in one direction, the particles become permanently imbedded, and grooves in the seat are the result. If the valves are not raised occasionally to allow the abrasive to distribute itself, the grinding will be ununiform. The machine here illustrated covers these points. When valves are to be ground with it, the seats, the style of which is shown in Fig. 1, are placed on the table of the machine. They are not secured, however, but allowed to center themselves at all times. The forks or drivers *A* grip the valves by means of suitable holes in the latter, and the valve stems extend through the table and directly above the lifter levers *C*. The variation in the length of the stems of the different size valves is regulated by means of parallel strips of thickness sufficient to make all stems extend through the table the same distance. Power is transmitted to the machine by means of a 2-inch belt on an 8-inch pulley which runs about 150 revolutions per minute. The power is then transmitted through a train of gears, which connects with the segment *M* plainly shown in the end elevation, thus giving a reversing motion to the shaft *D*. From this shaft through bevel pinions and gears, the spindles *E* are driven. The latter are held in quills *F* which, in turn, are held in heads *G* which are adjustable horizontally along the cross-rail *H*. The vertical adjustment of the spindles is automatic. Each spindle is splined in its quill, and the adjustment for different heights of work is made by spiral springs located above the spindles. The grinding pressure exerted is likewise regulated automatically. The larger seats, with larger valves and longer stems, must be raised from the table on strips so that the stems extend through just enough to clear the lifting levers *C*; consequently the spiral springs in the quills are compressed and press harder on the valves. Under the lifting levers *C* runs the shaft *I* upon which are located the cams *J* employed to actuate the lifting levers, which, in turn, lift the valves from their seats. The cams are placed quartering around the shaft so that but one valve raises at a time. The shape of the cams causes the valves to raise quickly, which, after revolving free momentarily, drop hard to their seats. The cam shaft is driven by means of sprockets and chains from the hub of the driving pulley. As will be seen by referring to the illustration, the lifting levers *C* may be operated by hand when desired. In order that work on any of the spindles may be stopped without interfering with the others, the little chains *K* are attached to the quills, and suitable button-head screws *L* inserted in the spindles, which, when raised, may be caught and held up by the chains.

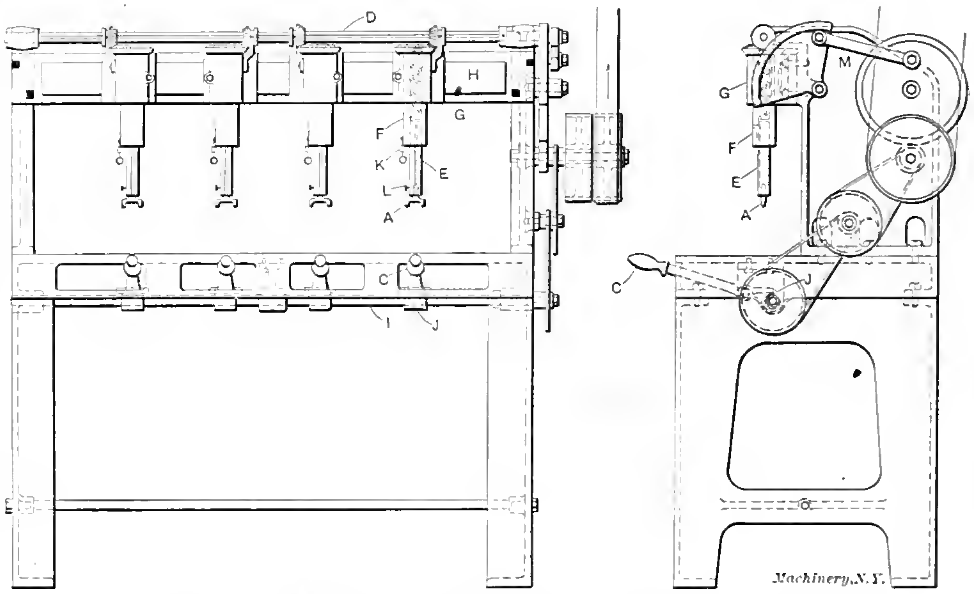

Fig. 2. Valve Grinding Machine which automatically Reverses the Movement of the Valves, and occasionally lifts them from their Seats.

The Maxim silencer or muffler for guns which has been referred to in recent numbers of MACHINERY was given a public test in New York, February 8. The silencer was applied to a variety of guns, from the 0.22 caliber to the high power Springfield 0.30 army rifle, and in all cases the efficiency of the device was conclusively demonstrated. The sound of the report was almost entirely eliminated, except in the case of the automatic rifles of the "blow-back" type. With these guns, the escape of gases at the breech made a perceptible report. With the other types of rifles the sound was confined to the whistle made by the bullet in its passage through the air, and its impact on the target. The silencer consists of a thin steel tube about 1½ inch in diameter, and 9 inches long, which is screwed onto the muzzle of the piece. The weight for the heaviest guns is about 11 ounces, and for the lighter ones about 8 ounces. The interior of the tube contains ten or twelve disks, perforated above center with a hole slightly larger than the caliber of the gun. The disks are rolled over into a shape somewhat like the vanes of a turbine water-wheel and cool and dissipate the gases at a low pressure because of the effect of the rotary and centrifugal action. The action is somewhat similar to that of water escaping from a wash basin. When the plug is pulled and the water allowed to flow, it acquires a circular action which may become so rapid that the water goes slowly through the hole and a clear space exists in the center through which air is drawn. The flow of the water is impeded by its rotary motion and the more rapidly it rotates the slower it escapes. Thus it is in the silencer; the gases are expanded and permitted to escape to the atmosphere only when the low pressure is attained. Perhaps the most useful purpose that the device will be applied to will not be as a silencer of guns but rather as a muffler for that useful worker, the gas engine.

STOVE BOLT TAPS.

S.

In the various articles that have appeared in MACHINERY from time to time regarding taps, nothing has been said about stove bolt taps, and as these taps, and likewise the bolts and screws, are provided with a form of thread which is an interesting example of a mongrel United States standard form of thread, perhaps some of the readers of MACHINERY would be interested in a description of them.

The thread has an angle of 60 degrees, with flat top and bottom which are equal in width. The width of the flats is wider than for the U. S. standard thread, being in some cases nearly one-quarter the pitch. The widths of flats being so wide as compared with the pitch, makes the thread shallow in comparison with other screw thread systems.

Below are given the widths of tools for the various sizes, and though the tools given are a little narrow in some cases, for reasons explained later, it will be shown that they are near enough for all practical purposes. However, if one wishes and has the proper instruments for measuring the widths of flats, the tools can be ground to the widths given. Where there has been any choice in the selection of the nearest U. S. standard threading tool, the one that is narrower than the width of the flat has been chosen, so that the flat on top of the tap would be wider than in the bottom, that it might be certain to take out enough material from the nut or tapped hole, to insure the bolt or screw turning easily. Should one, however, be making a hob tap to make a die for making stove bolts, it would be well to follow the dimensions given.

STOVE BOLT HAND TAPS.

Nominal Size.	Actual Diameter, Inches.	Root Diameter.	No. of Threads per Inch.	Total Length.	Length of Thread.	Length of Shank.	Size of Square.	Length of Square.	Approximate Machine Screw Tap Size.
5/32	0.167	0.134	28	2 1/8	13/16	1 5/16	1/8	7/32	8
3/16	0.200	0.157	24	2 1/4	7/8	1 3/8	5/32	1/4	10½
7/32	0.227	0.180	22	2 3/8	15/16	1 7/16	11/64	9/32	12½
1/4	0.260	0.203	18	2 1/2	1	1 1/2	3/16	5/16	15
5/16	0.317	0.2585	18	2 11/16	1 1/8	1 9/16	15/64	11/32	19½
3/8	0.352	0.287	16	2 15/16	1 1/4	1 11/16	1/4	3/8	22

Stove bolt taps are made 0.004 to 0.005 inch larger than the screw, so that the nuts may be a loose fit, a fit that would not be tolerated on any of the standard screw-thread systems for bolts and nuts. For this reason, the few ten-thousandths inch the threading tools are narrower than the table calls for would make but little difference in the fit of the nut.

NUMBER OF THREADS, WIDTH OF FLAT, AND THREADING TOOLS FOR STOVE BOLT TAPS.

Nominal Size of Tap.	Pitch.	Width of Flat.	Nearest U. S. Standard Threading Tool to Cut Thread.
5/32	28	0.0083	16 threads U. S. which is 0.0078 inch wide.
3/16	24	0.0084	
7/32	22	0.0092	14 threads which is 0.0089 inch wide
1/4	18	0.0113	11 threads which is 0.0114 inch wide
5/16	18	0.0109	12 threads which is 0.0104 inch wide
3/8	16	0.0125	10 threads which is 0.0125 inch wide

As mentioned, the taps are made oversize, and the nominal sizes are smaller than the actual sizes except in one case, the three-eighths, where the actual size is nearly one-thirty-second inch smaller than the nominal size.

It is obvious that special screws or bolts might become oversize before the days of micrometer calipers and screw-thread micrometer calipers, for unless the working gages are looked after carefully, and there is a master gage to which to refer these working gages occasionally, they will become worn, and so allow the screws to become larger than they were originally intended to be. This is probably what happened to stove bolts years ago.

Another example of this same idea is the so-called 41/64-inch shanks for twist drills, used principally by blacksmiths at the present time. These shanks instead of being 0.6406 inch, the decimal size of 41/64 inch, are 0.647 inch, which is about 0.006 inch oversize.

It is customary to make stove bolt hand taps with shanks the same diameter as the actual size of the tap, and the accompanying table has been figured to that end.

* * *

NEW HIGH-SPEED STEEL.

In an address delivered before the Royal Institution, Prof Arnold of Sheffield University said that within a year there would be on the market a British steel with quadruple the cutting power of any now known. What Prof. Arnold referred to was a product of the Continental Steel Works (Jonas & Colver, Ltd.) at Sheffield, just discovered and named "Novo Superior." Mr. B. W. Winder, the manager of the works, in an interview said the discovery was the outcome of litigation instituted by the Bethlehem Steel Company, which claims the patent rights on air-hardened high-speed steel. Experiments with a view to rendering themselves independent of the American claims, conducted by the Continental works, resulted in the discovery. A tool made of the old high-speed steel working on hard material at Sheffield had to be ground five times a day. A similar tool of the new process steel worked with one grinding for a day and a half, and was still sharp. The American agents for Jonas & Colver, Ltd., are Hermann Boker & Co., New York.

A later report states that the new steel can be readily annealed and that no other high-speed steel has any advantage over it in the matters of annealing, forging or nonsusceptibility to overheating. The makers recently tried a severe experiment. A tool made of the new steel was hardened seventeen times in cold water without showing a sign of a crack. It can be hardened also in oil, paraffin, or air blast. Prof. Arnold stated that it is an absolutely new departure in metallurgy to have obtained a water-hardened steel which will work for a long time with a keen edge at a low red heat when cutting hard steel. He added that in all probability every high-speed steel manufacturer in the country soon would be making the same steel, as the secret could not be long retained. From this statement it might be inferred that the process of manufacture is essentially simple.

* * *

TAYLOR-WHITE HIGH-SPEED PATENTS INVALID.

The United States Circuit Court of the District of New Jersey recently handed down a decision in the suit brought by the Bethlehem Steel Co. two years ago against the Niles-Bement-Pond Co. for infringement under the Taylor-White high-speed steel patents, deciding that the nineteen claims of the plaintiff were invalid. The testimony covered about 5,000 typewritten sheets and reviewed much of the history of steel making from the time cast steel was first made down to the discovery of the Taylor-White process. It evidently was shown to the satisfaction of the court that the process was not essentially a new one and that the testimony of important witnesses was biased. The case was reopened last November and then it was shown from certain copy books or other records of the Bethlehem Steel Co. that the principal inventor had received a valuable concession in consideration of testimony favorable to the Bethlehem Steel Co., to which the patent had been assigned. The court severely scored the witnesses and declared that all the claims made by the Bethlehem Steel Co. were invalid.

* * *

In its famous decision on eighty-cent gas legislation, the Supreme Court of the United States made an important ruling in regard to the value of good will. It is to the effect that good will is not a concrete thing that can be capitalized in a city where a public utility corporation has monopoly of its particular business. The decision virtually limits the value of the franchise to the allowable capitalization at the time the franchise was granted. The growth of a city and the increased earning power of the monopoly cannot be employed as excuses to increase the capitalization. A city's inhabitants are entitled to the same service for less cost when it can be shown that the increase of population enables the public utility corporations to produce much cheaper than before.

LETTERS UPON PRACTICAL SUBJECTS.

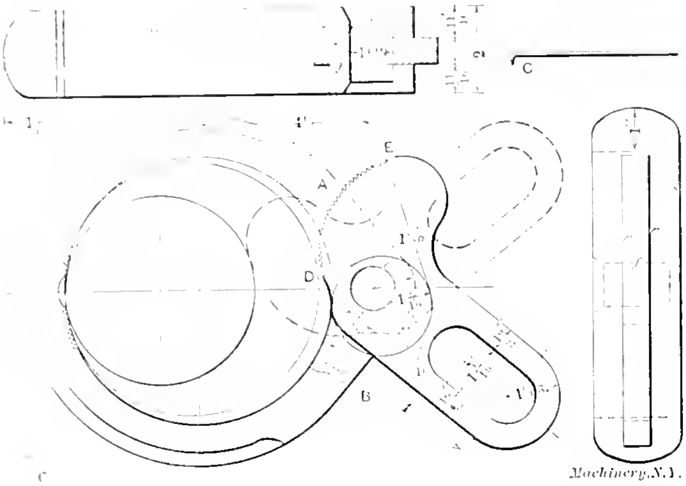
LATHE DRIVER FOR ROUND STOCK.

The accompanying engraving shows an excellent style of dog or driver which has been found by use to remedy the difficulties that often occur when driving large, round work in the lathe, which requires heavy cuts and high speed. The reader can readily see without a lengthy explanation, that it would be impossible for this dog to release its grip, for the larger the cut the more the teeth will bite. It is made of a low grade of tool steel, and the teeth are given a chisel temper, so that they will not bend or break when the strain comes. To generate the curve of the toothed surface *A*, secure a cylindrical piece having a diameter equal to that of the generating circle *B*, and locate it concentric with the generating circle. Obtain a piece of small wire, and bend and sharpen one end for a scriber, as shown at *C*. Wind the wire around the cylindrical piece, and, beginning at *D*, scribe the curve to a point *E*, as the wire is unwound. Those who have experienced difficulties in this line will be well repaid by giving this driver a trial.



Dog adapted to Driving Large Cylindrical Work in the Lathe

R. F. S.

GAGES FOR ACCURATELY SIZING BEVEL GEAR BLANKS.

In the manufacture of our sensitive high speed universal milling attachment, we use quite a number of small bevel gears, and as the gears sometimes run at a high speed, it is necessary that they should be accurately planed. To facilitate the sizing of the blanks, the writer designed the gages illustrated in Figs. 2 and 3, which were made to gage the blanks for the miter gears shown in Fig. 1. As these are miter gears, the face angles are, of course, the same, but it will be noticed that one has a longer hub than the other, which necessitates making two gages. The parts of the attachment in which these gears run are very accurately machined with reference to the distance from the hub of one gear to the center of the other, so that if the blanks are correctly sized and cut, they will go in place and run properly without fitting.

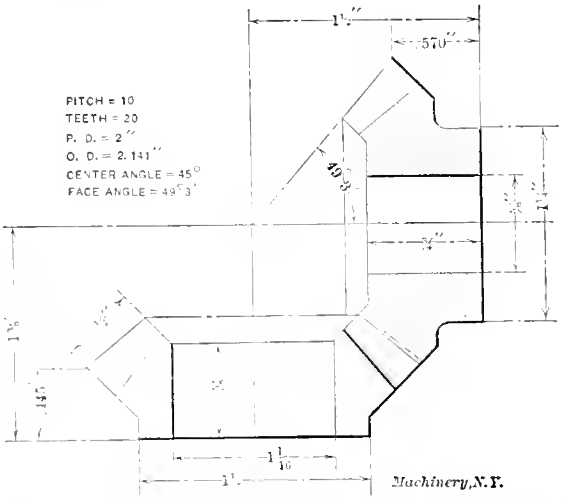


Fig. 1. Miter Gears for which Gages in Figs. 2 and 3 were made.

The following method was used to obtain the gage dimensions. We will take the gage shown in Fig. 2, which is used for sizing the gear with the long hub.

The distance from the hub of this gear to the center of the other shaft is 1½ inch, and the face angle is 49 degrees 3 minutes. The triangular opening in the gage should correspond exactly to these dimensions. To obtain this result the size of a circular plug gage which would just pass through the triangular opening, was determined as follows.

It is evident from Fig. 2 that as the triangle *A G B* is an isosceles triangle, if a circle be inscribed in it, the center of the circle must be somewhere on the line *C D* which bisects the angle *A G B* and the line *A B*. It must also be somewhere on the line *A E* which bisects the angle *G A B;* therefore it must be at the point where these two lines intersect. $GF = 1.5$ inch; angle $AGF = 49$ degrees 3 minutes; therefore $AF = 1.5 \times \tan$ 49 degrees 3 minutes $= 1.5 \times 1.1524 = 1.7286$. One-half of the angle $GAF = 20$ degrees 28½ minutes; $OF = AF \times \tan$ 20 degrees 28½ minutes $= 1.7286 \times 0.37339 = 0.6454$ inch, which is the radius of the inscribed circle; $2 \times 0.6454 = 1.2908$ inch, diameter of inscribed circle or plug gage. The same process was, of course, used to obtain the size of the gage shown in Fig. 3. The gages were made from ¼-inch cold rolled sheet steel; larger ones may be made from thicker material. The outside of the gages was worked out with a hacksaw and smoothed up with a file. The inside was drilled out, leaving about 1/16 inch on each side to be finished with a universal milling attachment. The gages were strapped to the face-plate of a Brown & Sharpe 60 to 1 index head while being milled out, the head being set at 90 degrees; the gage rested on three parallels to allow the end mill to get into the work without danger of milling into the head, and also to assist in using the plug gage. The job was set so as to bring the side *A G* in line with the table travel, and that side was finished down to the line with a small end mill; we now turn the head 98 degrees 6 minutes, which with a 60 head and 60 hole plate, is 16 turns and 21 holes for the index pin (one turn equals 6 degrees, and with the 60 hole plate 1 degree or 60 minutes equals 10 holes, and therefore 1 hole equals one-tenth of 60 minutes or 6 minutes.

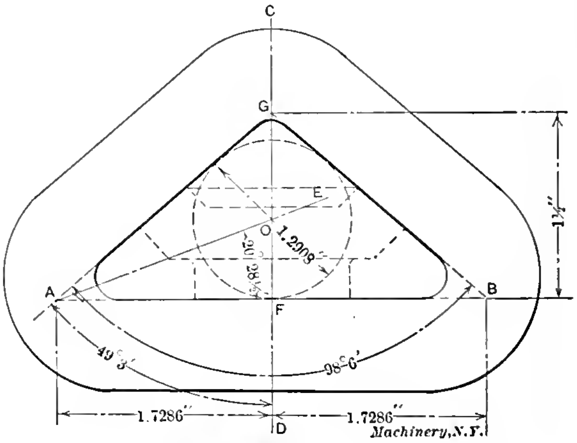

Fig. 2. Gage for Miter Gear with Long Hub in Fig. 1.

This brings the side *G B* in line to be milled. After it has been finished down to the line we turn the index pin 6 turns and 49½ holes farther, which brings the side *A B* in line to be milled, and this side is worked out until it is a good fit on the plug gage.

The ½ hole in the last indexing was guessed at, and this proved to be accurate enough, for when a blank had a good smooth finish on the face and was sized so that it would just pass through the gage without binding we could not see light through anywhere between the blank and the gage.

The indexing, of course, was just the same for the gage shown in Fig. 3, as the only difference in the two gages is the size of the opening.

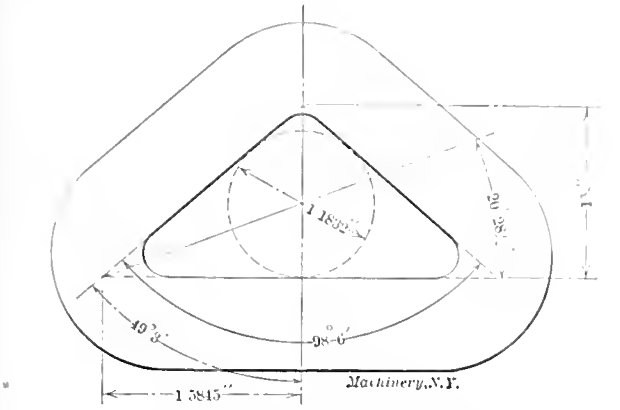

Fig. 3. Gage for Miter Gear with Short Hub.

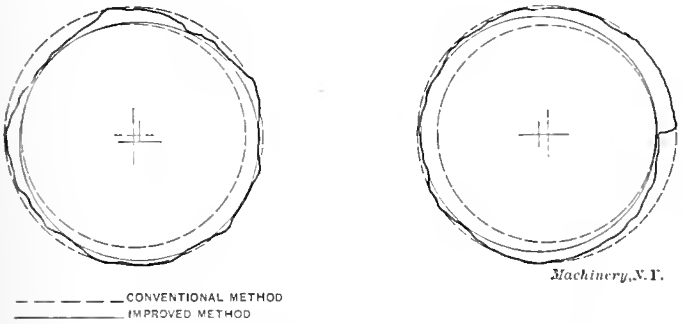
We have made up quite a number of these gages and they have given excellent satisfaction, and it would seem that this same scheme might be used to advantage in a good many instances and in various ways.

Syracuse, N. Y. GEORGE. D. PORTER,
The Porter-Cable Machine Co.

TRUING ROUGH WORK.

There is a fundamental error in the conventional method of truing rough work, such as forgings or castings, especially large ones, in the lathe. There are two requisites, either of which may determine whether the piece is true enough. First, it is desirable that the point of the tool should get beneath the scale on the first cut, and if the piece runs out too much, the point of the tool will not reach the low spots. This dulls the tool and it will probably be necessary to run the lathe at a slower speed. In the second place, the casting or forging may be barely large enough to finish to the desired size, and therefore requires to be trued accurately. The usual method is to hold a piece of chalk close enough to the work, as it revolves, to touch the high places. The work is then adjusted or re-centered, and tried repeatedly until the chalk will touch opposite points, and, perhaps, additional points between these. The result is that the highest points are running true, and when they are turned off it is the low spots that run out and cause the trouble.



Diagrams showing why Work should be trued by the Low rather than by the High Spots.

What is needed is a method that will true the work by the low spots, instead of by the high ones. To do this, place a tool in tool-post, parallel to the ways and say an inch from the work. Then turn the work a little at a time and measure from it to the tool until the spot farthest from the tool is found. This is, of course, the low spot, and we shall assume, for example, that it is 7/16 of an inch farther from the tool than the opposite side. Hold a scale against this low place and adjust the work until it has moved one-half of the distance it is out which, in this case would be 7/32 of an inch. Repeat this operation until the low spots all measure practically the same. The piece is then trued so that it will clean up to the best advantage. If the work is long, it is better to test both ends and the middle. When the lowest spot or depression is found, it is well to mark the place and then when the piece is ready to be turned, set the tool by this low spot and note the position of the feed handle. Then when setting the tool for the first cut, it may be adjusted so that it just cleans the entire surface of the work. On a long forging that is sprung, such as a crank shaft, this method will show whether it can be turned to size without straightening.

Wonalancet, N. H. CHARLES E. BURNS.

ATTACHMENT FOR MILLING HALF CIRCLES IN DROP-FORGE DIES.

In the engraving, Fig. 1, is shown an attachment for the milling machine, which is used for milling out circular recesses in dies used in drop forging. It consists of a frame *A* (see Fig. 2), which supports an arbor *B* upon which is mounted a spur gear *C*, which is in mesh with and drives the milling cutter *D*. This cutter is supported between two adjustable spindles *E* the ends of which fit into recesses in its sides as shown in the detail Fig. 3. When it is desired to remove the cutter, the spindles may be withdrawn by the screws shown. The spur gear shown on the arbor in Fig. 1, will drive cutters for milling any circle from 1¼ to 4 inches in diameter. The gear and cutter seen on the die are for milling circles smaller than 1¼ inch in diameter. Different size cutters may be placed in mesh with the driving gear by loosening the bolts which hold the slides *F* in place and adjusting the latter to the vertical position required. This driving gear is driven by a key and is made of machinery steel and case-hardened. The cutter is shaped somewhat like a spur gear, except that the cutting faces of the teeth are flat and part of the addenda or tops of the teeth are removed to make them stronger. The outside diameter may be altered, within reasonable limits, to suit the required diameter of the recess. The cutters should have 10 diametral pitch if larger than 0.9 inch pitch diameter, and 14

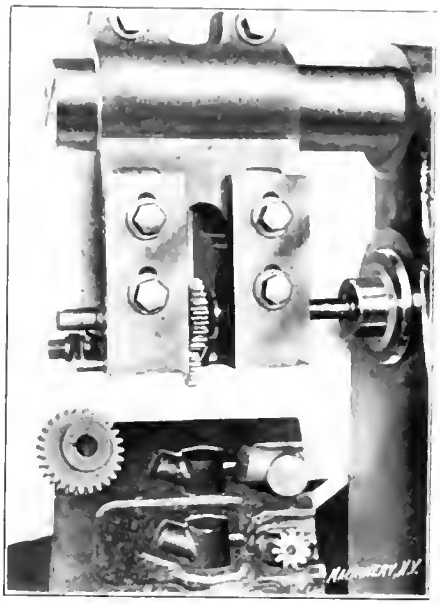


Fig. 1. Attachment for Milling Drop-forge Dies and Example of the Work.

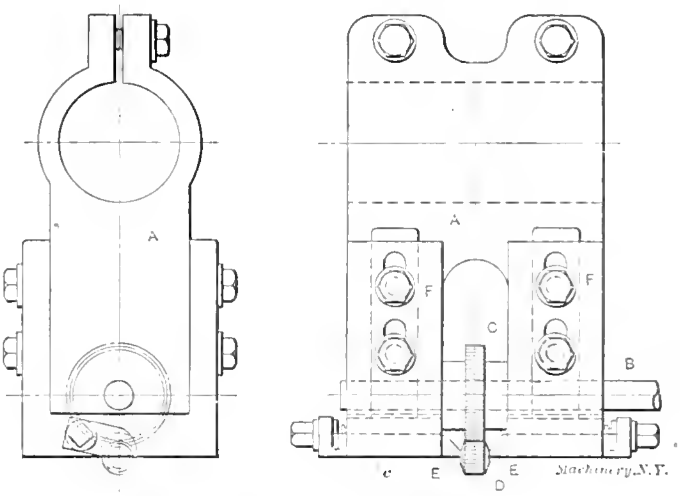

Fig 2. Elevations of the Die Milling Attachment.

diametral pitch if smaller. The centers of the circular ends of the spindles *E* are 1/32 inch below the bottom face *c* of the frame so that the center of a circular recess may be milled flush with or slightly below the surface of the die. The die shown in Fig. 1, which is used for forging brackets

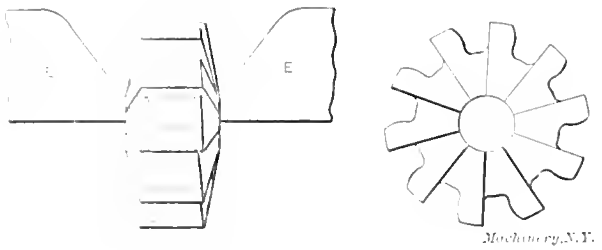

Fig. 3. Enlarged View showing Cutter and Ends of Spindles upon which it revolves.

for bicycle frames, is an example of the work done with this attachment. We have been milling dies in this way for some time and the method certainly "knocks the spots" out of chipping and filing. **Fred Terry.**

West Toronto, Canada.

BINDER FOR PRESERVING ARTICLES OF SPECIAL INTEREST.

The illustrations, Figs. 1 and 2, show a binder or holder which will be found convenient for preserving the various articles on special tools, processes, etc., published in Machinery, which I think will be appreciated by many mechanics wishing to keep these articles ready for reference. Fig. 1 shows a view of the closed holder, which is simply an old ledger book with all the leaves cut out to within about one inch of the binding. Pages from Machinery containing articles of special interest are fastened into the holder by pasting them to these short leaves, as indicated in Fig. 2. If the back of the page contains nothing of particular interest, short articles or interesting notes can be pasted upon it, as shown to the left, in Fig. 2. If possible, it is better to obtain a cover which exceeds the size of the page by about one-half inch. The writer was fortunate enough to secure a new invoice book with gummed leaves, which is admirably adapted to this purpose.

Fig. 1. View of the Closed Binder.

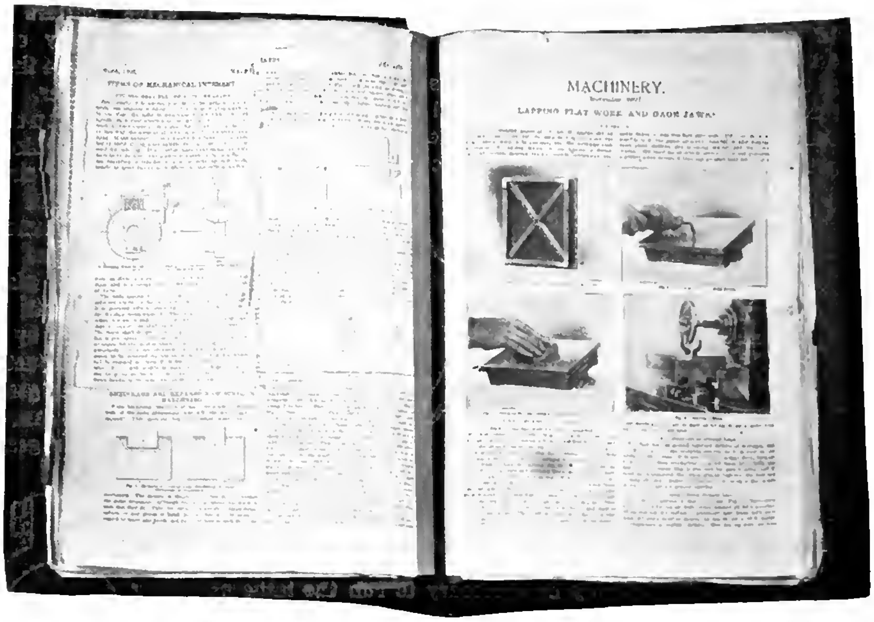

Fig. 2. View of the Opened Binder, showing the Method of Attaching the Leaves.

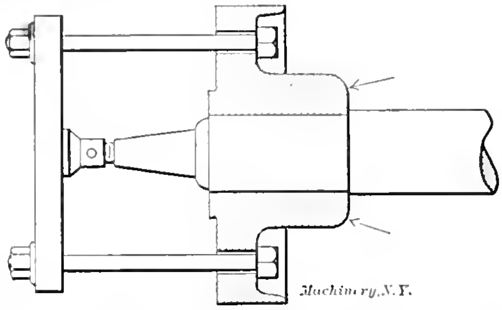
By the use of such a binder, a very valuable book may be made up in a comparatively short time, which will go well with Machinery's Data Sheets, and Shop Operation Sheets, and in this way a large amount of material, valuable for reference purposes, may be kept in a small compass, thus enabling the mechanic to keep track of various modern appliances and ways of doing work. **J. A. Caless.**

Providence, R. I.

REMOVING A FLANGE COUPLING FROM A SHAFT.

No doubt many of the readers of Machinery have had experience in removing flange couplings from shafts, and have found that it is not always an easy job. This is especially true if the shaft is of considerable size and has run in a damp pit for several years and consequently has become corroded. Such was the condition of a coupling on an 8-inch shaft in a tube mill in which the writer was employed. This coupling had to be removed, and, of course, it was a Sunday job. The honor (?) fell to another machinist and myself, with the assistance of a couple of husky laborers. The shaft was first jacked up in a convenient working position, and the coupling and shaft well soaked with kerosene.



Removing a Flange Coupling by the Application of Blows in conjunction with Pressure.

Sledging was then tried, but to no avail, so a fire was kindled under the coupling with the idea of expanding it and, of course, removing it with ease. To facilitate the heating process, a gas pipe was run from one of the nearby heating furnaces. After the coupling was thoroughly heated, sledging was again resorted to, but it seemed as solid on the shaft as ever and refused to move. It was then decided to subject the coupling to a pressure while it was being struck with the sledge. To accomplish this, a couple of 1¼-inch bolts, a heavy cross-piece, and a jack screw were procured and arranged as shown in the engraving. The jack was tightened as tight as one man could pull it, and then, while two men did the sledging at the points shown by the arrows, one man pulled on the lever of the jack-screw. In this way the coupling was moved an appreciable amount with each blow of the sledge. It was removed slowly, of course, but with comparative ease.

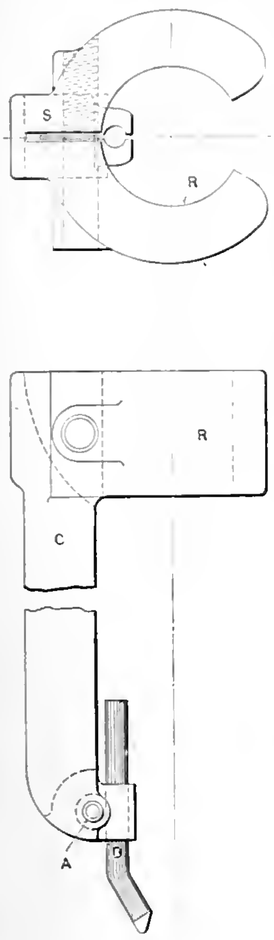
This "kink" may be familiar to some, and probably there are those who know of a better way of doing the job, but to any who have work of this nature to do and do not happen to have a better way, I can conscientiously recommend the above method, as it proved in actual practice to be effective. **T. W. H.**

[The method of removing the flange coupling, as described in the foregoing, by the application of blows from a sledge in conjunction with pressure from a jack, can often be advantageously applied in connection with work of this kind. Tight locomotive frame bolts can often be started by applying pressure from beneath with a jack, and then striking the frame, near the bolt head, a sharp blow with a sledge. The work of forcing crank-pins, locomotive driving-box brasses, etc., in place, when power presses are not available, can also be greatly facilitated by the application of this method.—Editor.]

DRILL STOP.

The appliance shown in the accompanying engraving is intended to act as a stop for the drill press when drilling holes required to be of a certain depth, using the hand feed. The feature of the device is that the stop pin *D* acts directly against the top surface of the work to be drilled, so that the depth of the hole to be drilled will always be gaged in relation to this surface. The appliance was introduced for the purpose of drilling a number of ⅝-inch holes exactly ¾ inch deep. The casting *C* is provided with an open ring *R* at the top, which is finished on the inside to fit the sleeve of the drill press. A ⅛-inch slot is sawed into the casting *C* at *S*, and a collar-head screw tightens the finished ring on the drill press sleeve. The pin *D*, at the lower end of the casting *C*, is made of ⅜-inch drill rod; the point of this pin is slightly rounded, so that it will always find its way through the chips down to the solid surface of the work. The point is adjustable up and down and is held in place by a screw at *A*. When the pin *D* is once adjusted so as to allow the drill to enter into the stock the required depth, no more attention need be given it. The point of the pin is bent so as to bring it near the drilled hole. The fixture is very cheap and simple to make, but it answers the purpose for which it is intended very nicely.

R. B. Lovejoy.



A Stop for Drilling Holes of Uniform Depth.

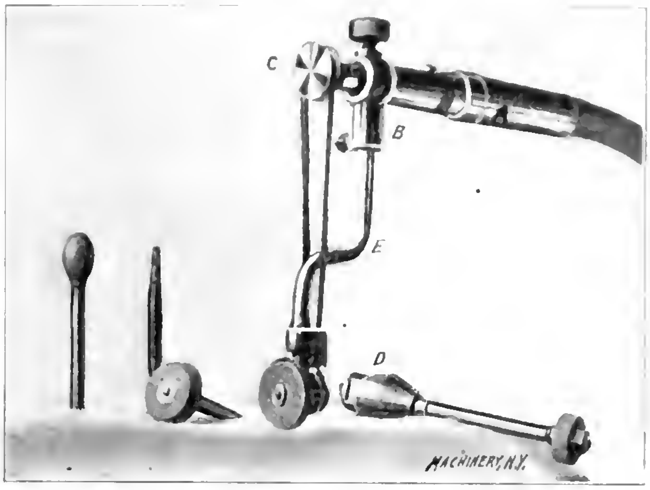
[It will be noted that this stop for the drill press differs in some important respects from such stops as may be provided right on the spindle in the form of collars, nuts, etc. When once set in relation to the drill employed, it will always prevent the drill from entering into a piece of work more than a fixed amount, inasmuch as the pin *D* stops against the top surface of the work itself. In the case of a collar or nut applied directly to the spindle, if the table be lowered or raised, the depth to which the drill will enter into the work will vary accordingly; hence the advantage of a drill stop such as illustrated.—Editor.]

ATTACHMENTS FOR FLEXIBLE SHAFT GRINDER.

The accompanying engraving shows the attachments that we use in connection with a flexible grinder, all of which will be found most convenient in any shop where steel of irregular shapes has to be worked or ground. *A* is the stationary part of the flexible shaft to which is fitted clamp *B* which holds the emery wheel extension equipped with a small pulley, as shown. On this extension and near to the emery wheel is soldered a piece of sheet metal which serves to increase the belt contact, thus preventing slipping. Slackness in the belt is taken up by adjusting the rod *E* in clamp *B*. Pulley *C* is the driver and is screwed direct to the revolving member of the flexible shaft. The belt is in one piece cut from the rawhide with a sharp knife, thus avoiding any joint.

This attachment is used principally on drop-forging dies, and with it concave surfaces can be reached and ground, that would otherwise be inaccessible. The attachment and pulley *C* can be removed and replaced by small chuck *D*, which holds the tools shown in the engraving. The two emery wheels are most convenient for grinding hardened punches and dies, or the rougher class of drill bushings that just need the high sides eased off. The burrs to the left, which are cut similar to a file, also fit chuck *D* and are used for drop forging dies. This flexible shaft is held in the hand, resembling an overgrown dentist's engine. It should run at about 3,000 R.P.M., and will save lots of hard scraping, lapping or polishing, according to the nature of the job.

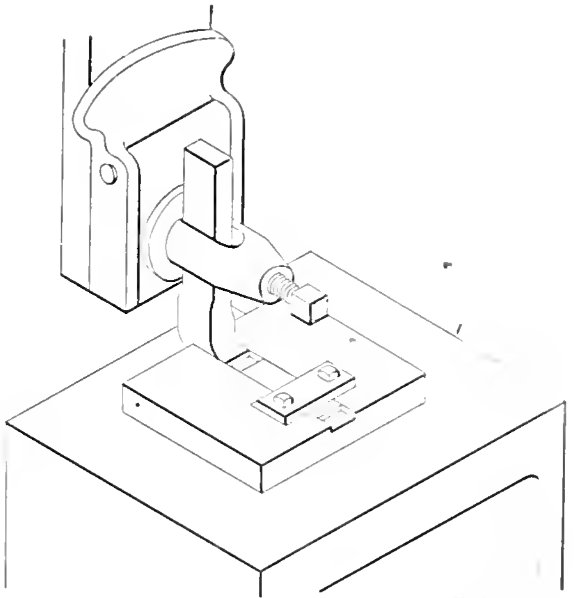
West Toronto, Canada. W. J. Thompson.



Attachments and Tools for Flexible Shaft Grinder

OLD SHAPER CONVERTED INTO A SHAVER.

An old, worn-out shaper was once put to work reducing the stock on printers' slugs, but not in the usual manner. These slugs were both of steel and of brass, some 0.083 inch and some 0.166 inch thick. The stock, as it came from the mills, was from 0.001 to 0.003 inch too large, and as these slugs were put through in lots of several thousand at a time it was no small task to bring them down to exact size. After experimenting in different ways that all proved too slow, an old shaper was converted into a "shaver," as shown in the line engraving. The block on the table was grooved 0.83 inch deep, and across one end of the groove was bolted a hardened strip of flat steel for a cutter. This strip was slightly raised



Shaving Printers' Slugs to the Proper Thickness in the Shaper

at the [illegible] end to give the slug clearance as it was passing through. The slugs were shaved as fast as they could be fed in by the succeeding pieces pushing out the previous ones so that the tool did not have to run far under the cutter and could therefore be made with a short and stiff end. Directly beneath the cutter was inserted a hardened plug furnished with means of adjustment after being ground. An occasional drop of oil on the cutting edge was necessary to prevent "lating."

When the thicker slugs were shaved the cutter was raised by putting under it steel blocks 0.083 inch thick, leaving a space 0.166 inch high. It will be noticed that one edge of the cutter is ground square and the other with a bevel face. For work on the brass slugs the cutter was reversed and the edge with no rake brought into service. **Donald A. Hampson.**

Middletown, N. Y.

[A device in which identically the same principle was made use of was illustrated in the March, 1900, issue of Machinery, and was contributed by Mr. W. A. Bright. Here drop-forged keys, which were too wide, were shaved off from 0.010 to 0.012 inch on the side.—Editor.]

MACHINE FOR GRADUATING INDEX WASHERS.

A hand-operated machine for graduating the index washers used on the screws of lathe saddles and milling machines, is shown in Fig. 1. This machine automatically indexes the work and varies the length, in this case, of every fifth and tenth graduation line as illustrated in Fig. 2. The cutting tool *A*, which is adjusted by the knurled screw *B* for dials of different diameters, is mounted on a slide *C* which is reciprocated back and forth by the handle *D*. The work is mounted on an arbor having a taper shank which is inserted in the spindle of the machine. Attached to the end of the spindle is a worm-wheel meshing with a worm on the shaft of which ratchet *E* is mounted. As will be seen in the engraving, the pawl which meshes with this ratchet is operated by tappets on the rod *F*, which is attached to the slide *C*. In this way the work is indexed for each stroke of the tool, the movement taking place on the back stroke. The lengths of the graduations are regulated by the adjustable screw *G*, which strikes against the top of the pivoted tool *A*, thus lifting it out of its cut. As the tool leaves the cut the marks are tapered to a point, and this finish gives them a very neat appearance. The lever *H* to which the stop-screw *G* is attached, is pivoted in the center, as shown. The end of this lever is pressed against a cam, by means of a flat spring, which is located just back of the ratchet wheel *J*. As the cam is rotated by means of the ratchet and pawl which connects with the rod *F*, it presents to the end of the lever *H* which presses against it, slight indentations at each half revolution, into which the end of the lever is pressed, thus varying the position of the screw *G* and changing the length of the graduation mark. This cam is rotated in such a ratio to the work, that the end of the lever sinks into a depression at every fifth and tenth stroke, and, as one depression is slightly deeper than the other, each tenth stroke of the tool is made longer, as illustrated in Fig. 2. The particular machine shown is geared to graduate the work into 250 divisions, but, obviously, different numbers of graduations could be provided for.

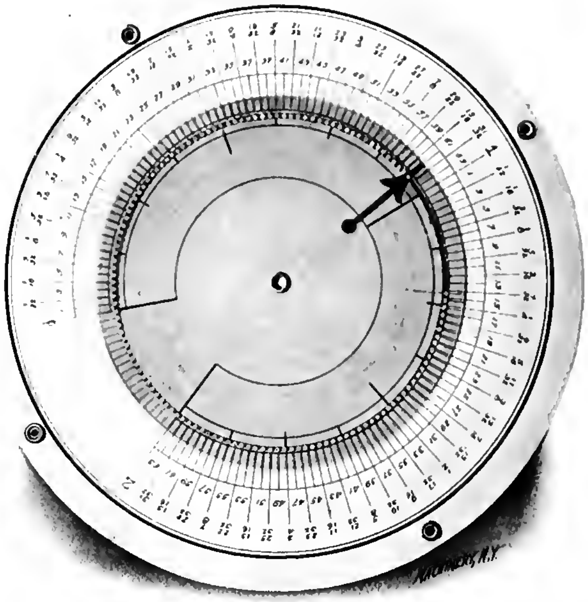
CIRCULAR "SLIDE-RULE" FOR ADDITION AND SUBTRACTION OF FRACTIONS.

The accompanying halftone shows a very useful device for use in any engineering office and for the aid of any shop man having considerable work to do in the way of checking drawings. The purpose of the device is to assist in quickly and correctly adding common fractions, and a little practice with the device will fully demonstrate its usefulness. It is made from two celluloid disks, one larger in diameter than the other, and pivoted together in such a manner that the upper or smaller disk can be moved around the center relative to the larger or bottom disk. The manner in which the larger disk is graduated is plainly shown in the illustration. Each of the small divisions represents one-sixty-fourth of an inch.



Device for Adding and Subtracting Fractions.

To illustrate its use, suppose we desire to work the following example: 5/64 + 5/16 + 1/2 + 1/16. The process would be as follows: Place the chart at your left hand with the ends of the fingers resting lightly upon the lower disk, and with the pencil in the right hand, place the point in the small hole at the arrow and move the disk around by this means until the arrow point is opposite and in line with the graduation 5/64, then hold the disk with the finger of the left hand and set the pencil in the small hole opposite zero; now again move the disk without removing the pencil from the hole until the line coinciding with this hole on the upper disk is opposite 5/16; again, hold the upper disk with the left hand and set the pencil back to zero without moving the disk; again, place it in the new hole opposite zero and move the disk around until the line coincides with 1/2; repeat the operation setting the pencil point back to zero and rotating the disk to 1/16; finally read opposite the arrow point 61/64, or the sum of the several fractions.

Any number of fractions can be added, if after the arrow has passed the point marked 1, the pencil is set in the hole opposite this point and the disk moved back to zero, which in reality deducts one whole unit from the sum of the fractions, and this point carried to the column of units, which are

added. The purpose of this device is for adding fractions only, the whole numbers being added mentally or otherwise. A fraction may be as readily subtracted as added if the operation is reversed. A column of fractions may be added and one subtracted from it without taking any note of any of the readings except the final answer. F. N. WHITESELL.

Three Rivers, Mich.

TOOLS FOR BENDING PIPES.

The articles describing pipe bending devices in the September and December issues, have been very interesting to me because they represent the very latest practice in fixtures of this kind. Especially is this true of Mr. Little's article in the December number, in which he takes pains to explain a few of the important details, the neglect of which is likely to cause trouble for a novice in this line. All of Mr. Little's suggestions are of a very practical nature, and my experience has been such as to give endorsement to them all with the slight exception of the one in which reference was made to the shape of the "business end" of the horn or mandrel. Where the wall of the tube is comparatively heavy and the radius of the bend large, it is possible to bend the pipe with a mandrel that is simply rounded on the end by a cut-and-try method, but the conditions are quite different when the material to be bent is thin brass tubing, say about 26 B. &. S. gage (0.015 inch thick). I will state my problem, describe the fixture for bending the tube, and also the method of obtaining the correct shape for the end of the mandrel.

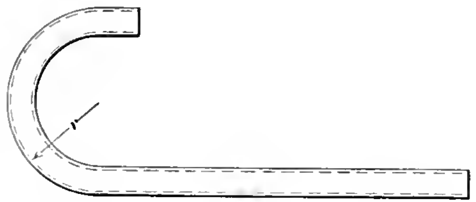


Fig. 1. Shape of the Bend produced by the Tools shown in Figs. 2 and 4.

The tube to be bent is shown in its finished shape in Fig. 1. It is used in the manufacture of a cheap inverted incandescent burner, and the output was required to be at least 2,000 per day. Subsequent polishing made it imperative that the bend should be clean, uniform, and free from any sign of buckling. The fixture shown in Fig. 2 is almost identical in construction with that shown in the December issue, and it is therefore unnecessary to describe it in detail. I was able to omit the backing block, and a slight variation in the size of the tubing made it inadvisable to continue the radius R of the swivel block beyond the center of the pipe. Inasmuch as the bend is a complete return, the pipe can be slipped off the mandrel without removing the cam-lever *D* and block *F*. In operating the fixture the tubing, having been cut to length, is slightly moistened with oil on one end and this end is slipped over the mandrel *A* to the stop collar *B*. Then, by grasping the long handle *C* and the cam-lever *D* at the same time, the tube is clamped and the bend quickly started. The bend is finished by bringing the handle *C* up to the adjustable stop *E*. While the long handle *C* remains in this position, the cam-lever *D* is opened and the bent tube is pushed off with the aid of any straight piece applied to the end which remains on the mandrel. The long handle is then brought around in position to make another bend. The method of shaping the end of the mandrel is illustrated in Fig. 3. The body of the mandrel is first finished so as to be a sliding fit in the inside of the tube. It is then centered in the chuck and formed by means of a radius tool *T*, having a radius *t* equal to the radius of the mandrel, and a compound rest set to the proper radius *r* (see Figs. 1 and 3.) As the cutting tool is swiveled about the end of the mandrel, which is held stationary, the latter is given the correct shape.

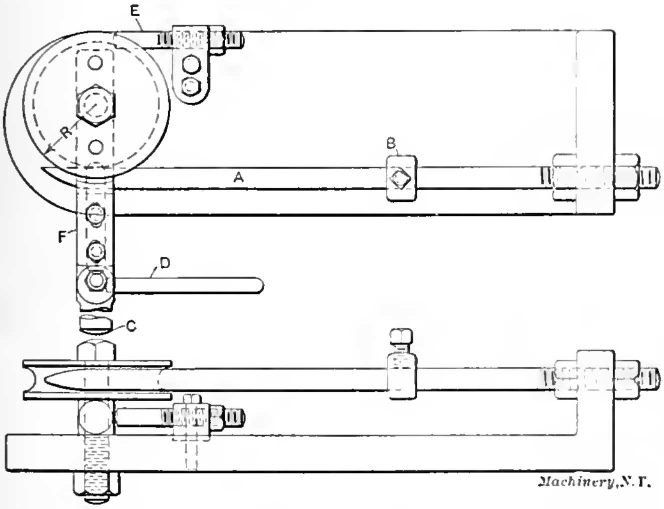

Fig. 2. Hand-operated Tool which bends Thin Tubing without Buckling.

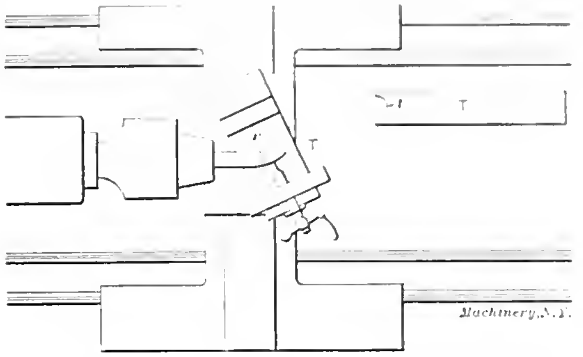

Fig. 3. Method of forming the End of Mandrel A in Fig. 2

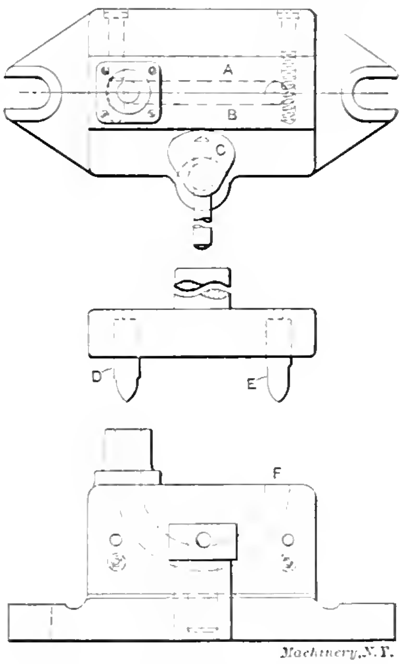

Fig. 4 Punch and Die for Forming the Bend shown in Fig 1

In connection with pipe bending devices, I wish to add a few words in corroboration of your very able editorial on Toolmaking and Manufacturing," published in the December number. There exists today among tool-makers and those having charge of laying out processes of manufacture, a very regrettable lack of knowledge and appreciation of the financial side of every proposition which comes up for consideration. To illustrate my meaning, I wish to call attention to the punch and die, illustrated in Fig. 4, for accomplishing the same results as the hand-operated fixture shown in Fig. 2. When the question of how this work was to be done came up for discussion, the foreman of the tool department (a first-class mechanic but a sad failure as a business man) was very positive about the meritorious features of the die, and the general manager and I, not having had sufficient experience in this particular line, could not, as a matter of course, offer any serious or well-based arguments against its construction. The die was made as shown, and consists essentially of two steel blocks held together by a cam *C*. A semi-circular groove of the radius of the bend was milled in the face of each block. The punch *D*, descending, pushes the straight piece of tube through the opening between the two blocks. When the operation has been almost completed, one end of the tube, slightly out of round, appears through the opening *F* in the die, and the punch *E* performs the function of giving the hole in this end its original round shape. The cam

is then released, two springs force the blocks apart and the completed article is withdrawn.

Mechanically, the die was a brilliant success and the operation itself was very interesting—so much so, in fact, that it was one of the things which was always called to the attention of visiting stockholders; but commercially it was a difficult matter to make it show a profit. You see it required that a specially-made, slow-speed, long-stroke press should be kept tied up, thus at the outset putting a big handicap on our capacity for some long-drawn brass shells, the weekly output of which was one of the main sources of the factory's income. Naturally, it was impossible to draw shells by hand, and after our good die had withstood a few days' competition with the bending machine, it was only to be expected that it would be put on the shelf, where it has been ever since. Even when the matter is figured down to a plain business basis, the balance is all in favor of the hand-operated fixture. The interest of the money invested in the press and die, the large amount of floor space occupied, the cost of power, maintenance and depreciation, were all heavy charges against the die as compared with the corresponding charges against the fixture; and above all, the accident liability, which is such a troublesome feature in all factories, was practically eliminated on this particular operation. Therefore it must not be taken for granted that everything that is new, novel, and different, will pay a good return on the money invested. HENRY J. BACHMANN.

New York City.

TURNING SOFT RUBBER.

An inquiry appeared in the December issue of MACHINERY in regard to the best method of turning soft rubber. In my opinion, there is nothing which beats grinding. If a knife must be used, it should be kept flooded with water, for as two freshly cut rubber surfaces (rubber being a homogeneous mass, i. e., when properly vulcanized) will adhere considerably if allowed to come together, a great deal of heat is also generated in parting the particles. After seven years experience in a rubber works, where a part of my duties were to weigh the various compounds, I would venture to state that the correspondent who advocates using no lubricant, has never had the pleasure of dissecting a hand of the pure upriver fine Para. He may, however, be correct in his theory about using no lubricant, when we take into consideration the article that perhaps he has been led to believe is soft rubber. The question naturally arises as to what soft rubber is. About the only pure soft rubber that I know of is found in the common rubber band. I do not say that pure, soft rubber cannot be bought, but years ago rubber manufacturers found that it was not the best to use, except for a few special purposes, such for example as linings for sulphuric acid tanks, rubber gloves for laboratory use, etc. If the rubber was white, and it is impossible to make pure white rubber, the correspondent referred to was probably cutting a compound having less than 10 per cent of a less than 90 per cent pure crude rubber, the balance consisting of the various white minerals, such as zinc, barytes, whiting, Paris white, etc., whose sulphites are white.

As one writer has suggested, it would be well to send a sample of the rubber to some reputable manufacturer of abrasive wheels, and abide by his judgment. It is not necessary, however, to buy a new wheel to grind one roll unless it is very large, as any wheel will do the work. Grind dry, but be careful that you do not have a fire—never mind a little smoke and the unpleasant odor. In the inquiry referred to, no specific information was given as to the form of the work, which is, of course, important. If, for example, rubber jar rings are to be parted, a knife is probably by far the most economical, since there is no waste; but for small rolls such as wringer rolls, for instance, for one or two, or even thousands for that matter, where a slight error in size is of no material account, sandpaper applied by hand to the roll, which should revolve at a high speed, is as economical as any. Of course, we are always governed, more or less, by our surroundings. If the piece is not too heavy to stand a high surface velocity, and where only a few slight ridges are to be taken out, with nothing but a lathe without a grinding attachment to do the work with, I would probably rough out the worst places with a file and then use a coarse garnet paper to make the roll approximately true, finishing with a fine grade of sandpaper. If a fine finish is required, it may be obtained on black rubber by the use of cocoanut butter, palm oil, linseed oil, cottonseed oil, or other vegetable oils. The oil is rubbed over the work by hand, until it is well spread, and the result is a nice-looking job, but the use of the oil is somewhat detrimental, as it has the effect of softening and destroying the rubber, more or less. For finishing white rubber, speed up the lathe and rub the work thoroughly with a little soapstone, Paris white or whiting; these latter are perfectly harmless. A. NEWTON HAMMOND.

Erie, Pa.

THE CASTING PUZZLE.

The casting shown on page 369 January number, engineering edition, was probably made by black-leading the bore of the ratchet and casting the bushing therein. Casting the ratchet about the bushing would probably split the former. I made "false-back" hose-couplings on this principle about 1874; they were subsequently patented by Allen. I illustrated them at the time in the *Journal of the Franklin Institute*. ROBERT GRIMSHAW.

Dresden, Germany.

I would like to submit an answer to the casting puzzle mentioned in the January issue of MACHINERY.

A bushing should be first cast from a separate pattern and a pattern made to represent the pawl with the bushing in place; then mold this pattern and let the flanges of the bushing serve as core prints to hold it in position. Next place the bushing in the mold in the same manner as a core or chill and pour the metal around it to make the pawl. This metal will shrink away from the bushing, allowing a little clearance and at the same time chilling the surface about the hole.

Pittsburg, Pa. WM. PFOUTS.

Referring to the casting puzzle in the January issue of MACHINERY, I should, if called upon to make a casting like the one there illustrated, make the pawl first and then machine the hole to size, taking care to make it perfectly smooth. I would then have the bushing cast in it. The pawl will act as a chill, and the iron bushing will shrink in cooling so that it will draw away from the pawl on the inside. To prevent the collars from shrinking fast to the pawl, I would insert some combustible material between the collar or flange and the pawl. The hot iron will burn this material, and after the casting is cool it can be worked out by revolving the bushing.

Windom, Kans. O. A. ANDERSON.

In the January number of MACHINERY, there is illustrated a casting puzzle in the shape of a cast iron pawl which is mounted on a solid bushing, having flanges on either end, on which it is free to rotate. As to the probable method of making this casting, I do not believe, from the foundry-man's point of view, that it would make much difference which piece was cast first—the pawl or the bushing; but, from the pattern-maker's point of view, it would be easier and more practical in making the patterns to have the pawl cast first. Then a coat of some suitable preparation could be applied to the parts of the pawl which come in contact with the bushing. Doubtless a thick coat of glue and very fine sand, supplemented by a coat of "black wash" such as molders use, would accomplish the purpose. In this way sufficient play would be obtained between the pawl and bushing, provided the casting were small, but for larger ones where the shrinkage is considerable, other methods would have to be adopted. A thin false flange of some suitable material could be used under the flanges of the bushing, while the shrinkage of the body would give sufficient clearance. H. V. B.

Calculated on the basis of present consumption, it is estimated that the available coal supply in Great Britain will last from 500 to 800 years.

SHOP KINKS.

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A HANDY PENCIL POINTER.

The illustration, herewith presented, shows a very handy instrument for a draftsman to have near his board. It is very easily turned, and ought to be of some hard wood, such as cherry. The slots *A* are gashed into the sides by a thin saw, and small wooden wedges hold emery paper in them. By making two gashes instead of one, two grades of emery paper, coarse and fine, may be used. A small eye is screwed into the handle to hang the instrument up with. The advantage of this kind of sharpener over the flat file, or flat emery paper, is the fact that the points are rubbed up on a rounded surface, which gives a point as shown in Fig. 3. This point is parallel for a short distance, which means that the point is the same for a longer period of use. Fig. 1 shows a point rubbed up on a flat surface, and it is easily seen that every stroke of the pencil makes the point thicker. F. C. DOUGLAS WILKES.

Scranton, Pa.

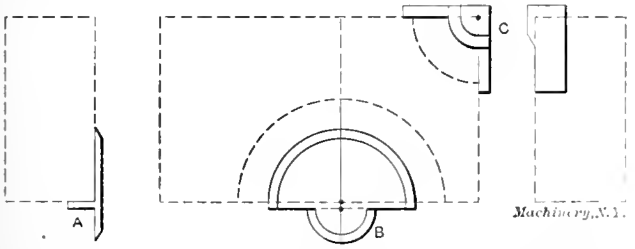
CENTERS FOR SCRIBING SEMI-CIRCLES FROM THE EDGE OF A BLOCK.

When it is necessary to draw a half circle on a block of metal or wood, the center of which comes on the edge of the block, the tool shown in the illustration will be found very useful, as it makes it possible always to have the center in the tool box. This tool is made of thin steel or brass and has centers which may be aligned with the edge of the block upon which the semi-circle is to be drawn. It will be noticed that there are two centers; one on each side of the perpendicular locating piece *A*. The side *B* is made smaller so that the tool can be reversed and used for drawing circles of smaller radii. The other tool shown at *C*, which is made on the same principle, is used on corners. F. A. ROSS.

Beloit, Wis.



Machinery, N.Y.

REMOVING BUSHINGS FROM TURRETS.

In the accompanying sketch, a common form of turret tool binder is shown, which consists of two bushings *A* and *B*, located about one-eighth inch apart, and cut out to the same radius as the hole for the tool. Tightening the screw which passes through the tool bushings, draws them together, as *B* is tapped and *A* is a sliding fit on the screw. In this way the tool is gripped tightly. After considerable use, it will usually be found that the two bushings have become so worn on their working faces that they come together and do not grip the tool. Upon trying to remove them so as to file the ends, difficulty will often be met with, as the ends are usually pressed out so that they are a tight fit in the holes, and the bushings are so located that they cannot be driven out. The illustration shows a very effective way of doing this work. A screw *C* is made longer than the regular one, and in addition, three or four collars *D* and one washer *E*. It is obvious, by referring to the sketch, that tightening down on the screw *C* will draw the bushings up. When *A* comes into contact with the washer *E*, the screw *C* can be removed, a thicker collar *D* put on, and the operation repeated until the bushings are out of the hole. In case there is only one bushing, as *A*, the binding screw working right in the solid metal as in some of the older types of machines, tap in the bushing *A*, and proceed to draw it out as described. PAUL W. ABBOTT.

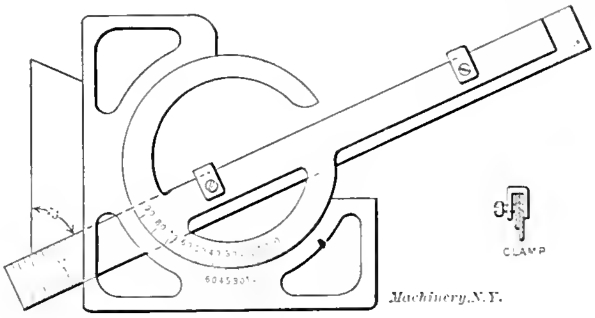
EXTENSION FOR DRAFTSMAN'S PROTRACTOR.

While the well-known draftsman's protractor, shown in the engraving, was no doubt designed to be used solely for drawing, it also has another use quite as helpful. If a scale is clamped to the blade as shown, it is adapted nicely for measuring or laying out angular pieces, which the draftsman often has to do. Although the scale can be used in many cases, a straight-edge, beveled at the end, could be used, perhaps, to better advantage, as it would permit getting into recesses where the scale could not be placed. As the vernier is graduated to read to 5 minutes, very accurate measurements can be made when necessary. C. E. J.



Machinery, N.Y.

METHOD OF MAKING PISTON RINGS.

The following is a brief description of a method of making piston rings, which may interest the readers of MACHINERY. First, the ring is roughed out and bored slightly eccentric, as shown in the illustration. The lap joint is then milled, as shown, the portions *A A* being removed on the thin side, after which the ring is clamped together and held with a small pin *B*, made of drill rod. The ring is next bored to the exact size desired, and then put on an expanding arbor and finished outside, care being taken to preserve the eccentricity. With this method, a ring can be made that is almost perfect, and one which is well adapted to gas engines. W. E. MOREY.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

[illegible] and name and address. The latter are for our own convenience and will not be published.

The following questions are referred to the readers.

L. S.—I wish to cast a 1/16-inch wall of rubber around a piece of sheet metal 1/32 x 3/4 x 3 inches long. What process is used to make rubber flow into narrow cavities?

L. B. D.—Please publish a table giving the proper proportions of steam whistles in all commercial sizes; also the same data for steam sirens.

K. A. T.—What is the practice followed in regard to shape of tools and grade of steel for grooving chilled cast iron rolls used in flour mills? What is the common cutting speed, and how are the rolls prepared for the grooving operation?

J. W. F.—Can you give me information regarding the bending and forming of fiber sheets 3/16 to 1/4 inch thick? We have been experimenting considerably, but cannot obtain satisfactory results. We soften the fiber by steam, but if we make it soft enough to form a square corner it splits up; and if it is not softened so that it splits, it breaks in making the desired bend.

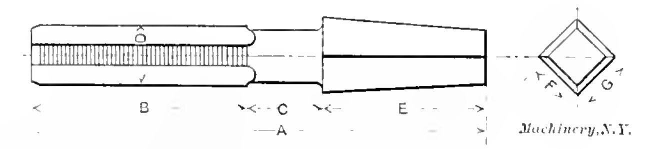
C. L. L.—Can you give me a good formula for a bluing compound, like that used by gun manufacturers for bluing the steel parts of revolvers, etc.? I have a formula which calls for 2 parts crystal chloride of iron, 2 parts solid chloride of antimony, 1 part gallic acid and 4 or 5 parts water. An expert chemist declined to fill it, saying it was not a practical formula, *i. e.*, the ingredients would not properly mix.

DIMENSIONS OF BIT-BRACE TAPS.

S. C.—What are the dimensions commonly used for bit-brace taps? Are the shanks of all bit-brace taps made the same, and what is the commonly used size of the taper square shank?

A.—Below will be found a table giving the dimensions generally employed by tap manufacturers in making bit-brace taps. Two sizes of shanks are generally used, the smaller size being employed for taps up to ½-inch diameter, and the larger size for taps ½-inch in diameter and larger. While some tap manufacturers list these taps up to ¾-inch size, they are not commonly used larger than ½-inch diameter, and it is evident that to tap a ¾-inch hole with a bit brace would be rather a laborious job. The taps are usually provided with four flutes. The shanks may be milled to size, in which case no further finish is required. In most cases, however, tap manufacturers forge the shanks to size and then simply grind or file off the fins or burrs. These taps are not made in sets of taper, plug and bottoming taps, the same as hand taps, but the chamfer on the end of the taps is made similar to a plug tap chamfer.

TABLE OF BIT-BRACE TAPS.



Diameter of Tap.	Total Length.	Length of Thread.	Length of Neck.	Length of Shank.	Size of Square, Small End.	Size of Square, Large End.
D	A	B	C	E	F	G
3/16	3 1/4	1	1	1 1/4	7/32	11/32
1/4	3 3/8	1 1/16	1 1/16	1 1/4	7/32	11/32
5/16	3 1/2	1 1/8	1 1/8	1 1/4	7/32	11/32
3/8	3 5/8	1 3/16	1 3/16	1 1/4	7/32	11/32

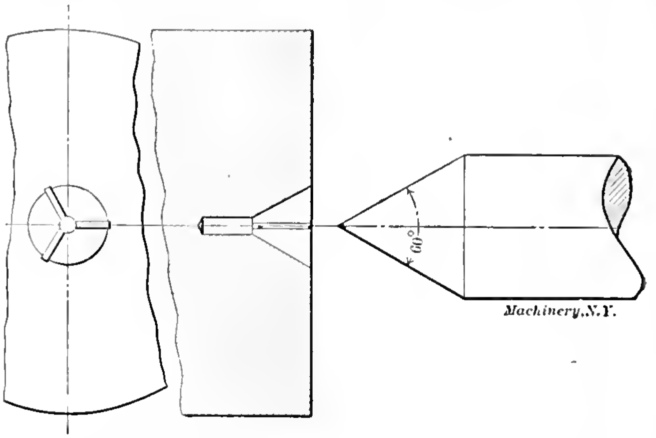
LUBRICATING GROOVES IN CENTERS OF HEAVY LATHE WORK.

W. U.—Having a cast iron cylinder weighing about 600 or 700 pounds to turn in a lathe I filed three grooves in the centers with a small square file, as shown in the accompanying illustration. These grooves were filed for lubricating the centers, and is a practice that I have followed very successfully, never having any trouble with centers cutting or squealing. A shopmate says he would not follow the practice as a cylinder turned with grooves cut in the centers, as shown, will be slightly out of round at points corresponding to the location of the grooves in the centers. Is his contention sound?

A.—Undoubtedly the narrow grooves cut in the centers do have a slight influence on the roundness of the work turned, but if the grooves are cut narrow, the influence would be so slight as to be practically negligible except, perhaps, for calendering rolls or other work requiring a highly accurate surface. No doubt the practice saves much trouble when turning long, heavy shafts, as thorough and constant lubrication is possible. The objection to cutting grooves in the work can be met by grooving the lathe tail-stock center, one groove being placed in a position midway between the horizontal and vertical planes so as to permit the oil to run into the bearing and still avoid the slight reaming action that might follow placing the groove at the top. Cutting spiral grooves in the work centers might overcome all objections.



Lubricating Grooves in Centers of Heavy Lathe Work.

* * *

The different spirit in Europe and America in regard to peaceful achievements and destructive policies of warfare is hardly ever better exhibited than by the manner in which advances in science and industry are commented upon in the old and the new world. Whenever some epoch-making invention has been made in Europe the European press, both the daily and the engineering, first of all consider what influence this invention may have on military developments; and it seems as if the whole purpose of existence, in the opinion of a large majority of editorial writers abroad, is merely to excel in military achievements. In America, on the other hand, the first consideration is what influence the new invention will have on the peaceful industries of the country. Perhaps it is laregly due to this fact that the industrial progress of the United States has made such rapid strides. Of late, the tendency has been, more than before, to introduce the European military idea in the United States also; but it is to be hoped that any such tendency will be ephemeral, and that in this country industrial progress will never be considered merely as an incident in the perfection of military armaments.

* * *

The latest record to be broken by Wilbur Wright and his aeroplane was that for distance. On December 31st, 1908, he made a continuous flight of 76.5 miles, in 2 hours, 9 minutes and 33 seconds, giving a speed of about 35 miles an hour. This flight was made for the Michelin prize of $4,000 cash, and a $2,500 trophy.

* * *

Maple is recommended by the *Practical Engineer* as the best material for wood pulleys. A pulley made of maple, forty-six inches in diameter by sixteen inches face, was successfully run at a speed of 2,400 revolutions per minute, which is equivalent to a peripheral speed of 5½ miles per minute.

THE PASSING OF THE SHARP V-THREAD.*

Nearly forty-five years ago the Franklin Institute of Philadelphia recommended the Sellers screw thread system for general adoption in the United States, as the United States standard thread. Over forty years ago this system was authorized for the naval service by the Secretary of the Navy, and soon afterwards the system was adopted by the Master Mechanics' Association and the Master Car Builders Association. Nevertheless, the engineering profession has been slow to adopt universally the U. S. thread, and in spite of its shortcomings, the sharp V-thread has been, and still is, used to a considerable extent. It is evident that for the purpose of standardization, the use of two systems of threads where one would be sufficient, is undesirable; and in the case of the sharp V-thread its use is all the more objectionable because a "standard" sharp V-thread does not exist. The shortcomings of the sharp V-thread have been referred to several times in MACHINERY; and the fact that various tap manufacturers have each a different "standard" for V-threads was pointed out, in particular, in an editorial in the engineering edition, October, 1906, entitled "The Flat on the Top of Sharp V-Threads," and also in an article on "Screw Thread Systems" in the February, 1908, issue. The subject has also been referred to in other publications, and a thorough treatment is given in "Hand-Book of Small Tools," by Erik Oberg, pages 8 to 14, inclusive.

For a number of years the tap and die manufacturers in the United States have been considering the advisability of discontinuing the regular manufacture of taps and dies with sharp V-thread. An agreement has now been reached to this effect. The causes which have been active in bringing about this decision may be best set forth by quoting from our editorial in the October, 1906, issue of the engineering edition:

"While theoretically the sharp V-thread is not flatted on the top of the thread, it has, on account of practical reasons, become necessary to provide this kind of thread with a slightly flatted portion. In the first place, it is very difficult to produce a perfectly sharp edge on the top of the thread, and, in the case of a tap, the sharp edge would be very likely to be impaired in hardening, leaving the top of the thread less perfect than if provided with a slight, uniform flat. In the second place, the sharp edge would wear away very rapidly both in the case of a tap and a screw, and as the wear could not be expected to be uniform, the ultimate result would be far less desirable than the one obtained by slightly flatting the top of the screw from the beginning.

"For the reasons mentioned it has always been the practice of tap manufacturers to provide the top of the thread on V-thread taps with a slight flat; but as a standard outside diameter always had to be maintained, the diameter in the angle of the thread had to be increased. This has caused difficulties, inasmuch as there has been no established standard as to *how much* of a flat the thread ought to be provided with; the various manufacturers have each had their own practice in this particular. The result has been that the gages from one firm have not corresponded to the taps manufactured by another, and many customers, not familiar with the reasons for this confusion, have questioned the correct sizes of gages as well as taps. The question has been still more confusing on account of the fact that many manufacturers did not have even a certain standard for all taps manufactured by them, but working to their old-established gages, they often produced large taps with smaller flats on the top of the thread, proportionally, than the flats on smaller taps.

"In order to overcome the difficulties arising from the facts mentioned, we understand that the tap manufacturers are endeavoring to establish a standard flat for the top of sharp V-threads. While, as far as we know, nothing has been definitely agreed upon as yet, there seems to be opinions favoring a flat equal to one-fifteenth of the pitch. This is a greater flat than has hitherto been employed by some leading tap makers. Some have used the same flat for the V-thread as is used for the Brigg's standard pipe tap thread, which, although theoretically rounded at top and bottom, is, in this country at least, made with a small flat on the top of the thread. The width of this flat is selected so as to give exactly the same angle diameter as is obtained when rounding the top of the thread in accordance with Briggs's original proposition. This flat is equal to about one-twenty-fifth of the pitch."

Apparently the various tap and die manufacturers failed to agree upon a definite standard for the flat on the top of the V-thread so as to establish what would have been an exact *standard*, and therefore the discontinuing of the manufacture of taps and dies with this thread has been agreed upon.

As an example showing how the gages for V-threads of different manufacturers vary, the following figures giving the pitch diameter of a $\frac{3}{4}$-inch tap, 10 threads per inch, as made by ten manufacturers, may be cited. The following are the ten pitch or angle diameters: 0.6702, 0.673, 0.671, 0.6731, 0.6715, 0.671, 0.6711, 0.6715, 0.677 and 0.671. The theoretical pitch diameter is 0.6634.

For a 2-inch gage, with $4\frac{1}{2}$ threads per inch, the pitch diameters of eight manufacturers are as follows: 1.8219, 1.818, 1.833, 1.8176, 1.8187, 1.8197, 1.828, and 1.831. The theoretical pitch diameter in this case is 1.807. It will be seen that in this case a difference of approximately 1/64 inch exists between the gages of two of the manufacturers.

In view of this condition it is clear that it would be advantageous for the manufacturers and the users alike to discontinue the use of the sharp V-thread. It is also clear that the discontinuing of the use of the V-thread is a better solution of the difficulty than the standardization of the thread; because the latter would involve a change in the present practice of all the manufacturers, and during the transition period the standardization would create quite as many serious difficulties as the adoption of a practically new standard. In fact, it seems that it is easier to abandon the sharp V-thread entirely than to try to force a somewhat different standard of the same thread on the trade. As the U. S. standard form of thread fills the requirements of a desirable screw thread so much better than the sharp V-thread, it is to be expected that the majority of the present users of the latter will cheerfully accept the change, and aid the tap manufacturers in their commendable effort of establishing *one* standard. A rapid acceptance of the U. S. standard in place of the V-thread is all the more likely to take place, because the manufacturers propose to charge special prices for V-thread taps and dies, as well as for tools with the old machine screw thread, the place of which latter will be taken by the A. S. M. E. standard for machine screws.

A fact that will be useful to know in making the change is that the pitch diameter of the U. S. standard thread is somewhat larger than the pitch diameter of the sharp V-thread, so that a V-threaded hole can be re-tapped by a U. S. standard thread tap.

TREND OF AUTOMOBILE DESIGN.

An analysis of the cars of the exhibit at the last Madison Square Garden Automobile Show, made by the *New York Times*, is of interest, giving as it does the general trend of design and use of motor cars. There were on display 117 complete gasoline cars, 28 gasoline chassis, 19 motor business wagons, 5 motor business chassis, 3 taxicabs, 6 steam cars, 1 steam chassis, 37 electric carriages, and 5 electric chassis. A great majority of the gas engines had water-cooled cylinders, there being 138 water-cooled, and 7 air-cooled. The four-cycle type of engine was in the majority; there were 140 of the four-cycle type and only 5 of the two-cycle type. In cylinder construction there was considerable variety, there being 25 six-cylinder models, 116 four-cylinder, 3 three-cylinder, and 1 single cylinder. Of these, 96 were in pairs, 41 were cast separately, and 6 *en bloc*. The jump spark ignition was used on 125 cars and 20 cars had the make-and-break system; 48 of the cars used the double-jump spark system, 56 the dual, and 21 the single system. In clutches the cone and multiple-disk were equal, each type being used on 56 cars. On the remaining cars, 22 used the expanding clutch and 10 the contracting type. The selective gear was the most popular in transmission devices, 121 using the selective and only one using the planetary system.

---

* The following articles relating to screw-thread systems have been previously published in MACHINERY: Whitworth *vs.* Sellers Thread, May, 1899; Screw Pitches in Foreign Countries, February, 1900; Screws, September, 1903; Proposed Standards for Machine Screws, June, 1906; British Standard Fine Screw Thread, October, 1906; The Flat on the Top of Sharp V-Threads, October, 1906, engineering edition; Automobile Fine Screw Threads, November, 1906, engineering edition; Standard Proportions for Machine Screws, December, 1907, engineering edition; Screw Thread Systems, February, 1908. NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

BICKFORD & WASHBURN TAP THREAD MILLING MACHINE.

In the article on The Manufacture of Taps in the January, 1909, issue of Machinery, was shown an engraving (Fig. 6) illustrating the method of threading and relieving tapered taps by milling. This method of cutting taps has been used for many years, special machines having been built by tap manufacturers for the purpose. The firm of Bickford & Washburn, Greenfield, Mass., has now for the first time placed a machine of this type on the market for general use in tap manufacturing. It is the design of Mr. O. S. Bickford, who has had many years experience in tap manufacturing. It has been his aim to incorporate in this machine such improvements and adjustments as will fit it for a wide range of work in general use.

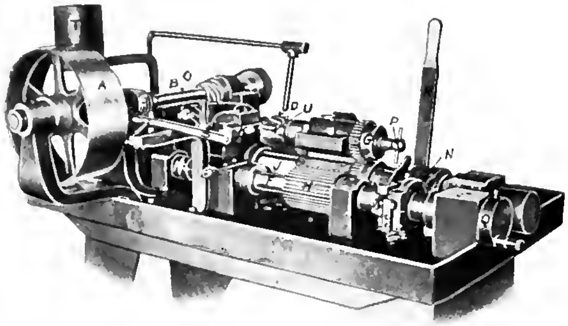

Fig. 1. Mechanism of the Bickford & Washburn Tap Machine.

Briefly, the operation of the machine is as follows: The milling cutter *D* is cut with circular (not helical) grooves of the cross section of the desired tap. This cutter is fluted helically to give a smoother cutting action than would be possible with straight flutes. This cutter revolves continuously. The tap *U* is mounted in front of it, parallel with it if a straight thread is being cut, and at a suitable angle in the case of a taper thread. The tap revolves slowly at a feed suitable for the cut being taken. It is moved forward as it is revolved by a lead-screw geared to the pitch of the thread. The blank is fluted previous to this threading operation, to permit the machine to be arranged for relieving as well. For relieving, mechanism is provided which moves the tap in as the cutting action approaches the heel of the land, and brings it out again to the full diameter when the hob starts in again on the next cutting edge. The arrangement of mechanism provided for giving these movements, will be understood by reference to the accompanying engravings and the following description.

The driving pulley is shown at *A*. This is connected to the driving shaft *B* by a clutch which is automatically disconnected at the completion of the work. This clutch may be operated by hand lever *S*. Coarse pitch spiral gears, one of bronze and the other of steel, connect this driving shaft with the cutter spindle *C*, on which the hob *D* is mounted. This spindle has a taper front bearing with a large collar for end thrust. The rear bearing is of the tapered and split bushing type, adjusted by threaded collars at each end. The cutter or hob, as is shown more plainly in Fig. 2, is carried on a short stiff arbor supported at its outer end. This rigid mounting permits the taking of very heavy cuts without vibration. The whole of this hob driving and carrying mechanism is mounted on a slide which may be adjusted in or out to suit the diameter of the work, though a fine adjustment for accurate sizing is provided in addition to this, as will be explained later.

The rotary feeding movement of the blank is obtained from the driving shaft through worm gearing *E*. The vertical worm-wheel shaft in turn drives (through a second set of worm-gearing) a short shaft which is connected by change gears (not visible in either illustration) with the camshaft *F*. The gears provided at this point give five changes of feed. One of the principal functions of shaft *F* is to revolve the work and feed it forward to agree with the pitch of the thread being cut. To permit this movement, the work *U* is driven from its squared end by work spindle *G*, which is in turn connected by the gears shown with driving gear *H* on camshaft *F*. Spindle *G* is mounted in an adjustable head clamped to bar *J*, which forms the real carriage of the machine. The outer end of the blank is supported by a center in slide *K*, also held in a second head on bar *J*. The axial movement is given this bar and the work which it supports by a short lead-screw at *N*, which, through the split nut at *L*, controls a yoke on shaft *J*. It will thus be seen that as camshaft *F* slowly revolves, the work is revolved in unison and fed forward at the same time by lead-screw *N*, which is made of the same pitch as the work.

Besides having this axial movement, bar *J* and the work holding members may be rocked about the bearings of the bar to bring the work closer to the hob or further from it. This movement is controlled by a series of cams *M*, any one of which may be brought beneath the point of adjusting screw *O*. These cams have four lobes for four fluted hobs, three lobes for three fluted hobs, etc. The point of screw *O*, which is seated in the tail center head, bears on the cam surface, and rocks the work in and out from the cutter to give the desired relief. Screw *O* is also used for the fine adjustment for the diameter, being provided with a graduated dial for that purpose. Weight *T* keeps the point of *O* in contact with the cam.

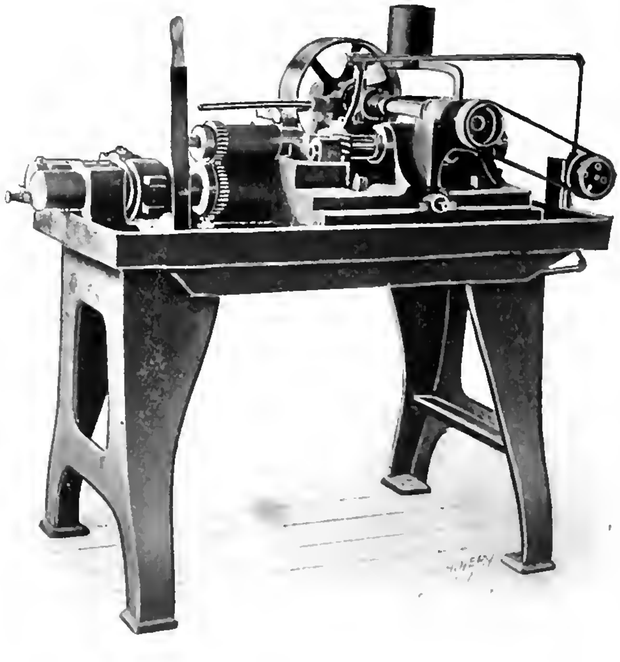

Fig. 2. A Machine for Threading Taps with a Hob.

The tap being cut is driven by a dog in the front end of work spindle *G*. Provision for cutting taper taps is made by adjusting tail center *K* crosswise, a fine screw movement being provided for this purpose. The other center is the point of screw *P*, which forms part of the work spindle and is readily tightened. The lead-screw *N* is so attached as to be readily removed for changing from one pitch to another.

In the operation of the machine, the split nuts *L* are first opened allowing bar *J* to be drawn back by lever *R*. The nuts are then closed, the finished tap is removed, the new blank is inserted, and the clutch lever *S* is thrown over, starting the machine again, which completes the new tap and stops itself ready for another blank. The operation in the case of ¾-inch pipe tap requires about three minutes.

The machine is also arranged for threading the hobs *D* which it uses as cutting tools. For this work an ordinary V-milling cutter is used, of the proper shape for the thread. One groove at a time is cut in the hob blank. At each revolution the machine stops and the operator indexes the work ahead by hand to the next groove. The lead screw is free from the influence of the feeding mechanism, and is operated by the knurled index pin in disk *Q*, which seats in a taper hole in the bed.

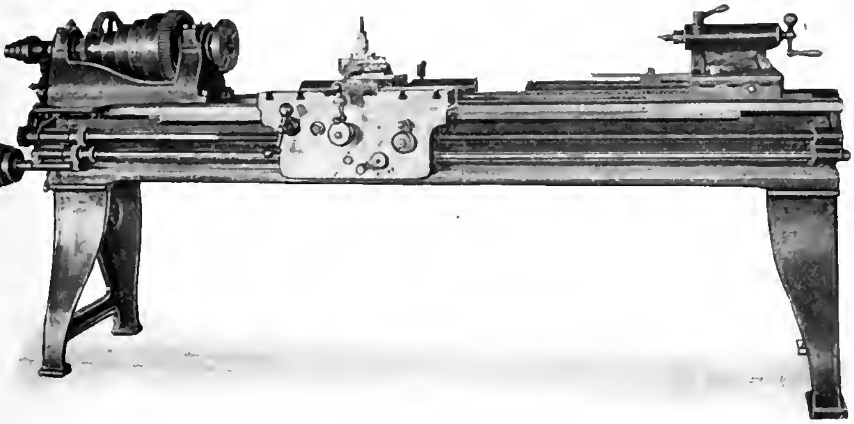
The regular equipment of the machine, so far as the movable parts are concerned, consists of a full set of extra lead screws and nuts, and the dogs necessary for driving the sizes of taps as required by the range of the customers' work; depending on whether right- or left-hand taps are to be cut, and whether Briggs standard or Whitworth shapes and sizes are to be used.

The first machine of this type has been in use for some time and is giving, so the builders state, complete satisfaction to the purchaser. It is threading 2-inch pipe taps at the rate of one hundred per day.

MIAMI VALLEY 15-INCH STANDARD ENGINE LATHE.

The Miami Valley Machine Tool Co., of Dayton, O., has added to its line the 15-inch standard engine lathe shown herewith. Particular attention has been paid in this lathe to giving a strong rigid construction, which will permit heavy cuts without chattering or vibration. The head-stock is massive and has long spindle bearings, bushed with phosphor bronze. The spindle is of high-grade crucible steel, bored with a 1⅜-inch hole. The cone pulley has five steps for a 2¼-inch belt, and the back gear ratio is 9.6 to 1.

Among the conveniences of the carriage is the provision made for reversing the feed in the apron, as well as in the head-stock. The feeds are so arranged that it is impossible to throw in the screw and feed rod motions at the same time. A positive geared feed is provided, obtainable from a connection of the feed rod with the lead-screw. This is in addition to the four belt feeds, which range from 50 to 150 turns per inch. A chasing dial is provided to permit threading without stopping or reversing the lathe.



Miami Valley 15-inch Standard Engine Lathe.

The price includes follow and steady rests, change gears, large and small face-plates, double friction counter-shaft and wrenches. The lathe is equipped with a compound rest, but a plain rest will be substituted if ordered. The lathe has an actual swing over the bed of 16½ inches. It will weigh approximately 1,600 pounds with a 6-foot bed.

ACME GAS-ENGINE AIR COMPRESSOR.

The gas-engine-driven air compressor shown herewith is an unusual example of neatness and compactness in design, made possible by combining two separate units in one machine. This apparatus comprises a 5-inch by 5-inch 4 H.P. gas engine and a 5-inch by 5-inch air compressor cylinder, mounted in one frame, and with all parts conveniently arranged for inspection and repair. It is built by the Acme Mfg. Co., Bradford, Pa.

The two cylinders form one solid casting with the valve chambers and the upper half of the crank case. This casting is made of fine gray iron, and has an ample water jacket cast integrally with it, serving for both the gas engine and air compression cylinders. The pistons are duplicates, of the usual gas engine type; they are very light and extra long, and the rings are placed well to the top. Oil grooves on the lower face of the piston ensure even distribution of the oil thrown against it when exposed at the lower end of the stroke. A flywheel is mounted on each end of the gas engine shaft. They are carefully balanced and of ample weight. The crank-shafts are duplicates except in the matter of length, and are made of a tough, mild open-hearth steel, forged in one piece from the solid billet. The connecting-rods and other parts are also duplicates.

A Gas-engine-driven Air Compressor of Simple Design.

One of the features that allows simplification of the mechanism, is the gearing of the engine crankshaft with that of the compressor in the ratio of two to one. This allows the two members to work at suitable speeds for each, and at the same time permits the use of the compressor crankshaft as a lay shaft for operating the valves of the gas engine. The gears are cut from forged steel blocks and are designed with a factor of safety of ten. They run in a bath of oil, so that the loss of power is negligible. The valves and stems are of special nickel steel drop forgings formed in one piece and carefully turned. They operate vertically, and their stems are guided in long bushings, giving great durability of alignment. The inlet valve area of the compressor cylinder is 35 per cent of the piston area.

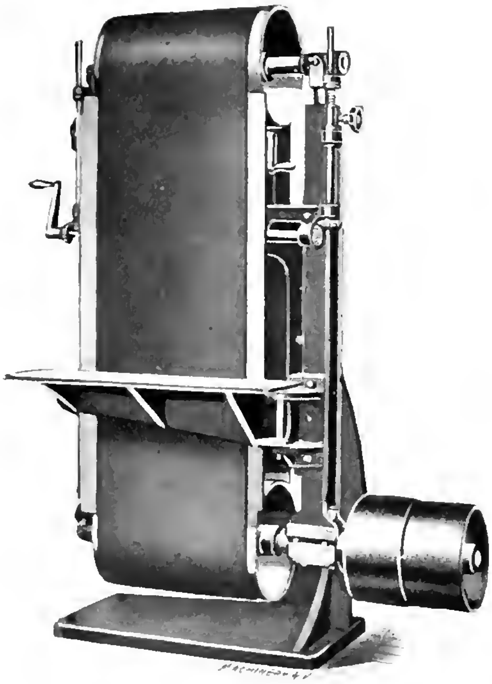
The advantages of this arrangement may be summed up as follows: compactness of design; simplicity and consequent low first cost; thorough lubrication of all working parts from the oil bath in the crank case; vertical mechanically operated valves; rigid cylinder castings and frame; removable long bronze bushings for the shafts, with ring oiling bearings; easy access to the valves; quietness of operation; availability for use under any conditions, with natural, producer or illuminating gases, gasoline or denatured alcohol as a fuel. In

order [illegible] purchaser should state the fuel it is proposed to use.

An [illegible] device, adjustable for different pressures, will be provided if it is desired to maintain a given pressure in the receiver. This allows the engine to be operated continuously. High efficiency is assured by the careful design, the high compression obtained, and the large and freely moving valves. The machine has a capacity of 17 cubic feet of air per minute at a pressure of 250 pounds. It weighs 600 pounds completed.

GILMER IMPROVED VERTICAL BELT SANDER AND POLISHER.

The L. H. Gilmer Co., 501 Arch St., Philadelphia, Pa., is well known as the maker of the Gilmer endless belt, which was first described in the New Tools department of the October, 1905, issue of MACHINERY. The use of these belts for polishing and similar purposes has resulted in the design by this firm of the vertical belt sander and polisher shown herewith. This is so constituted as to run successfully at a belt speed of 4,000 feet per minute, without heating the bearings or causing appreciable vibration. The work is supported by a swinging table, which may be adjusted to any convenient level to suit the work in hand. This supports the weight of the part being polished, so that the operator is free to guide the work with as much care as may be required.



Endless Belt Sander and Polisher for Wood and Metal Work.

By means of double screws and bevel gears the tension of the belt is adjusted from one side by a single crank. This adjustment keeps the shafts always in line, so that the belt is in no danger of being thrown off. Various special appliances for special work may be used. One of the most useful of these is the provision made for fastening felt or other backing to the machine plate, thus giving a cushion which is very effective for some kinds of work. The working surface is 18 by 24 inches. The bearings are dust-proof and of solid construction. While the machine runs regularly at 4,000 feet a minute, it is tested thoroughly at a speed of 5,500 feet. It may be used as a sand belt for wood-working or (with proper abrasives) for metal finishing.

WEISS REVOLVING WRENCH.

The instrument illustrated in Figs. 1 and 2 should perhaps be called a parallel jaw plier rather than a wrench, if strict definitions are to be followed, but the revolvable feature included in the construction fits it so well for use as a wrench on all parts of work and in all sorts of places, that the title "revolving wrench" is decidedly appropriate. The tool is the invention of Mr. Karl Weiss, 118 Cherry St., Waterbury, Conn.

Fig. 1 is reproduced from a photograph of the tool, and Fig. 2 shows details of its construction. Jaws *A* are guided in suitable slots in the body bushing *B*. In this latter member is mounted a pivot *C*, which carries two gear segments *D*, whose teeth mesh with rack teeth cut on the inner edge of jaws *A*. The longitudinal movement of a thrust bushing *E* presses it against the ends of segments *D*, and rotates them about pivot *C*, thereby closing the jaws together. This longitudinal movement of *E* in the direction of the axis of the tool is effected by gripping the handles *F*, which are thereby rotated about their fulcrums *G*, causing their inner ends to press against *E*. When the grips *F* are released, the coiled springs shown attached to segments *D* open the jaws and the handles again.

Body bushing *B* and the jaws *A* which are mounted in it may be revolved with relation to the handles. The fulcrums *G*, which are cast solid with the handles, bear against the inner end of a sleeve *H*, threaded to *B*. When jaws *A* and bushings *B* and *H* with their contained parts are rotated in relation to the handles, the latter remain stationary along with bushing *J* which supports *E*. When the handles are tightly gripped and the jaws close on the work, the parts are locked against revolving owing to the heavy thrust of pivots *G* against *H*. This makes of the tool an automatic wrench for turning in either direction. In screwing in a nut, for instance, it is tightly gripped between the jaws. This gripping locks the tool, so that the twisting of the wrists turns the nut. A slight release of the pressure loosens the contact between *G* and *H*, and allows the wrists to be twisted back again for a fresh grip. The tightening again locks the tool, so that another turn may be given the nut—all of which is done without removing the jaws from their contact with the work.

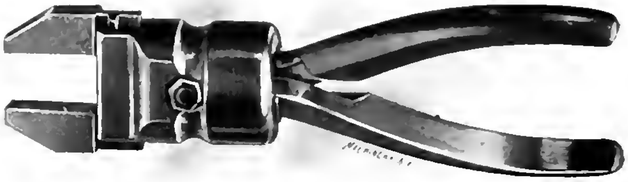


Fig. 1. The Weiss Combined Parallel Pliers and Revolving Wrench.

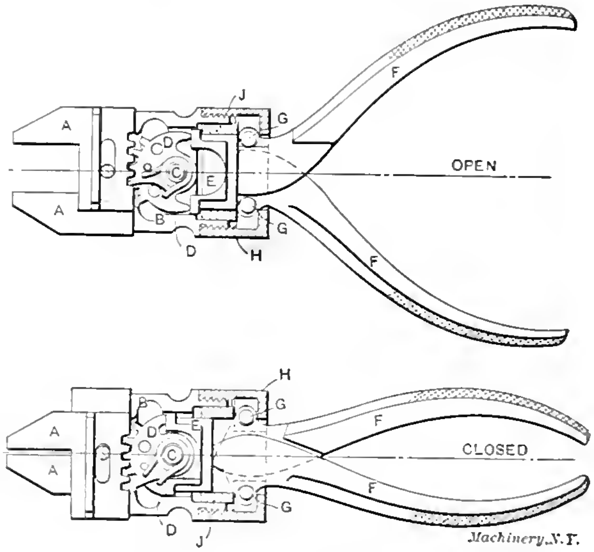

Fig. 2. Details of the Construction of the Tool.

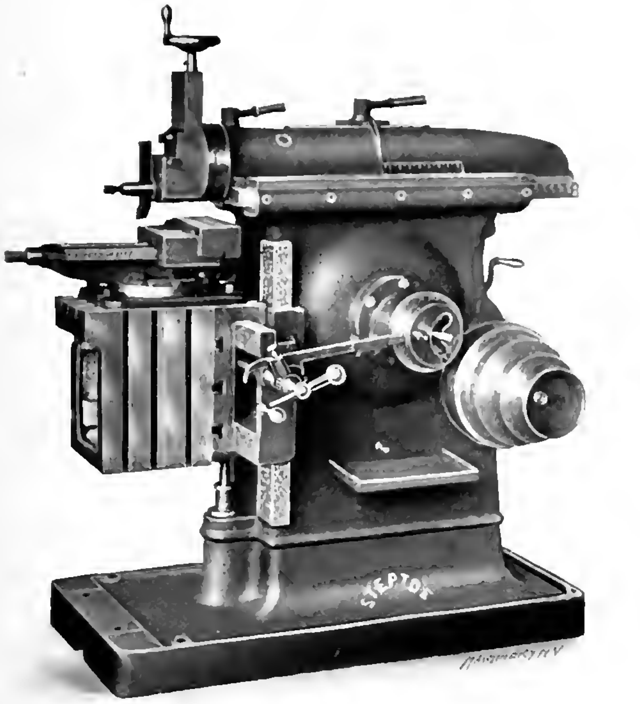
An ordinary ratchet wrench will not reach in every hole or corner where there is a nut or screw to be tightened. This tool will reach and stay on, giving the operator a chance to rotate the part by the very smallest amount required in a corner, or by the full swing of the hand where that is possible. It does not require a new grip for each one-quarter turn, as with the common parallel pliers. It follows the quickest motion of the workman's hand without loosening the grip on the work or requiring a change of hands.

STEPTOE 16-INCH CRANK SHAPER.

The illustration shows a newly designed back-geared crank shaper made by the John Steptoe Shaper Co., of Cincinnati, O. This design incorporates a number of improvements, among them being a stiffened form of base, a clamping arrangement for the tool-head, and convenient and durable feed mechanism.

The base of the machine on the operating side is strengthened by a basin-shaped brace of thick section. The whole of the base casting is made very heavy to avoid vibration, and consequent unsteadiness of cutting action. The shaft bearings are provided with press-fitted, cast iron, ring oiling bushes. The rings are made of wide strips of brass, giving a much more liberal supply of oil than when wire rings are used. The back gears are operated by a lever at the back of the column within easy reach of the operator. The driving gears are of a high grade of phosphor bronze.



An Improved Design of the Steptoe Crank Shaper.

The ram is strongly ribbed and heavily braced. The head can be instantly loosened and swiveled to any angle by pushing the lever seen at the back of the head. Pulling the lever forward again clamps the parts together. No wrenches need to be used for this adjustment, thus saving time and annoyance. The change in the length of stroke is controlled by a lever projecting through the feed plate, which can be operated when the machine is in motion. The adjustment in the bull gear is self-locked, being held firmly in position as soon as the adjustment lever is taken off the shaft.

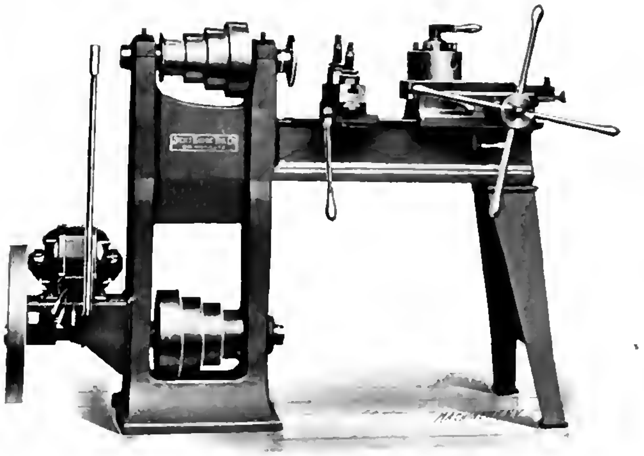
The feed motion is obtained from a variable throw eccentric on the bull wheel shaft. The eccentric is pivoted so that it can be swiveled in either direction, and locked at the desired adjustment by a tapered pin entering reamed holes in the plate. The holes are drilled and numbered to agree with the number of teeth in the feed ratchet, for convenience in changing the feed. The eccentric strap is split and fitted with a fiber washer, so that adjustment for wear may be easily effected by filing this washer as much as may be required. The elevating screw fõr the table is entirely enclosed, and is of telescopic construction. This prevents oil and chips from getting in under the base, and obviates the necessity for a hole in the floor as well. The base of the vise is graduated for its angular setting on a beveled surface, so that the setting can be easily seen by the operator. Another vital improvement in its construction is offered by the bolts provided for drawing the sliding jaw down onto the base, after it has been set up against the work. As is well known, when fastening work in a vise the outer jaw has a tendency to tilt under the pressure. These clamping screws avoid the possibility of this tipping and thus assist in securing accurate work.

The builders also manufacture a single geared crank shaper of similar design, with the gear ratio of $6\frac{3}{4}$ to 1. The back-geared crank shaper herewith illustrated has a single geared ratio of $6\frac{3}{4}$ to 1, and a back-geared ratio of about 20 to 1.

DRESES MOTOR-DRIVEN TURRET LATHE WITH SELF-CONTAINED COUNTERSHAFT.

A striking arrangement of self-contained motor drive for a brass turret lathe is shown herewith. It was designed and built by the Dreses Machine Tool Co., Cincinnati, Ohio. The motor is of the constant speed type, all the changes being made by shifting the belt, as with the usual countershaft arrangement; in fact, the substance of the design consists in placing the countershaft in the cabinet leg beneath the head-stock, instead of mounting it on the ceiling above the machine. The constant speed type of motor was used in preference to the variable speed form, because the high rate of rotation of the spindle in brass work makes a geared speed changing device practically out of the question. Variable speed motors are also open to the objection that they are most conveniently mounted on the head-stock, where their large size gives an unsightly appearance to the machine, and sets up disturbing vibrations as well. The motor shown in this particular installation has $1\frac{1}{2}$ H.P. capacity, and is of the alternating current, high speed type.

The motor is mounted on a bracket at the left side of the cabinet leg. A rawhide pinion on the armature shaft meshes with the large gear on the cone pulley shaft journaled in the leg. To start and stop the spindle more quickly than is possible by the motor controlling switch, a friction clutch is furnished, operated by the long lever shown at the left, which thus serves to connect and disconnect the lower cone pulley and the driving shaft. It will be noticed that this pulley is placed as near the floor as possible to give a long belt and avoid vibration. The bed and cabinet leg are constructed to avoid interference with the shifting belt in any position.



Motor-driven Brass Finishing Lathe with Countershaft mounted in Cabinet Leg.

LANGELIER SWAGING MACHINE FOR FINISHING VALVE STEMS.

The Langelier Mfg. Co., of Providence, R. I., has equipped its regular swaging machine with tools and attachments which adapt it to the finishing and sizing of gas-engine valve stems. The advantages of doing this by swaging, rather than by grinding as usual, are two: first, the operation is much more rapid and less expensive; and second, the quality of the metal is materially improved by the compression to which it is subjected in the swaging process.

Fig. 1 shows the machine equipped for this work. Fig. 2 shows the valve in three conditions: the rough forging; after turning the head, and after swaging. The forging (see *A*) is first clamped by the shank in a lathe, the head is turned

end finished all over, and the tapered swell of the shank into the head is machined. The forging is shown in this condition at *B* in Fig. 2. The holder for the swaging operation is shown in Fig. 3. The work is grasped by the finished head in a spring chuck *D*, of ordinary construction, tightened by the coarse-studded screw *E* and nut *F*. To make the operation of this nut and screw by handle *G* as nearly frictionless as possible, a ball thrust bearing is used, as shown. The holder is mounted on a slide *H*, which is actuated by hand lever *I* to force the work back and forth between the dies. The whole attachment is supported by bracket *K*, clamped to the face of the machine.

The finished work is shown at *C* in Fig. 2. It will be noted that a reduction of 1/32-inch has been made in the stem with a corresponding increase of length, which of course is allowed for in making the blank. As the valve stem is held by the chuck on its outside diameter and the angular face *x* of the head, this insures the finishing of the stem true with the valve seat. After the swaging operation, the valve is chucked by the swaged surfaces of the stem, and surface *x* trued up by grinding, thus insuring the truth of the important surfaces. Where great accuracy is required, the makers advise doing the swaging in two operations. The first operation roughs the stem down to within five or six thousandths of the required dimension; the second operation sizes it and gives it the desired finish. The roughing can be done very rapidly as the finish is not of great importance. The second operation must be done more slowly. In the examples shown, the time required for swaging was six per minute for the first operation, and three per minute for the second. This included the time for putting the work into the machine and taking it out again.

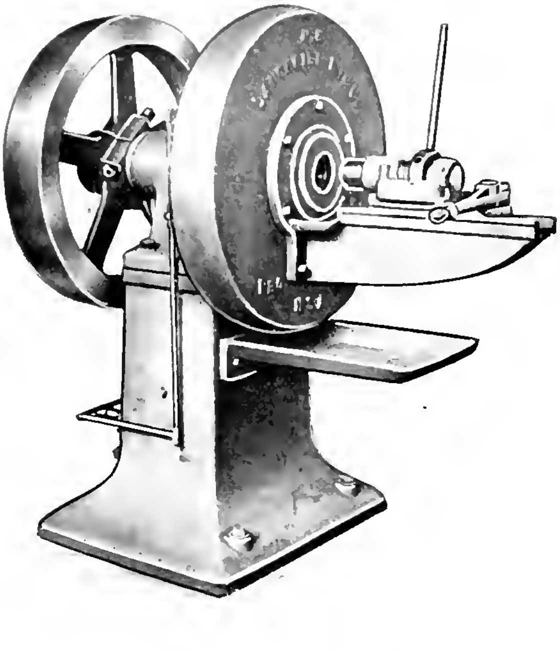


Fig. 1. The Langelier Reducing Machine, fitted with Attachments for Finishing Automobile Engine Valve Stems.

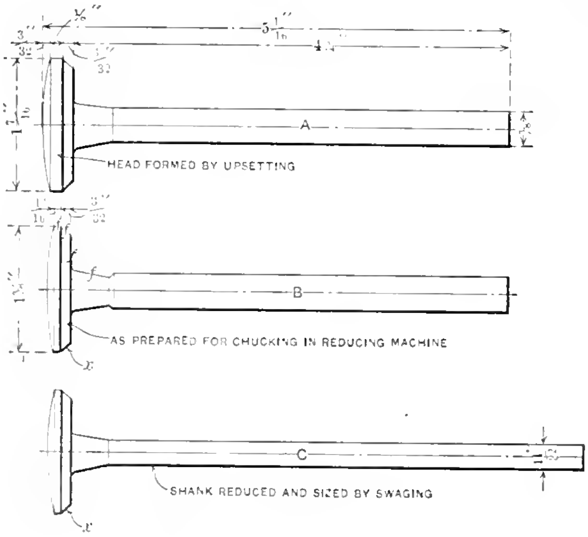

Fig. 2. Three Stages in the Making of a Gas Engine Valve.

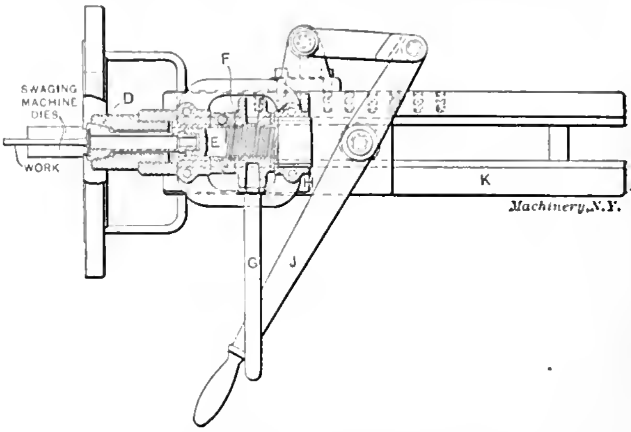

Fig. 3. Plan of the Attachment for Holding the Work and Presenting it to the Machine.

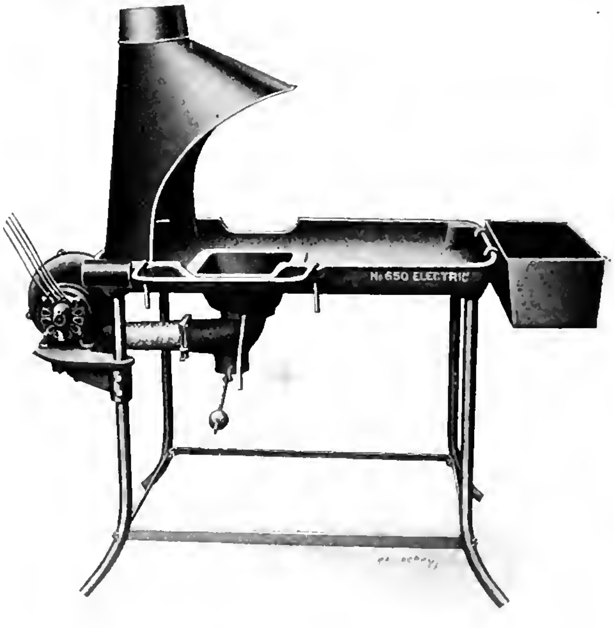
BUFFALO FORGE WITH MOTOR-DRIVEN BLOWER.

The forge shown herewith is built by the Buffalo Forge Co., of Buffalo, N. Y. It is a new design embracing, among other improvements, an all steel fan directly connected to an electric motor, running 1,700 revolutions per minute. The motor and fan case are securely mounted on a bracket fastened to one of the rear legs. Being mounted on the same base, they are kept permanently in alignment. The only wiring necessary is a plug connection to a lamp socket or, if the forge is permanently located, suitable wiring connections may be made in the usual manner. While the regular motor furnished is intended for a 110 volt circuit, suitable windings will be furnished for any desired circuit.



Forge with Direct-connected Motor-driven Blower.

The forge itself is well constructed, having a large, heavy cast iron fire pan, with a sheet steel hood for an 8-inch smokepipe, and a detachable sheet steel tank with an extension or tong support. This gives the operator every convenience for a wide range of the work. The tuyere is of the deep fire, anti-clinker type, provided with a controlling ball having three openings, which allow the blast to be directed to any part of the fire bed, and also give a blast distribution which results in quick, even heat penetration with great economy of fuel. The blower gives an adequate air supply through a short, straight blast delivery pipe, in which all joints are eliminated with the exception of the connection between the blower and the tuyere.

CUTLER-HAMMER SELF-STARTING SWITCHES FOR ALTERNATING CURRENT MOTORS.

The Cutler-Hammer Mfg. Co., of Milwaukee, Wis., has developed a line of alternating current motor controlling apparatus, conveniently mounted on slate panels for immediate installation. Different equipments of apparatus are used for various types of alternating motors. The entire line includes apparatus for use with the slip ring type of motor or the squirrel cage motor, and for single, two- or three-phase currents. They may be furnished adapted to the purposes of both manual and automatic operation.

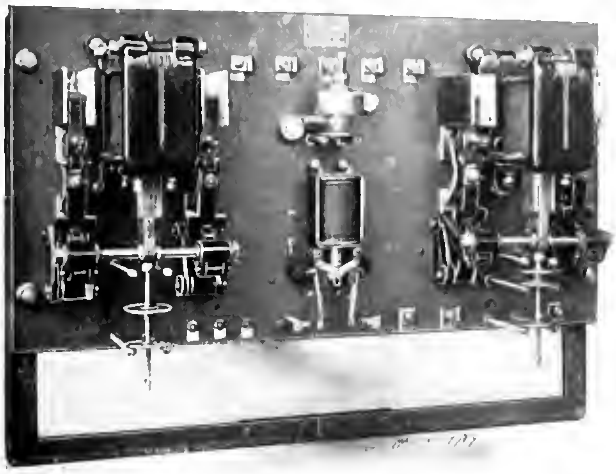


Fig. 1. Self Starter for Squirrel Cage Type of Alternating Motor.

Two examples of this line are shown herewith: Fig. 1 illustrates a self-starter for use with a squirrel cage motor, in such work as driving centrifugal pumps, or similar machines, where the starting torque necessary is materially less than the normal full load torque of the motor, and where the motor will accelerate promptly with a voltage not exceeding 60 per cent of the line voltage. This self-starter is of the multiple solenoid type, and is entirely self-contained. It consists of a slate panel carrying the solenoid switches and relays, which is mounted on a supporting frame with the starting resistance. The primary circuit to the motor for either two-phase or three-phase motors is controlled by a double pole switch in the smaller sizes. The primary switch and starting switch are of open construction, operated by single-phase solenoids. The current carrying contacts are laminated copper brushes pressed against stationary copper contacts by a toggle joint mechanism, insuring a perfect contact. The circuit is always opened and closed at the arcing contacts, which are of carbon and copper and are readily renewable. The starting resistance is non-inductive, and has ample capacity for starting the motor intermittently under light load conditions.

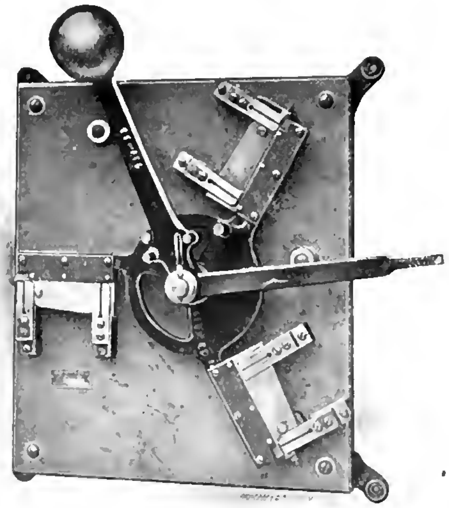

Fig. 2. Automatic Float Switch for Alternating Current Motor.

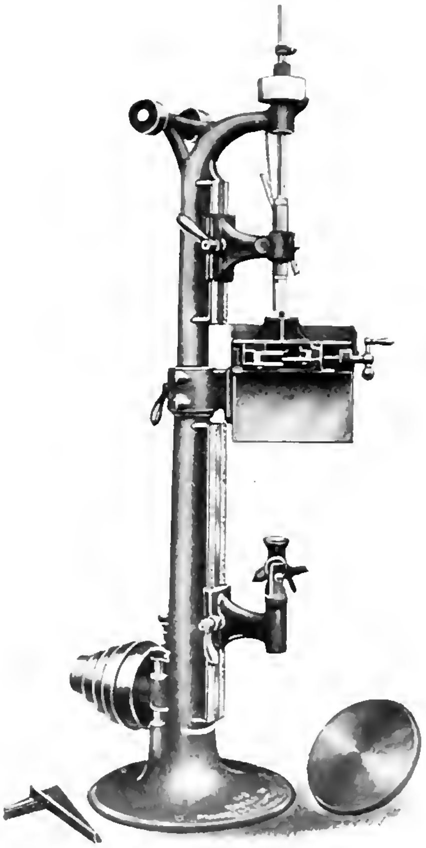
For automatic operation such as is required for electrically driven pumps, which have to be controlled by the water level in a tank, the three pole float switch shown in Fig. 2 may be used, controlling the main line circuit to the motor. It is intended for use only with self starting, single-phase motors, or squirrel cage type two- or three-phase induction motors, which may be thrown directly across the line to start. No self-starter is required when this method is permissible. As will be seen from the illustration, the float switch consists of a plain slate base with supporting feet carrying the switch parts, weight lever and operating lever. The operating lever is to be connected by a chain or other suitable means to the float in the tank, so that it will be moved up and down the proper distance as the water level in the tank falls and rises. When the operating lever moves the weight lever just past the center, the weight falls the rest of the way and opens or closes the switch with a snap.

ROCKFORD MACHINE & SHUTTLE CO.'S IMPROVED SENSITIVE DRILL.

The Rockford Machine & Shuttle Co., of Rockford, Ill., has improved the design of the sensitive drill shown in the department of New Machinery and Tools in the June issue of Machinery. This improvement relates particularly to the drive, the general arrangement of the machine being unchanged.

The driving cone, as shown in the accompanying engraving, is placed near the base of the column, and mounted on a slide which is vertically movable by means of an adjusting screw, to vary the tension on the driving belts. It affects both the countershaft belt and the quarter-turn belt which drives the spindle. This movement gives 3 inches of adjustment, which is sufficient to take care of the stretch for a long time without requiring the belt itself to be shortened.

The general features of the machine will be understood by reference to the illustration, where the table is shown tilted vertically and carrying a centering vise. Round stock, resting in the cup centers at the base of the column and held in this vise, is in proper position for centering, making the drill practically a special machine for that work. For regular work, the round table may be substituted for the combined cup, V and solid centers shown. The spindle boxes are adjustable for taking up wear.



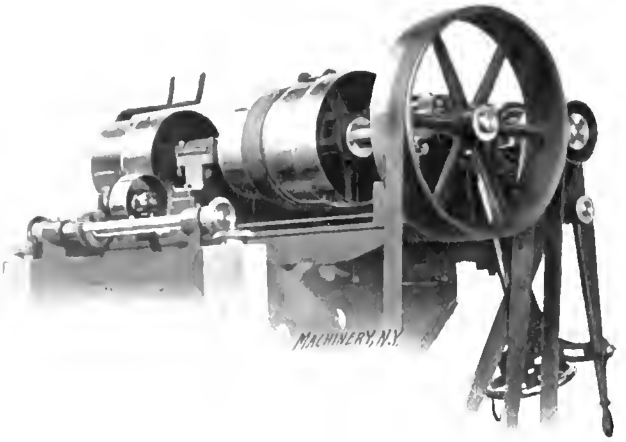
Sensitive Drill with Improved Drive.

GRAY VARIABLE SPEED PLANER DRIVE FOR BELT-OPERATED MACHINES.

In the department of New Machinery and Tools in the December, 1908, issue of Machinery, we illustrated and described a self-contained variable speed drive which the G. A. Gray Co., of Cincinnati, O., has developed for use on motor-driven planers. This drive has been adapted to belt-driven

machines as well, and we herewith illustrate the driving mechanism of a small planer thus equipped.

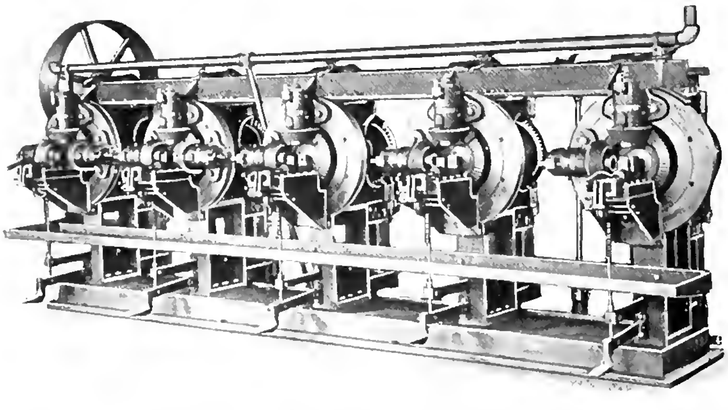
This countershaft, as on the larger motor-driven machines, gives four changes of speed, any one of which may be obtained without shutting off the power or stopping the planer; so no time is wasted in making changes. The return speed is constant, being obtained from the primary driving shaft, which is driven directly from the line-shaft by a belt on the tight and loose pulleys shown. The loose pulley is the smaller of the two, so that the belt pull is lessened when the machine is not working. The usual beveled shoulder between the pulleys facilitates shifting. The belt shifting fingers for the tight and loose pulleys are universal, and can be set to work properly when the planer stands in front of, or behind, or directly underneath the line-shaft. The handle for controlling this shifting is located at the front of the machine.



Application of the Gray Variable Speed Counter-shaft to a Belt-driven Planer.

POTTSTOWN MACHINE CO.'S AUTOMATIC TAPPING MACHINE.

The Pottstown Machine Co., of Pottstown, Pa., is building an automatic machine for tapping T's, 45-degree L's and similar fittings. The mechanism of the machine is such that its movements are automatic, there being nothing for the operator to do except place the work in the machine and remove it when completed.



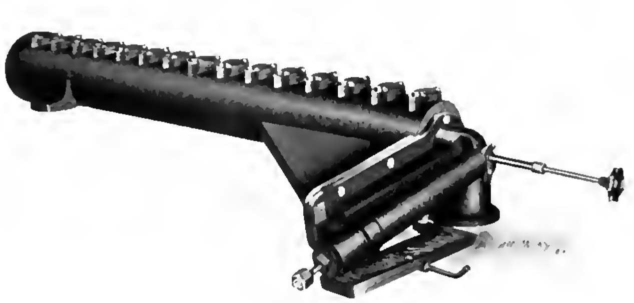
A Gang of Automatic Tapping Machines for T's, Elbows, etc.

From two to six machines may be mounted on a single base as shown. Any one of these may be started, stopped or adjusted without interfering with the other. The work is held in a vise having jaws of suitable form to center the work with the tapping spindles. These are carried in heads which are adjustable about a circular face, as shown, to any position on the quarters, or on the intermediate 45-degree angles. From one to three heads for each piece may be employed as required. The tapping spindles are arranged to make a definite number of revolutions, adjusted to agree with the length of thread to be cut. This adjustment may be made by even quarters of a revolution while the machine is in motion. It is stated that the reversing motion is so positive that the tapping depth is accurate within 1/16 of a revolution. This insures a high degree of uniformity in fit in the finished threaded joints.

The driving mechanism, when the depth has been reached, stops and returns the spindle automatically, when it again stops, waiting for the operator to remove the work. There is thus no danger of injury in the way of getting the fingers caught in the mechanism. When the new work has been clamped in place, the machine is started by a foot lever after the operator has left the working position.

GLOBE MACHINE & STAMPING CO.'S KEROSENE OIL BURNER.

The Globe Machine and Stamping Co., 974 Hamilton Ave., Cleveland, O., is manufacturing a kerosene oil burner under patents of John A. Mathes, a California inventor. It is designed to fill a wide field of industrial uses, where the installation is not so large as to warrant putting in an independent gas plant. For most industrial work the artificial gas is too expensive, and coal or coke is not convenient or efficient, and requires constant attention. The new burner, using kerosene oil is thus adapted to the heating of drying ovens, heat-treating furnaces for steels, enameling ovens, water heating apparatus, and numerous other industrial purposes.



A Gravity-fed Burner for Kerosene Oil.

As compared with other forms of apparatus for burning oil of various kinds, this apparatus does not require a forced blast, and does not use an atomizer of any kind. The oil is atomized by heat under conditions that prevent the deposition of carbon in the vaporizing chamber. There is thus no interference with the operation of the burner. The burner does not require pressure pumps for forcing the oil, which is fed to it from a reservoir or barrel placed about 10 feet above the level of the burner. The construction is the simplest possible and the flame is controlled with all the ease of a gas burner. The flame resembles very much that of natural gas. Three of these burners in a brick oven about 4 by 5 by 15 feet (300 cubic feet) heat the oven to a temperature of 1,000 degrees Fahrenheit, and consume collectively about four gallons of oil per hour. Five natural gas burners consuming about 700 feet of gas per hour were required to do the same amount of work. It will thus be seen that the cost of operating this burner on kerosene oil (a fuel obtainable anywhere) puts its use practically on a par with that of natural gas.

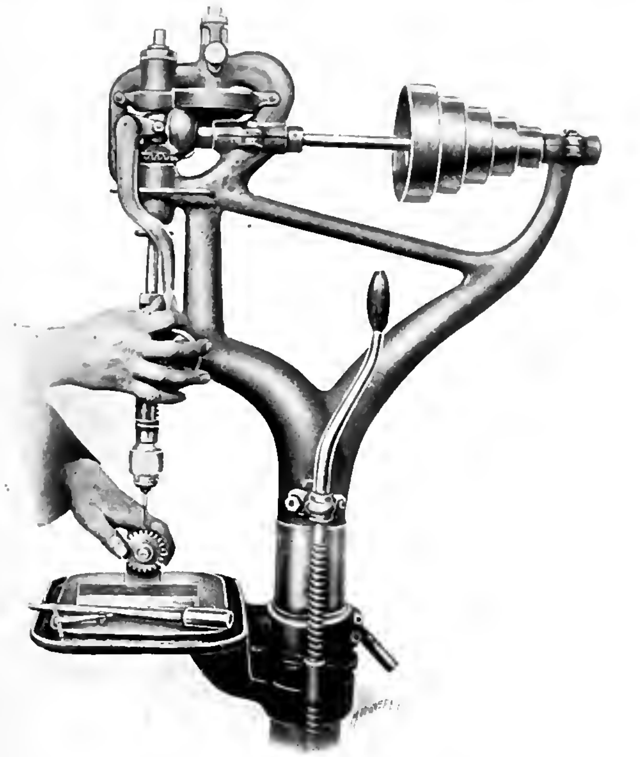
ROCKFORD COMBINED DRILLING AND TAPPING MACHINE.

The bench drill, and the 12- and 14-inch drilling machines manufactured by the Rockford Drilling Machine Co., of Rockford, Ill., are now provided (if desired by the customer) with a tapping mechanism of unusual convenience, built into and a part of the machine itself. The construction of the device will be understood after a study of the accompanying engraving and description.

For drilling, the usual bevel gear connection is made between the horizontal cone pulley shaft and the spindle. The quick reverse for tapping is driven from a separate bevel gear face on the driving bevel pinion on the cone shaft. This

rear bevel face meshes with an intermediate gear on a vertical stud in a housing at the top of the frame. An intermediate spur gear is keyed to this, which in turn meshes with a spur pinion on a sleeve surrounding the upper end of the spindle. The clutch playing between the bevel gear and spur pinion on the spindle thus serves to engage it with either of these gears, giving a forward movement in one direction and a quick reverse in the other.

The operation of the machine for tapping is very simple. The clutch lever on the right-hand side of the spindle is so located that the operator can control it by the thumb and the forefinger of the right hand, which at the same time grasps and operates the knurled hand-wheel which controls the feed. The operator is then free to use his left hand to hold the work, and to rapidly change the pieces. The intermediate gears of the tapping device are mounted on an upright movable shaft which, when lifted up, disengages these gears from the rear bevel face on the wheel drive shaft. When the gearing is thus disengaged the machine is free for straight drilling at high speeds. The tapping mechanism may thus be instantaneously engaged or disengaged without requiring the operator to move from his position.



Rockford Drilling Machine with Built-in Tapping Attachment.

This mechanism has the advantage over the ordinary removable or portable tapping attachment in allowing the work to be done at the normal height. When the usual attachment is used, mounted in the spindle by a tapered shank, the operator is required to hold his work six or eight inches below the natural level. The builders state that they are preparing to furnish this arrangement in modified form to suit their entire line of upright and gang drills.

HOB SHARPENING ATTACHMENT FOR THE WALKER UNIVERSAL GRINDER.

In last month's issue of MACHINERY, in the department of New Machinery and Tools, we described certain improvements in the universal grinder built by the Walker Grinder Co., of Worcester, Mass. These improvements related particularly to the method of mounting the wheel spindle universally so that it can be swiveled to any angle about a vertical or horizontal axis. This universal adjustment is obtained through a wide range in every direction, without any difficulty in the belt drive, which is so arranged that the belt passes freely over the various driving and idler pulleys without change of tension, and without tending to crowd against the flanges. This spindle drive has made possible an ingenious and effective hob sharpening attachment (see Fig. 1) which is the subject of this description.

Method of Grinding Hobs and other Formed Cutters

To understand the principle of this device it will first be necessary to examine the different methods that are employed for sharpening hobs or other form cutters. The common way of doing this is shown in Fig 2. The face *x* of the wheel is trued up to a plane at right angles to the spindle axis. This face is fed against the cutting face of the hob tooth, the feed movement being in the direction of the arrow. The face of the wheel covers the whole surface of the tooth as the work is passed back and forth in front of it. The difficulty of obtaining good results by this method lies in the fact that the wheel wears away (as it must to cut freely and effectively), and as the outer corner is subjected to the most severe duty, it wears away fastest. The wheel thus tends to assume the shape indicated by the dotted line *a b*, which is obviously not fitted for giving the proper shape to the cutting edge.

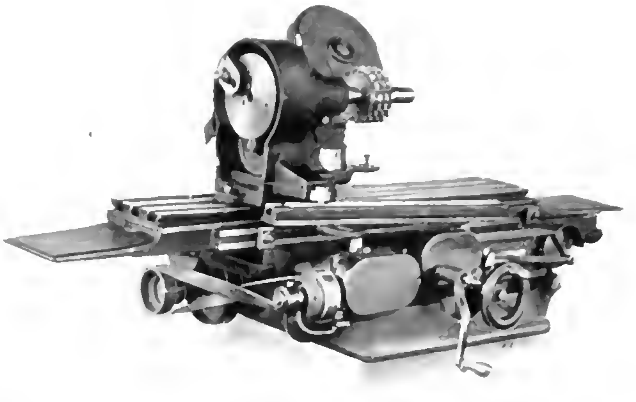


Fig. 1. Hob Sharpening Attachment for the Walker Grinder

The better procedure is shown in Fig. 3. Here the grinding spindle is tilted so that the flat surface of the wheel clears the work; the wheel is set to the proper depth of cut and then fed downward as shown by the arrow, until the bottom of the groove is reached. This is much more satisfactory than the first method, producing a flat radial cutting edge until the wheel has worn back beyond line *a b*. The principal objection to this method of grinding lies in the fact that it requires a vertical feed, which is inconvenient for any ordinary design of grinding machine.

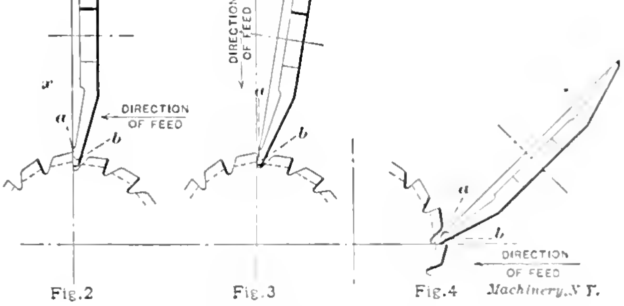

Fig.2 Fig.3 Fig.4

Figs. 2, 3 and 4. Various Methods of Sharpening Hobs and other Formed Cutters.

The objections applying to the other two methods are obviated by the process shown in Fig. 4, which is employed in the Walker grinder. Here the face of the tooth to be ground is placed on a horizontal plane, and the grinding spindle is set at the proper angle to conform to the shape of the groove in the cutter. The radial face of the tooth is thus surface ground by the beveled periphery of the wheel; and by referring to line *a b*, it will be understood that the wear of the wheel simply reduces its diameter and slightly rounds its outer corner, without affecting the finished surface. The feed is horizontal as shown. Other advantages

of this method are a reduction in the heating effect, the possibility of grinding into a sharper corner, and of grinding a spirally grooved cutter. This is impossible by either of the other two methods, as plain surfaces do not clear spiral grooves readily. There is no difficulty on this score with the beveled cutting face in Fig. 4. The Walker grinder has been designed to permit the placing of the wheel in the particular position required for grinding spiral hobs properly.

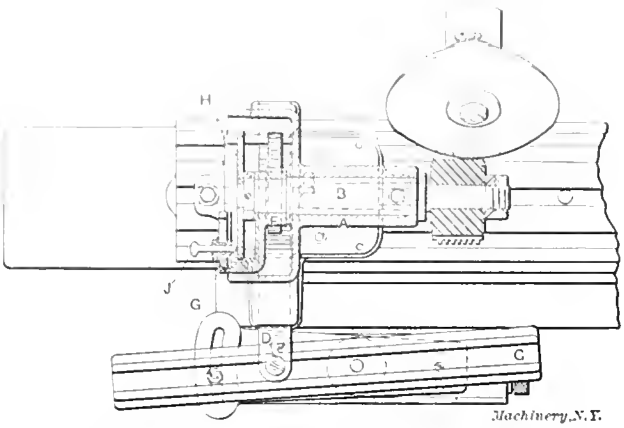

Fig 5. Plan View of Hob Sharpening Device with Helical Attachment.

The Hob Sharpening Attachment.

The mechanism of this attachment is shown in detail in Figs. 5 and 6. The stand *A*, fastened to the top of the grinder table, carries work spindle *B*, which is provided with a tapered hole for receiving the hob or cutter arbor. For hobs with spiral grooves a mechanism is provided for rotating the work in unison with the longitudinal table movement. This rotation is governed by a swiveling bar *C*, identical in construction with that used on lathe taper attachments. The block sliding in this guide is pivoted to the end of cross-bar *D*, which thus receives a greater or less cross movement in unison with the table, depending on the angle at which the slide *C* is set. Rack teeth cut in *D* engage intermediate gear *E*, which in turn meshes with pinion *F* on the spindle. For grinding straight grooved hobs or cutters, the bar *C* is set parallel with the table movement.

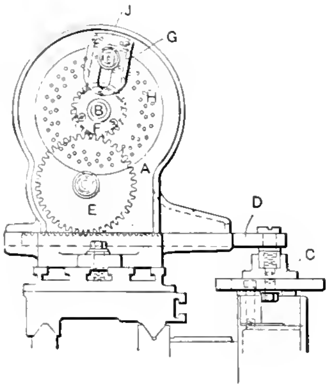

Fig. 6 End View of Device.

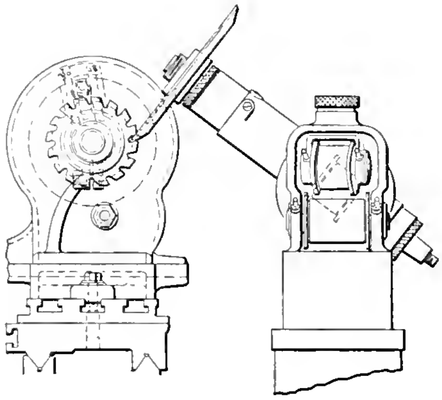

Fig 7. Arrangement of Machine for Grinding a Right-hand Hob.

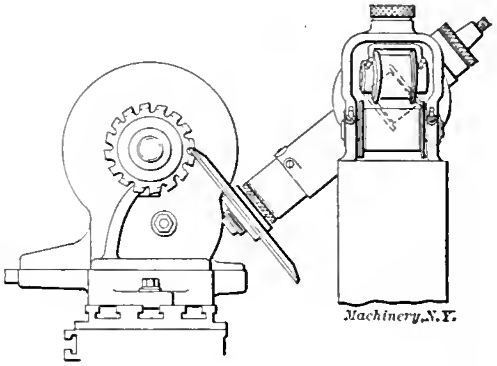

Fig. 8. Arrangement for Left-hand Hob.

The indexing mechanism is plainly shown in Figs. 5 and 6. Pinion *F* is not keyed to spindle *B*, but is part of arm *G*, which carries the index pin, *J*. The index plate *H* is keyed to the spindle. The index pin may be adjusted radially to line up with any particular row of holes in the index plate. The latter may be changed to give any required indexing. It will thus be seen that the rotary movement for the spiral attachment is transmitted from cross-bar *D* to intermediate gear *E* and pinion *F* to index arm *G*, and thence through pin *J* and plate *H* to the spindle *B*.

Method of Setting up the Machine.

Figs. 7 and 8 show the arrangement of the machine for grinding right- and left-hand teeth respectively, when the cutter, as would be the case if made with a solid shank, cannot be reversed in the spindle. The arrangement for the right-hand teeth in Fig. 7 is the same as in Fig. 4. For left-hand teeth the cutter spindle is tipped to the corresponding position below the horizontal, and the grinding is done on the under side of the tooth face, as shown in Fig. 8. This latter illustrates the flexibility of the spindle drive provided.

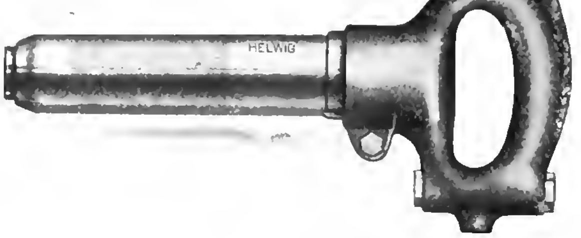
It is understood, as explained in connection with Fig. 4, that the face of the cutter tooth is thus finished by a surface grinding operation, using the automatic cross-feed in the regular manner. The sharp corner of the grinding wheel is maintained by the wear of the periphery. There is practically no danger of drawing the temper of the cutter, and when the tooth is ground it presents a keen edge, without discoverable evidence of round edges and other imperfections.

HELWIG PNEUMATIC CHIPPING AND RIVETING HAMMERS.

The Helwig Mfg. Co., St. Paul, Minn., is building the hammer illustrated herewith. It is designed to meet the severest requirements for tools of this kind, being of large capacity, simple design, substantial construction, convenient of manipulation, and low in cost of operation and maintenance.

The handle is drop-forged and of the closed type, having a shape conforming to the grip of the hand. The locking device makes it impossible for it to get loose on the barrel. The hose connection is at right angles with the barrel, making it more convenient to handle and lessening the pull of the hose on the operator. It also gives more clearance in close quarters, and obviates wear and tear on the hose and the threaded connections.

The valve chamber is hardened and ground, and solidly bedded in the barrel, though it is easily removable. The whole valve mechanism is very simple. The valve is balanced and of the positive type, with a large wearing surface. As it operates in the same direction as the piston, the wear on it is reduced to a minimum, and the full power of the air is utilized for effective work, instead of being wasted in overcoming friction. The piston is a solid piece of tool steel, also hardened and ground. The construction is such that the operator does not feel the hard metallic blow met with in some tools of this kind. This lessens his fatigue and increases his efficiency. The hammer will not operate unless the chisel is in place.



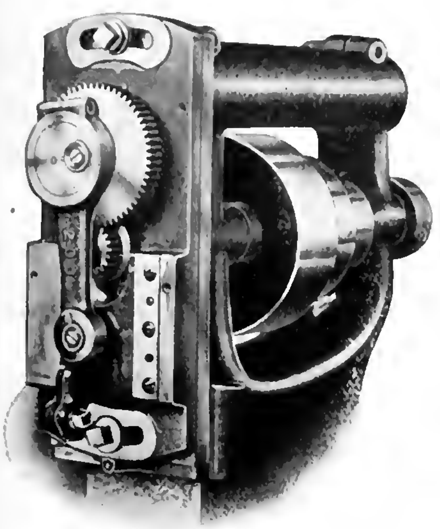
Helwig Chipping Hammer.

This tool is made in a wide variety of sizes and capacities, both for chipping, calking and beading, and for riveting. To

illustrate the power of the tool, it is said that the 4-inch stroke riveting hammer, weighing 11 pounds, will drive ¾-inch rivets steam tight.

SLOTTING ATTACHMENT FOR THE BURKE MILLING MACHINE.

The accompanying illustration shows a back-geared slotting attachment designed by the Burke Machinery Co., 1837 Thirty-fifth St., Cleveland, O., for use with its No. 3 and 4 milling machines. One of the novelties in the construction of this attachment is the geared drive, which makes heavy cuts possible on a high speed miller.



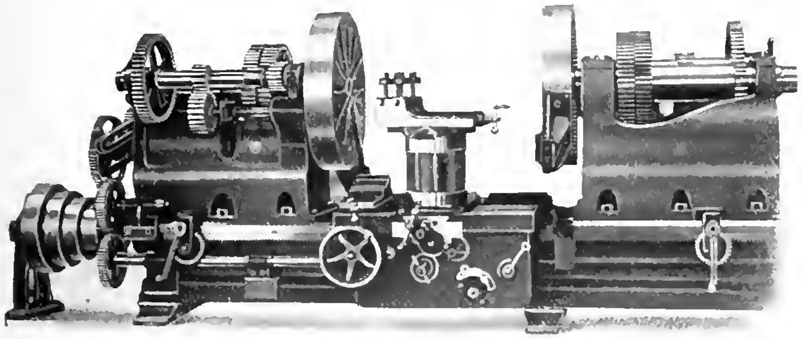
Back-geared Slotting Attachment with Gear Case removed.

The attachment is clamped to the face of the column, and to the over-hanging arm support, making it, for all practical purposes, a part of the machine. The guides for the slide swivel on this support about the axis of the driving pinion, to any angle up to 10 degrees either side of the center. The graduated dial for reading this adjustment, and the bolt for clamping the slide to the desired angular position, are clearly shown in the engraving. The stroke is one inch. The device weighs, complete, twenty-three pounds.

FAY & SCOTT DOUBLE-HEAD FACING LATHE.

The 62-inch double-head lathe shown herewith is a combination of facing machine and lathe. It is particularly designed for use in facing flanges, girders and similar work held in stationary fixtures on the bed. For this purpose it is provided with facing slides and tool-holders on the faceplates. It is also adapted to the boring of cylinders by means of a traveling head boring bar. The machine was constructed from the stock parts of the builders' regular 38-inch standard lathe, raised to swing to 62 inches over the bed, and 50 inches over the carriage.

The machine is fitted with a regular carriage, having an extension for the extra swing; it is provided with the usual feeds and screw cutting features, making the machine available for ordinary lathe work. The head-stocks are each adjustable lengthwise of the bed by a rack and pinion movement; they may be clamped in any position to suit the work in hand. The facing heads, which also form the faceplates of the lathe, are driven by the usual triple-geared mechanism, being provided with internal gear teeth in their rims engaging driving pinions in the head-stock. Each head-stock is driven from a spline shaft passing through the center of the bed. The spindles run in opposite directions to equalize the strain on the work.



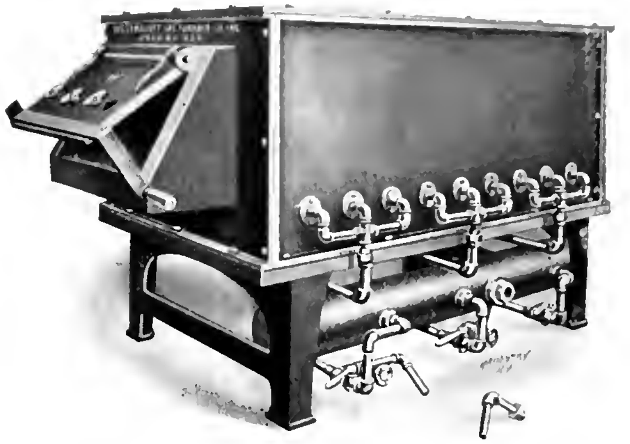
A Modified Lathe, adapted to Facing and Boring Work mounted on the Bed or Carriage.

The back gear ratio is 12½ to 1, the gear ratio with the triple drive into the faceplate is 40 to 1. The maximum distance between the facing heads with a 22-inch bed is 13 feet. The weight is 24,000 pounds. The builders are Fay & Scott, Dexter, Me.

WESTMACOTT HARDENING AND ANNEALING FURNACE.

The accompanying engraving shows a hardening and annealing furnace recently furnished by the Westmacott Gas Furnace Co., Inc., of Providence, R. I., to the Rock Island Arsenal. It is notable for the small gas consumption due to a new style of burner with which it is equipped.

The furnace is intended for annealing and hardening carbon steel, the maximum temperature required being 1,600 F. The space to be heated is 62 inches long and 26 inches wide. Nine burners on each side are provided, or eighteen in all. These are divided into three sets of six each, controlled independently, as shown in the engraving. The furnace operates satisfactorily on about 425 cubic feet of gas per hour; the fuel in this case has a richness of about 425 B. T. U. per cubic foot, and the air pressure is 1½ pound per square inch. The net weight of the furnace is 6,500 pounds.



A Hardening and Annealing Furnace, which shows great Fuel Economy.

CUTLER-HAMMER ALTERNATING CURRENT DRUM CONTROLLERS.

The Cutler-Hammer Mfg. Co., of Milwaukee, Wis., has recently developed a line of drum controllers for use with two- or three-phase slip ring motors, operating cranes, hoists, and other classes of machinery which require frequent starting or stopping. Both the drum and resistance are rated for intermittent duty not exceeding 150 per cent of the motor rating, for both primary and secondary circuits; and they are designed to reduce the motor speed 50 per cent under average load conditions. Where the service is exceptionally severe, or where special specifications are to be met for which the standard controller may not be suitable, the builders are prepared to give estimates on special equipment.

The drums consist of a three-pole primary, combined line and reverse switch, with a cylinder for controlling the secondary starting and regulating resistance, mounted on the controller shaft and driven directly by the operating lever. For all sizes of drums the secondary resistance controller is of open construction. For the types A, B and C drums the primary switch is also of open construction, but for the types D and G drums the primary switch is immersed in oil. The A, B and C drums are arranged for wall mounting, but the D and G drums are for floor mounting, in order to provide properly for the oil tank containing the primary switch. The installation of the latter should provide space for the removal of the oil tank for connecting and inspection. The drums are constructed of the best materials throughout. All contacts

[illegible] of hard drawn copper and are easily [illegible] renewed. The contact segments are firmly mounted on a metal cylinder, which remains perfectly true under all climatic conditions. The oil tanks for the types [illegible] are of seamless steel and will not leak. These tanks should be kept full of a clear mineral oil. Machine oil must not be used.

Resistance is provided in each of the three phases of the motor circuit, mounted in comparatively small frames for convenient installation. Except for the small sizes, the resistance is of the cast metal grid type. The resistance is as compact as possible, consistent with ample capacity for intermittent regulating duty.

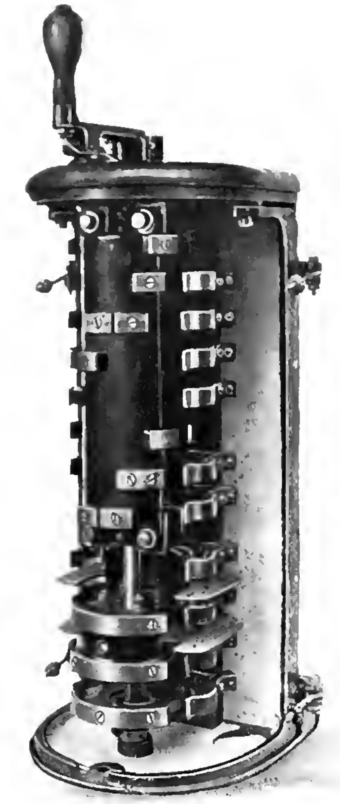


Fig 1. Reversible Drum Controller for Alternating Current.

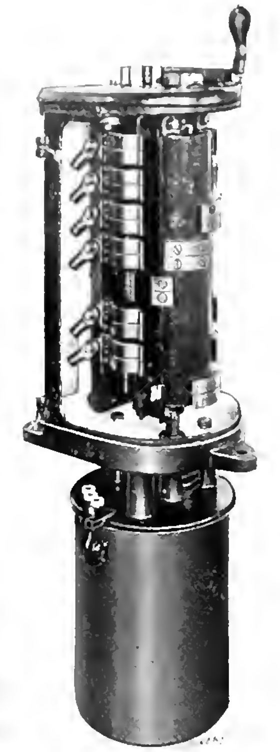

Fig 2. Drum Controller with Oil Tank for Primary Switch.

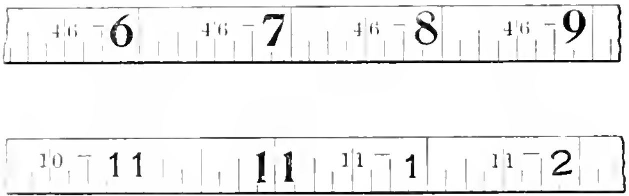
LUFKIN STEEL TAPES FIGURED FOR INSTANTANEOUS READING.

The accompanying illustration shows at a glance the nature of an improvement in the figuring of steel tapes, which has been devised by the Lufkin Rule Co., of Saginaw, Mich. Everyone who uses a long tape has suffered the inconvenience which arises from the fact that the number of the feet is only registered at the end of each 12 inches. When an exact measurement is required which comes between two foot marks, it is necessary to first ascertain the number of inches, and then go back carefully to discover the last registered foot.



Machinery,N.Y.

Instantaneous Reading Graduations for Steel Tapes, giving both Feet and Inches

The improvement consists, as may be seen, in printing the number of feet in smaller figures, at each inch mark, immediately preceding the number of inches. This makes it possible to read without risk of error the exact measurement at any point. On the upper tape, for instance, the dimension 16 feet, 7½ inches may be read at a single glance. A common error is that of reading 11 feet, when the figures for 11 inches immediately precede the figure for 11 feet. No such error in reading can occur with this new form of "instantaneous readings," as the makers term it, as may be seen in the lower section of tape in the engraving. This form of dimensioning will be furnished without extra charge on all steel tapes made by this firm of ¼- and ⅜-inch width, up to 100 feet long. The design is patented.

BEMIS & CALL ADJUSTABLE SQUARE-JAWED AND PIPE WRENCH.

The well-known "S" square-jawed wrench and the corresponding pipe wrench made by the Bemis & Call Hardware & Tool Co., of Springfield, Mass., have been combined in the form shown herewith. This combination wrench at the present time is made only in the 6-inch size. It is particularly adapted for automobile and gas engine use. The sliding jaws are provided with full bearing on the frame when opened to their widest capacity. The parts are all carefully hardened and tempered for the duty expected of them. The operating nuts of these wrenches are of steel and the sliding jaw is a steel drop forging, notched on the pipe wrench side with teeth for engaging the pipe. It will be found useful for turning pipes or unscrewing bolts and nuts in confined places, such as corners or close to walls. The price of the single pipe wrench has lately been reduced to agree with that of the square jaw style.

Adjustable Combined "S" Pipe and Nut Wrench.

DELTA NEW CUT FILE FOR SAW SHARPENING.

A file specially designed for saw sharpening is being made by the Delta File Works, Carver File Co., Philadelphia, Pa. This file is made on a slim tapered blank in lengths from 4 to 10 inches. The tang is drawn without a shoulder, and the lines on the edge of the file run parallel until very close to the point, where they taper very sharply. The angle of the tooth is made more acute by 10 degrees than that ordinarily used for saw files. This enables more teeth to the inch to be cut, and also strengthens the edge of the file. This edge receives the brunt of the work in saw filing, as it is in action in the gullet at every stroke removing more stock than the side of the file. These improvements combine to give the tool a high efficiency. The makers have reports of tests in two different saw factories giving records of the filing of as many as eight saws with one file.

AMERICAN BLUE-PRINT PAPER CO.'S REPRODUCTION PROCESS.

The American Blue-Print Paper Co., 294 Dearborn St., Chicago, Ill., announces the introduction of a new process of printing by means of which reproductions may be made from black line, blue line or any color print, directly on drawing paper, cloth, tracing paper or cardboard as quickly as blueprints are made. Tracings may be reproduced on cloth or paper, which will be fac-similes of the original and true to scale; there is no difficulty from shrinking as is the case when the reproductions have to be washed in water and dried. The new prints are flat and permanent. The lines do not fade nor the background turn yellow. The body of the paper or cloth is not coated with an acid solution as is in other processes, so that it is in the same condition as when received from the manufacturer. It is stated that the black prints made with this process are jet black and not dark brown like

those made from negatives. Any part of the original not wanted in the reproduction can be blocked out without damage to either original or reproduction.

This process is an extremely rapid one. The firm mentioned above has such facilities for the work that all orders sent are shipped the same day the tracings are received, so that the work is practically done as quickly as though it were not sent out. The process has not been as yet developed for individual use by customers, as it requires unusual care and experience. The demand for prints made in this way has been so great as to severely tax the equipment of the manufacturers.

NEW DESIGN OF LEA SIMPLEX COLD METAL SAW.

The Lea Equipment Co., 136 Liberty St., N. Y. City, has recently re-designed the "Lea Simplex" cold metal saw, introducing important improvements, particularly in the feed mechanism. The machine as a whole is shown in Fig. 1, while the new mechanism is seen in detail in Fig. 2. The general arrangement of this saw is well known. The blade is driven by a pinion whose teeth mesh with slots cut in the blade itself near its periphery, thus giving a drive nearer the cutting point of the saw than can be obtained by other methods. This drive also gives a maximum of capacity for a given diameter of blade, as no clearance for the driving gear on the spindle has to be allowed for. The saw arbor, blade, and driving mechanism are mounted on an arm which is swung upward about a pivot at the rear, to feed the saw into the work.

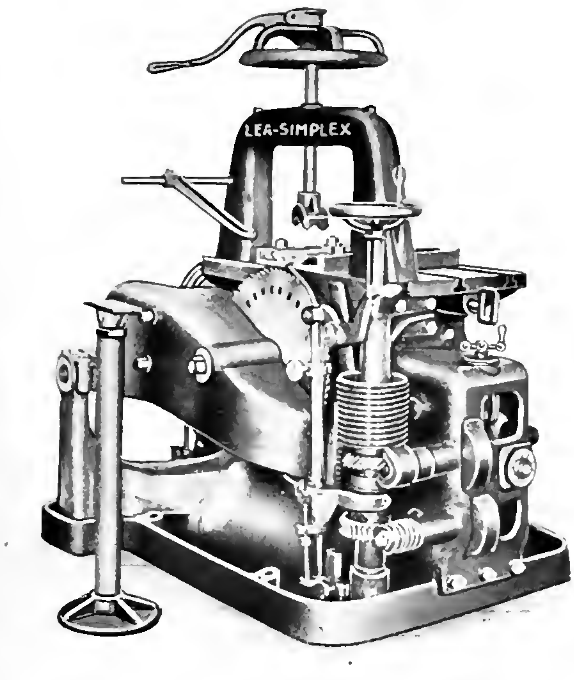


Fig. 1. Lea Simplex Cold Saw with Improved Feed Mechanism.

As shown in Fig. 1, the swinging arm which carries the saw is fed upward in the new design by a worm of large diameter, engaging a segment of a wormwheel clamped to the arm. This worm is driven from a feed-box by either the spiral or worm gearing shown. The former is used for the quick return, while the latter is operated by the variable feed mechanism. The feed mechanism (see Fig. 2) is driven by a sprocket and chain from the driving shaft at the rear of the machine. This sprocket is mounted on the constant speed shaft of the gear-box, which drives the feed worm directly through spiral gearing, as previously mentioned. On this same shaft is mounted the first member of a Sellers friction drive. The intermediate member, with the two beveled, spring-pressed disks, is mounted on a swinging sector below it, while the driven member is mounted on a third shaft at the bottom of the feed box. The intermediate member is swung up or down, thus increasing or diminishing the feed, by means of a screw and ball crank shown projecting through the case at the top. The rate of feed is indicated by a dial at the front of the box as seen in Fig 1.

This improved mechanism takes the place of an older friction cone arrangement, which sometimes gave trouble from oil on the bearing surfaces. The Sellers disks are unaffected by oil. The intermediate disks are made of soft steel, while the driving and driven members are of bronze. The sides of the intermediate disks which bear on the bronze disks are beveled to an angle of about two degrees. When the operator grasps the knob on the intermediate disk shaft, which projects through the side of the casing, this action screws up a spring and increases the pressure on the bearing surfaces. An automatic stop and reverse are provided for the feed mechanism, controlled by an adjustable dog, as shown in Fig. 1. Both the worm and spiral gear shafts are fitted with roller thrust bearings.

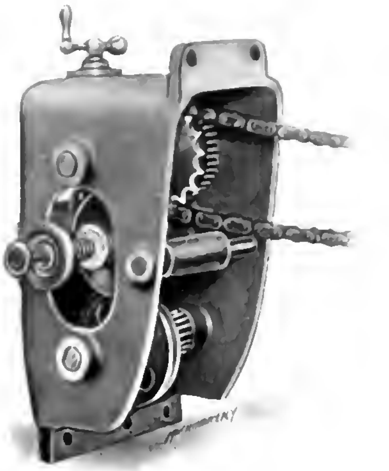

Fig. 2. Detail View of Feed Box, showing Sellers Drive.

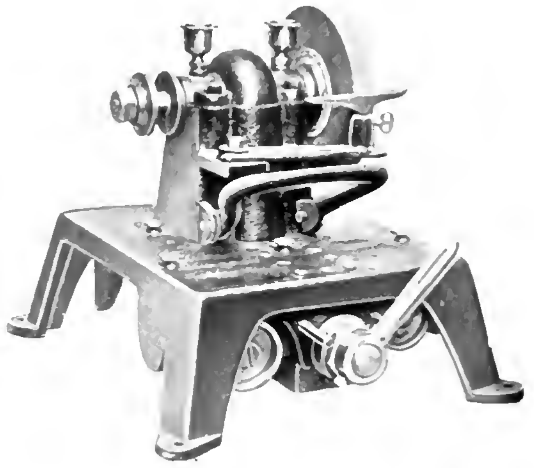
Another improvement made on this machine relates to the form of V-block used. This is adapted to holding either round or square stock, as it is made in two sections which may be reversed if required. It is shown in place on the table in Fig. 1. In cutting round stock the two tapered edges are put together, allowing the stock to rest almost in contact with the table. In cutting square stock, the two castings are turned end for end, thus practically making two knee plates. The holes by which the blocks are bolted to the table are lengthened to form slots, so that the blocks may be swiveled to 45 degrees, permitting angular cuts to be taken.

HELWIG PORTABLE PNEUMATIC GRINDER.

The portable pneumatic grinder built by the Helwig Mfg. Co., of St. Paul, Minn. (shown in the accompanying engraving), is intended for use in railroad shops, shipyards, and places where structural erection is going on, and for other places where there is more or less grinding to do. It saves the time and labor required for carrying tools back and forth to the shops.



A Portable Air-driven Grinder for Tool Sharpening.

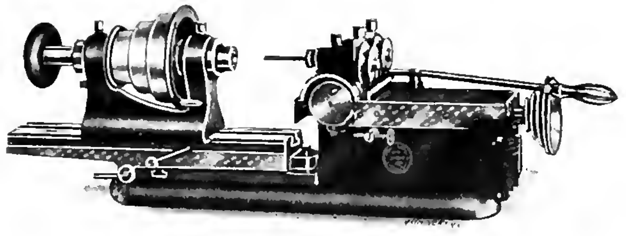
The grinder has a handle by means of which it may be carried from place to place; and it is provided with a clamping device for fastening it to an I-beam, angle iron or other support, convenient to the workman. The tool is made in two sizes. No. 1 weighs 130 pounds, requires 18 by 20 inches of floor space, and may be equipped with two wheels up to 1½-inch

face and 10-inch diameter. No. 2 is smaller, taking a ¾- by 6-inch wheel, and occupying 12 by 15 inches of floor space.

WALTHAM AUTOMATIC INTERNAL GRINDING MACHINE.

The Waltham Machine Works, Newton St., Waltham, Mass., is building the automatic internal grinding machine illustrated herewith. This machine is adapted for grinding holes, from the smallest size up to an inch in diameter. The only limit in size for the minimum hole is that of the smallest practicable diamond charged lap. This machine has the advantage of a drive which permits the maintaining of extremely high spindle speeds; and the further advantage of automatic action, which permits two or more of them to be taken care of by one operator.

The bed of the machine carries ways for the grinding slide at the right, and is provided at the left with an extension on which is mounted the work-carrying head. This can be swiveled from 0 to 45 degrees, and by means of a micrometer screw, readings to minutes may be easily obtained. The swiveling plate has ways of the same profile as the builders' regular 8-inch bench lathe, so that the 8-inch head-stock may be used. The machine can be made, if desired by the purchaser, to fit the head-stock of any other similar lathe, providing standards are furnished for fitting. If the machine is to be used continuously, a special head-stock is recommended, made to take spring chucks. The bed is long enough to permit the use of a back-rest, so that straight or taper holes in the end of small spindles can be accurately ground.



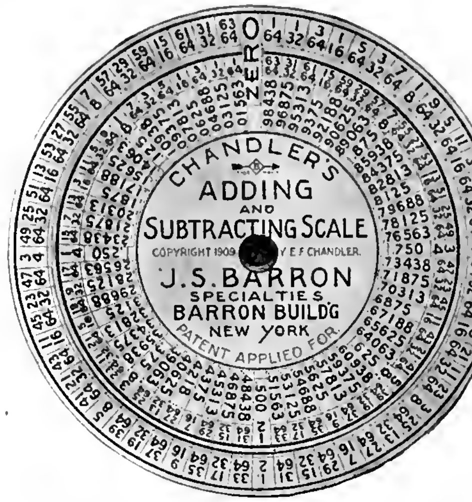
A Precision Internal Grinder with Friction Spindle Drive.

The reciprocation of the grinder head slide on the bed is effected by a cam and slotted link movement, which can be altered to any desired length of stroke within the range of the machine (from 5/16-inch to 2 inches), and to any convenient number of strokes per minute as determined by the cone pulley which drives this mechanism. The cross-slide on which the wheel spindle is mounted is provided with an automatic feed. This is operated by a ratchet mechanism which strikes the adjustable knurled screw seen at the front of the bed in the engraving. By altering the adjustment of this screw, any feed from 1/15,000 to 1/1,500 inch can be given at each stroke of the slide. A stop is provided which throws out this cross movement when a predetermined diameter has been reached. The cross-slide can be withdrawn from alignment with the work by a lever, so that the diameter of the work can be more easily measured. Springs return the cross-slide to exactly its original position.

Two styles of grinding head are made, either one or both of which will be furnished as desired. The high-speed head is shown in the illustration. In this a small straight spindle is driven by two friction disks, mounted on each side of it. The two driving pulleys for these disks are plainly shown. The belt from the countershaft passes down under both of these pulleys and revolves them in the same direction. The friction disks attached to the pulleys spin the grinding spindle between them in the same way that a pencil might be spun between the thumb and forefinger. This method would appear to permit a much higher speed than could be maintained with a belt-driven spindle. Since the belt itself runs comparatively slow, it may be larger and of more durable construction than would be possible if it drove the spindle directly. For larger work where slower speeds can be used, a plain direct belted grinding head is used. On both styles provision is made for maintaining vertical alignment.

CHANDLER'S ADDING AND SUBTRACTING SCALE FOR FRACTIONS.

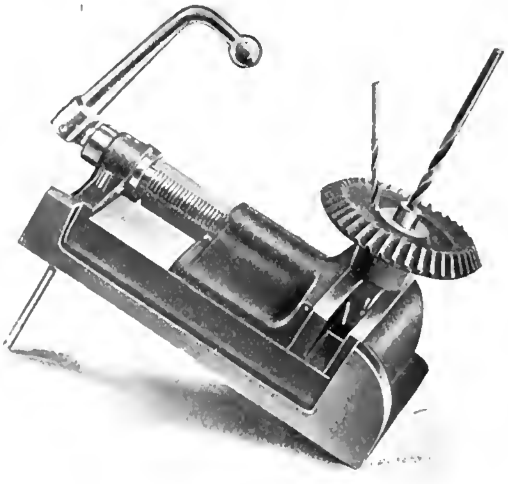
The device shown herewith for adding and subtracting fractions and their decimal equivalents, has been placed on the market by James S. Barron, Barron Building, New York City. The scale is formed by two celluloid disks pivoted at the center, and each provided with two rows of concentric graduations, one of which gives the common fractions and the other the decimal equivalents. The fractions are located on the upper and lower disks, and when two of them are to be added, the disks of the circular slide rule are shifted to bring these two fractions together. The sum will then be found opposite the notch cut in the small disk. Both the fraction and the decimal equivalent are displayed, the latter showing through the notch on the lower scale. For subtraction, the slot on the small disk is set opposite the minuend, when the answer will be found on the large disk opposite the subtrahend on the small disk. The instrument is made of celluloid, so it may be washed whenever it gets soiled. It should prove a very useful device, particularly for draftsmen, machinists, tool-makers, etc. It is sent postpaid to any address for $1.00.



A Circular Slide Rule for Adding and Subtracting Fractions and their Decimal Equivalents.

MOHN UNIVERSAL VISE FOR DRILLING, MILLING, ETC.

The universal vise for holding work for drilling and milling operations, etc., shown herewith, is built by W. D. Mohn & Co., Reading, Pa. The simplicity of its construction is at once apparent, particularly in the matter of setting for drilling angular holes. This is effected by a rod. which may be extended more or less to tip up the vise to the angle required There are no loose parts, as even the wrench is permanently mounted in place on the screw.



A Simple Adjustable Vise for Drilling, Milling, etc.

The base of the tool has a ledge on all four sides, so that it may be clamped securely to a machine table from any side without springing either the vise or the machine. The front side in the view shown in the illustration is machined, so that the vise may be set on edge. The sliding jaw has a vertical groove (which does not show plainly in the illustration) for holding round work. The handle is carefully proportioned to allow firm pressure to be brought to bear on the work, without danger of an excessive strain, the handle having a length proportioned to the size of the vise. The screw and nut cannot be ruined by an attempt on the part of the workman to increase the leverage by a piece of pipe stuck over the end of the handle, as this is bent at right angles, as shown, to prevent such abuse.

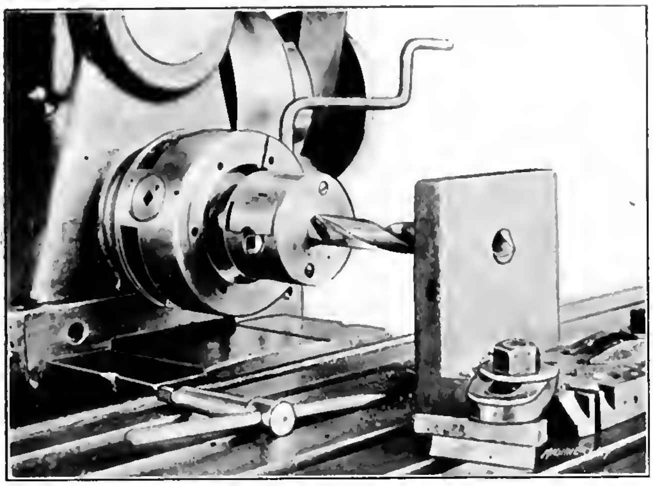


Fig. 1. Casler Eccentric Boring Head, Centered for Drilling.

The tool is made in three sizes. The smallest has a jaw 3½ inches in width and 1 inch deep, giving a maximum opening of 2 inches; the weight is 6½ pounds. The largest size has a jaw 6½ inches wide and 1¾ inches deep; the maximum opening is 6 inches, and the weight is 45 pounds.

CASLER ECCENTRIC BORING HEAD.

The eccentric boring head, illustrated herewith, is designed to be fitted to milling machines, drill presses, boring machines and lathes, and is used to bore holes accurately and to size on any class of work where it is convenient to hold the work stationary, rather than to fasten it to a rotating spindle. It is particularly adapted for use on milling machines, in laying out and boring holes in jigs and tools. It saves time in that it offers means for making minute adjustments quickly and surely, without the uncertainty of adjustment found in using a boring bar with an inserted cutter held by wedges or set-screws. It is a difficult matter to adjust such a cutter with a hammer to exactly the right diameter.

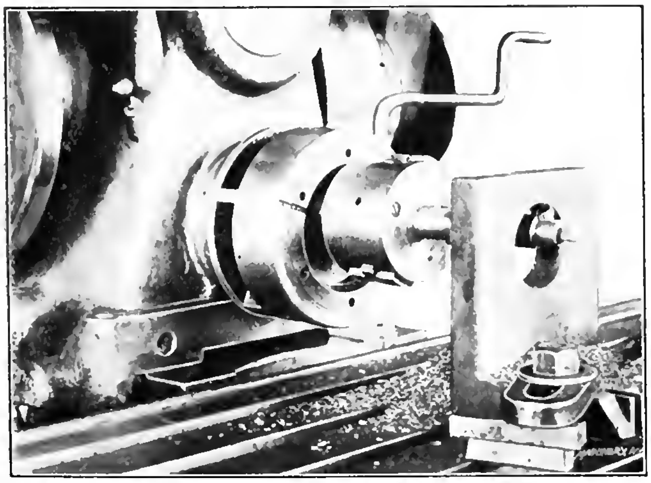

Fig. 2. Enlarging the Drilled Hole with a Boring Tool.

Figs. 1 to 4 show the device in use and Fig. 5 shows its construction. The tool consists of a body *A*, which is threaded to the spindle *B* of the tool on which it is used. The outer face of this body is recessed to receive a plate *D* into which is threaded the tool-holding chuck *C*. *D* is of smaller diameter than the recess in which it is laterally adjustable, so that the chuck may be set at any position from exact concentricity with the center line of the spindle to the maximum offset shown by dimension *F* in the face view. This latter adjustment is controlled by a screw in the side of the body *A*. The head of this screw is provided with graduations reading to 0.001 inch, and has a squared socket so that it may be operated by the chuck wrench. It is not shown in Fig. 5, but may be seen plainly in Figs. 1 and 3. When the adjustment has been made, the floating disk *D* is clamped by screwing down the threaded ring *E*, firmly binding the whole head together.

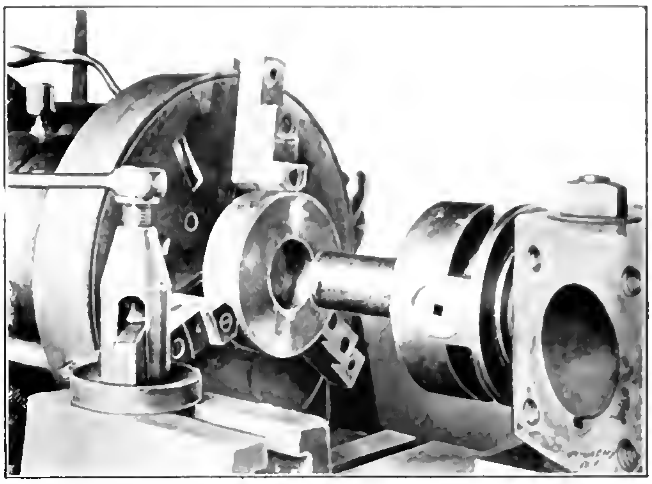

Fig. 3. Use of Adjustable Head in Turret Lathe. Chuck replaced by Heavy Boring Tool.

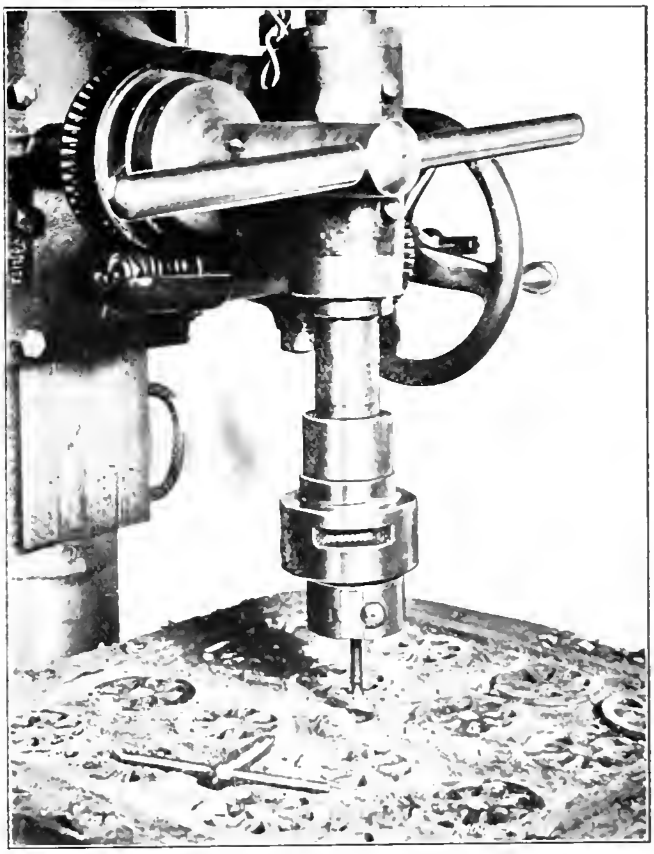

Fig. 4. Boring Head in Use on Drill Press

In using the tool for boring moderate sized holes, the drill chuck is first set concentric with the boring head, and the ordinary twist drill is used in the chuck to start the hole, as in Fig. 1. After the hole has been brought nearly to the size by the use of twist drills, the drill is replaced by a tool with a single cutting point, similar to a lathe boring tool (see Fig. 2). By means of the offset movement of the drill chuck, this tool is easily brought to the proper position to

[illegible] to [illegible] to the required diameter. But very few tools [illegible] a wide range of work, for the reason that [illegible] between the minimum and the maximum diameters [illegible] tool will cover, is equal to four times the offset [illegible] the boring head.

In cases where a tool which could be held in the drill chuck would not be heavy enough, the latter can be removed from the boring head and a heavy bar of the required length inserted in its place; cutting tools can be secured in this bar by set screws for the coarse adjustments, and the finer adjustments obtained by the graduated screw on the boring head. The head is shown thus equipped in Fig. 3, where it is being used as a stationary tool in the turret machine for a boring operation. Fig. 4 shows its use in the drill press.

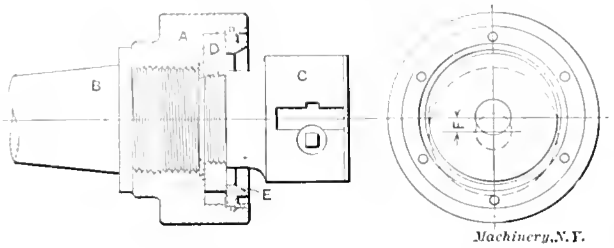

Fig. 5. Details of Construction of Eccentric Boring Head.

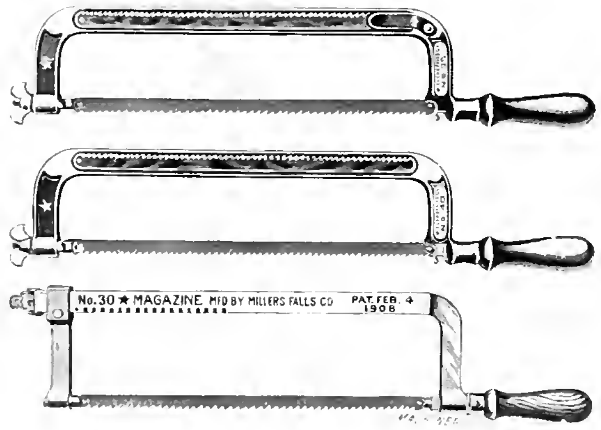
It should be noted that the head allows drills or tools to be passed clear through the chuck into the spindle hole, if desired. The end of the drill chuck or boring bar is supported very close to the end of the spindle, so that very little space is required for the head. The rigid construction of the tool (which will be easily appreciated from Fig. 5) permits the use of heavy cuts, as the whole device forms practically an extension of the spindle. The Marvin & Casler Co., Canastota, N. Y., is the builder.

MILLERS FALLS CO.'S MAGAZINE HACK-SAW FRAME.

The Millers Falls Co., 28 Warren St. New York City, has devised a new form of hack-saw frame which provides a receptacle for extra blades. This provision may be truthfully described as "filling a long-felt want," as it is not uncommon to see a hack-saw frame with extra blades tied to it with a string to keep them from getting lost. The improvement will be, perhaps, more appreciated for individual than for factory use.



Various Styles of Hack-saw Frames, with Provision for Carrying a Supply of Blades.

This hack-saw frame is made in the three styles shown in the accompanying engraving. The upper frame for 12-inch blades is made from cast iron. The magazine is formed by a deep recess cast on each side of the back of the frame, into which six 12-inch blades can be placed for storage, three on each side. The blades are held in place by a flat retaining spring. The second frame is the same as the previous one, with the exception of the provision for holding the blades in the magazine. In this case they are simply sprung into shields or pockets at the ends of the recesses. The adjustable style of frame is made to hold blades from 8 to 12 inches inclusive. These have the magazine in the back of the frame, which is hollow, being made of rectangular tubing. There is room here for a dozen blades. The depth from the back to the cutting edge is 3½ inches.

ROOT COUNTER.

The C. J. Root Co., Bristol, Conn., manufacturer of counting machines, has produced a new design which presents a number of advantages over other machines previously built. The instrument is contained within a case fastened with a Yale lock as shown, and it is so constructed that the mechanism is safeguarded against any tampering from the outside. It is provided with a glass cover, but even should this cover be broken, the figures cannot be changed until the apparatus is unlocked.

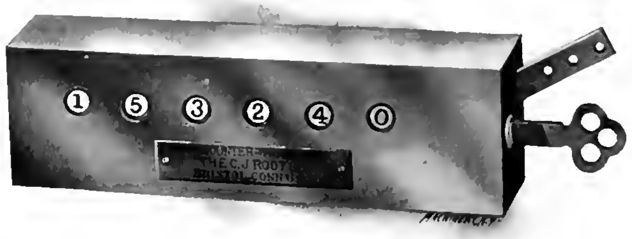


Fig. 1. The "Root" Counter, with Lock Cover to prevent Tampering.

The mechanism is shown with the cover open in Fig. 2. As may be seen, it is of the simplest form imaginable. There are no springs and the action is positive. It is impossible for the figures to jump. It will register at any reasonable speed and lock the dials at each change of the figures. Very little power is required to move it, even when the whole six figures are changed at once. The wearing surfaces have been reduced to a minimum. Resetting the counter is a matter of the utmost simplicity. The cover is thrown back, and each dial in turn is pulled out ¼ inch, set at the desired figure, and returned, beginning at the right-hand figure. The closing and locking of the cover again holds the dials firmly at the new setting, without any possibility of change except with the movement of the counting lever.

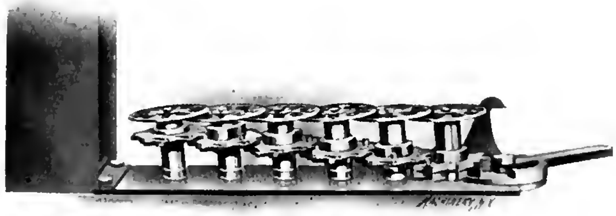

Fig. 2. Cover Raised, showing Simplicity and Positiveness of Mechanism.

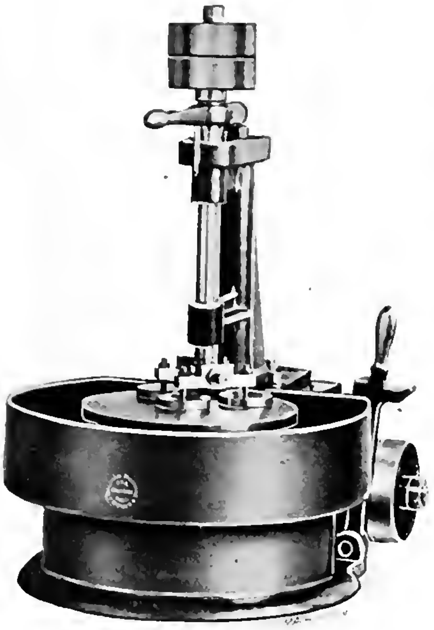
WALTHAM FLAT LAPPING MACHINE.

The Waltham Machine Works, Newton St., Waltham, Mass., builds the flat grinding or lapping machine shown herewith. It is intended for the finishing of flat parts on a revolving disk or lap of glass, tin, cast iron, or other material, charged with an abrasive of a kind and grade suited to the material worked and the finish desired. The principal points of interest in the machine are a solid, compact construction, every part being above the bench and easy of access; the geared drive to the work and lap spindles; and the pressure equalizing arrangement for the driving arms.

In using this machine, the work is secured (usually by shellac) to suitable cast-iron blocks such as the four seen resting on the lapping plate in the engraving. These blocks are guided by center holes in their upper faces in which are pressed center points mounted in arms on the upper shaft.

These four points are mounted on the opposite ends of two arms, pivoted on a rock shaft as shown. This rock shaft is pivoted in turn to the vertical spindle, which is provided with weights at the top to give the desired pressure between the work and the lap. The system of pivoted arms and cross-bars evidently equalizes the pressure on the four pieces of work. The weights may be changed to suit the area and material of the work being finished.



A Lapping Machine for Flat Surfaces.

The upper shaft and that carrying the lap both revolve—the former four times as fast as the latter, and in the opposite direction. This constantly changes the position of the work on the disk, and breaks up all the lines formed by the continued action of the abrasive. By swinging the head carrying the upper shaft and by adjusting the distance of the center points which guide the disks, the work may be so located that exactly the full surface of the lap is covered while in operation.

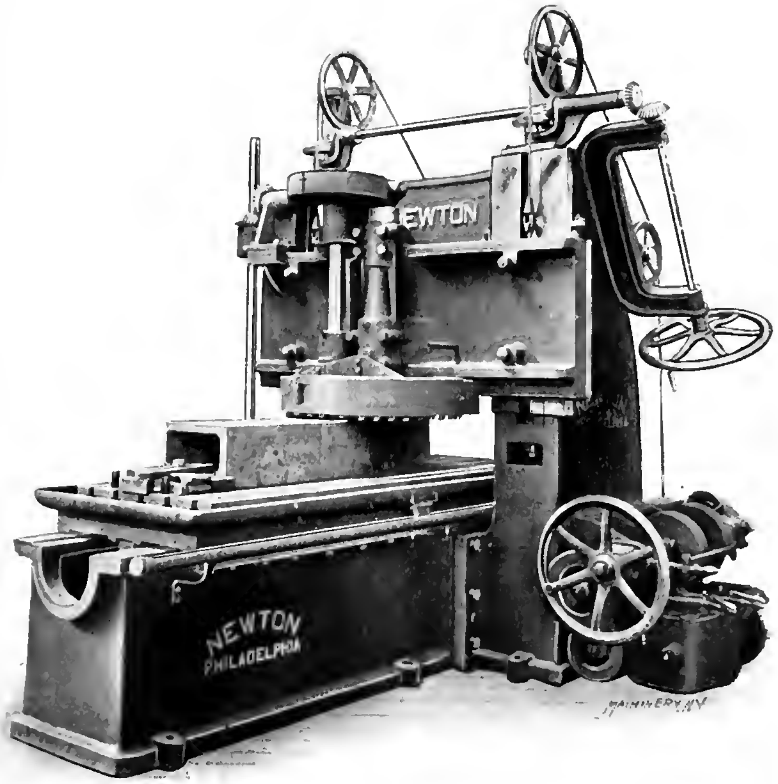


Fig. 1. Newton Vertical Spindle Rotary Planing Machine, with Adjustable Cross-rail.

The diameter of the lapping disk is 12 inches. The weight of the machine is 365 pounds.

NEWTON VERTICAL SPINDLE ROTARY PLANING MACHINE.

The Newton Machine Tool Works, Inc., Philadelphia, Pa., has developed a vertical spindle rotary planing machine, specially adapted to machining turbine segments such as required in the building of the Curtis turbine by the General Electric Co. The machine itself, as shown in Fig. 1, has the drive applied directly to the cutter-head, by means of a pinion engaging internal teeth in a rim on its upper face. The cutter-head or face-plate gives a width of cut of 30 inches over the extreme diameter of the cutting tools. The power is furnished by a 10-H. P. motor with a speed variation of 750 to 1,000 revolutions per minute. This is connected by the spur and bevel gearing shown with the worm and worm-wheel keyed to the driving pinion.

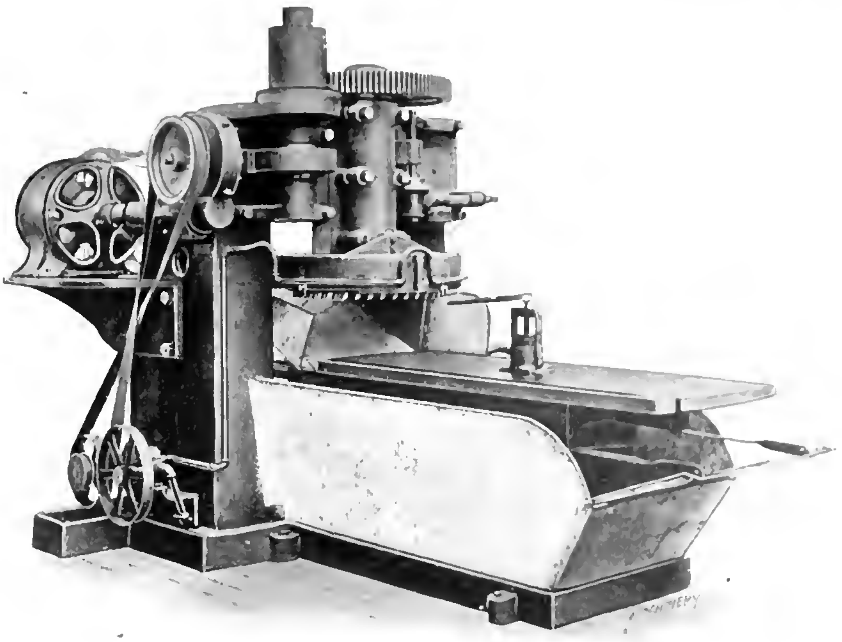

Fig. 2. Rotary Planing Machine with Revolving Table, for Changing Work while the Machine is in Operation.

The saddle which carries the spindle has a firm bearing on the upright, on which it has a hand vertical adjustment, giving a range of 8 to 26 inches from the points of the tools to the top of the work-table. The latter is 30 inches wide, and 7 feet 3 inches long, with a working surface 6 feet long. It is entirely surrounded by an oil pan. The feed movement is through a spiral gear and rack. Nine changes of geared feed are provided, ranging from 0.941 to 9.75 inches per minute. Hand adjustment and power quick return are provided, if a reversing motor is used; this gives a fast traverse in either direction. The hand-wheels for adjusting the rail and the table, and the levers for engaging the feeds and fast traverse motion, are located on the working side of the machine within easy reach of the operator.

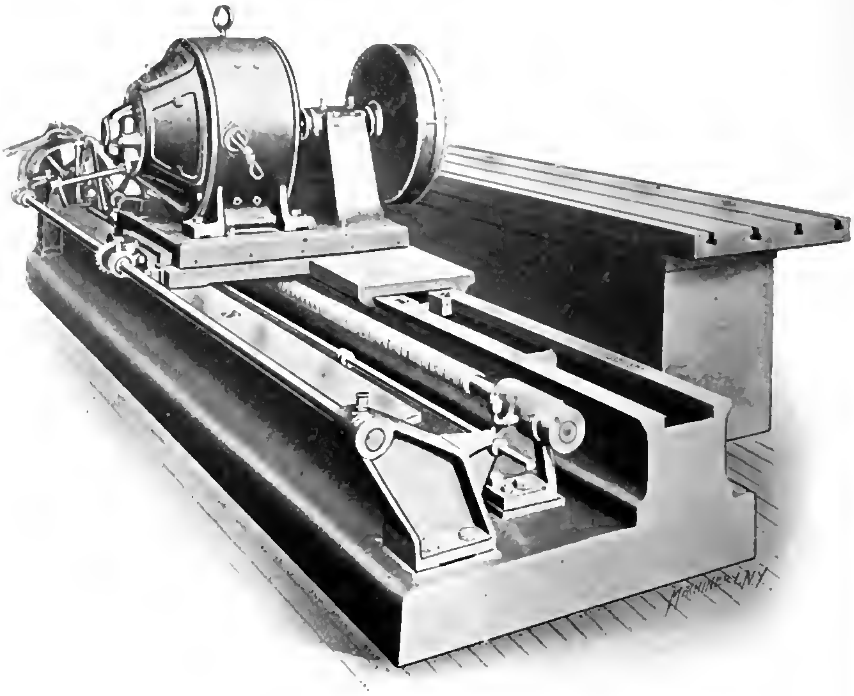
Fig. 2 shows a machine of this type provided with an auxiliary table, which may be revolved about a central pivot. This allows work to be set on one end while the work at the other end of the table is being machined. When the cut is finished the platen is run back and the table is swung half way around, presenting the new lot of work to the cutter, while the old work is in position for changing. This gives practically continuous operation.

DIAMOND MACHINE CO.'S TRAVELING-HEAD FACE GRINDER.

The heavy face grinding machine shown herewith is built by the Diamond Machine Co., of Providence, R. I., for the use of structural iron workers, bridge builders, safe makers and manufacturers in similar lines, where it is necessary to grind to close dimensions such parts as beams, columns, steel safe-plates, cast iron floor plates, etc.

As shown in the illustration, the grinding head is direct connected to an electric motor, which, together with a very heavy outboard bearing is mounted on a large base moving on ways. The motor has an extended shaft to carry the grinder chuck. The work is stationary, being bolted to the large platen in front of the 22-inch emery ring, while the ring rotates and also moves slowly back and forth from end to end of the platen. The reversing is done by a hand lever when the machine is in use, but automatic stops are provided at each end of the $8\frac{1}{2}$-foot traverse, to prevent over-travel should the attendant neglect to reverse the feed. The maximum cross feed of the grinder is $\frac{1}{2}$ inch, and is operated by a hand wheel and miter gear on a splined shaft in the front of the machine. The longitudinal travel of 20 feet per minute is obtained from the triple-threaded feed-screw shown; the lead screw is driven by a second motor not visible in the illustration.

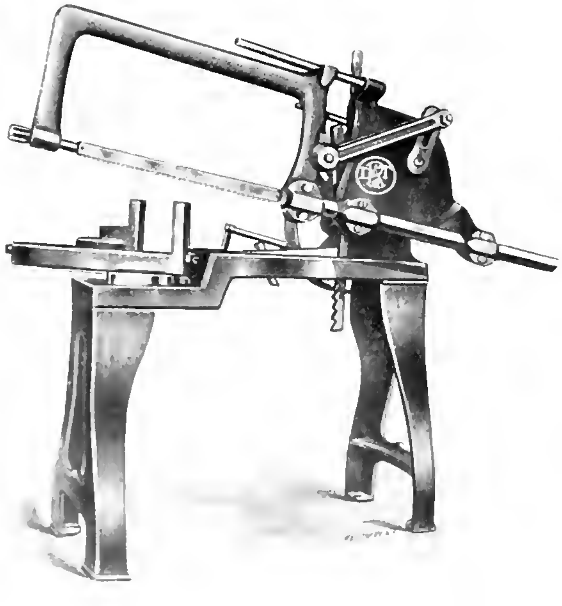
The grinder is direct connected to a standard Westinghouse totally enclosed motor, type "S" compound wound, direct current, giving 10 horse-power at 1,100 R. P. M. Where required, an alternating current motor may be supplied in place of the direct current machine. The size of the motor to operate the lead screw is dependent upon the amount of metal to be removed.



A Traveling-head Grinder for Heavy Surfacing.

ROBERTSON POWER HACK-SAW.

The power hack-saw shown herewith is made by the Robertson Drill & Tool Co., 1848 Niagara St., Buffalo, N. Y. It is called by its maker the "Royal 1909 Power Saw." It incorporates a number of improvements which will be readily understood from the following description:



Power Hack-saw made by Robertson Drill and Tool Co.

The driving mechanism is contained, as may be seen in the engraving, in a hollow gear box which is pivoted about the driving-shaft, and carries the guides for the saw-slide. The crank-shaft is connected to the drive-shaft by spur gearing inside of the gear box; the crank gives a stroke adjustable from 4 to 9 inches in length. The saw frame slides on a long, square guide, which is in line with the blade, and nearly in line with the thrust of the crank movement. This gives a smooth reciprocating action without the cramping met with in the usual construction. The feed is by gravity and means are provided for increasing the pressure as the saw wears. The saw is relieved on the return stroke. The vertical handle shown in the rear lifts the frame, while placing new work in the vise. This handle operates a notched lever, that holds the frame at any desired height in even inches, within its capacity. The frame can also be raised to a vertical position, thus providing ample space for handling large work held and conveyed by a crane.

The vise has a swiveled jaw for holding taper work, and itself swivels on the bed, being provided with graduations up to 45 degrees. This permits the taking of angular cuts. It will be noted that the bed is lowered where the vise is located. This enables the saw to be started at a good cutting angle when the largest work (8 by 8 inches) in the capacity of the machine is being operated on.

. The parts are fastened together as far as possible with tongue and grooved connections, insuring first-class alignment. All plane surfaces are milled. The length of the blade used may be from 14 to 17 inches. The machine should run at from 60 to 70 strokes per minute. A high-speed design is furnished by the makers which has a tank for holding lubricant, which is pumped onto the saw. The pump is located in the head, and is geared to the driving pinion, which operates the pump only when the saw is cutting. Suitable provisions are made in the motor for straining the lubricant, and returning it to the tank for re-using.

* * *

Alteration sales are a common excuse made by a certain class of tradesmen for alleged reductions of prices. The gullible public is asked to believe that so great is the need of alterations to accommodate new stock in a growing business, that the merchant will sell his present stock at prices below cost in order to make the clearing out necessary for the changes. The fact that the business of the merchant is *selling goods* for profit and not making alterations stamps most of such claims as deceitful devices, and they insult the average intelligence, but strangely enough, though entirely unsubstantiated by logic, they are daily made the pretence of price reductions. The question is, who is most deceived, the public or the proprietors themselves. Whatever the answer is, the practice is a strange and interesting example of the confusion of cause and effect existing in the minds of a large part of apparently intelligent people.

NEW MACHINERY AND TOOLS NOTES.

All-Steel Screw-Driver: Billings & Spencer Co., Hartford, Conn. This screw driver is forged in one piece, including both handle and blade. The former has a shape which gives the workman a firm grip on the tool.

Sectional Flanging Press: Wm. H. Wood, Media, Pa. A flanging press of 200 tons capacity, adapted to the sectional flanging of work too large to be done in a single operation. Three plungers are provided, one for holding the work, one for outside flanging, and a third for reverse flanging.

Test Indicator for Lathe Work, etc.: Benjamin F. Ennis, 214 W. Beard Ave., Syracuse, N. Y. This tool is an indicator of sensitive construction, arranged to be conveniently used for testing the truth of internal or external revolving surfaces. It may also be used as a depth gage for comparative readings.

Motor-Driven Saw: Crescent Machine Co., 56 Main St., Leetonia, O. In this machine the motor is mounted on an extension of the base and is directly belted to the saw arbor. The machine can be located in any position desired, independently of line shafts. It is provided with complete adjustments, making it suitable for cutting sharp tools.

"Toggle-grip" Wrench: Lever Co., 45 Cedar St., New York. In this tool the sliding jaw is set to the desired adjustment by means of the usual knurled screw. The jaw may then be closed firmly on the work by a lever operating a toggle movement which firmly holds the wrench on the nut, without the possibility of slipping.

Automatic Unloader for Air Compressors: Hunneymen Co., Concord, N. H. This is a device for regulating the delivery of air from the compressor to the receiver. It is operated by the variation of the receiver pressure, and controls the valve action of the compressor, being thus more economical of power than the safety valve arrangement often used.

"Indestructible" File Handle: J. L. Osgood, Buffalo, N. Y. This design obviates the splitting of the handle—an accident which is liable to be dangerous, as well as costly in the aggregate. The tang is held in a steel tube, which receives all the strain of compression due to the driving in of the file. This steel tube is flanged and headed over the ferrule, which is thus held firmly in place.

Threading Tool: William Avery & Co., Foxboro, Mass. The design of this tool permits the swiveling of the holder in the shank to agree with the angle of the thread. The tool may be used as a solid or spring holder, at will, the change being effected by the simple removal or insertion of a pin. A tongued and grooved connection keeps the springing motion radial to the work, preventing sidewise movement.

Tait Universal Tool-Holder: Van Doren Mfg. Co., Chicago, Ill. This holder consists of two pieces between which the cutting blade is clamped by the action of the tool face screw. These blades may be round, square or of several sections for boring, turning, parting and side tools or other forms. The holder is made in eleven sizes ranging from ¼ x ½ x 4 inches for the smallest up to 1¾ x 2¼ x 18 inches for the largest.

Heavy Lincoln Miller: Hendey Machine Co., Torrington, Conn. This miller is intended for the heaviest formed cutter work for interchangeable manufacturing. The table has a working surface if 15 by 54 inches, and an automatic feed of 36 inches. Twelve feed changes are provided, in a gear box of the standard Hendey-Norton type. The cone pulley has three steps for a 4-inch belt.

The Universal Woodworkers' and Patternmakers' Vise, made by the G. M. Yost Mfg. Co., Meadville, Pa., is so constructed that it can be used in the usual method with the vise jaws flush with the edge of the bench, or it may be universally adjusted by swiveling about two axes at right angles to each other. The jaws have different forms in their different faces, to hold a variety of work. It is unnecessary to mortise the bench in mounting the vise. The jaws are 8 inches wide and 16 inches long.

Automatic Calculating Time Stamp or Chronograph: Baird Mfg. Co., 1592 North Halstead St., Chicago, Ill. This instrument is designed to print the elapsed time on a card or ticket, and is useful in keeping track of the delivery of messages, telephone calls, and cost accounting systems of various kinds. The mechanism is simple, compact, and durable. It may be set into a desk flush with the top, with only the printing levers exposed. A ribbon is provided which is self-feeding, presenting a new and fresh surface for every impression.

Semi-Automatic Nut Burring Machine: National Machinery Co., Tiffin, Ohio. In this machine the nuts to be burred are placed by the operator in an inclined trough at the side of the machine. They are taken from the bottom of the trough and passed through the machine without further attention. The cutting head automatically adjusts itself for different thicknesses of nuts and is provided with safety trips for blank nuts, etc. As the operator does not work in close proximity to the cutters, the chance for accident is practically eliminated.

Internal Fire Continuous Furnace: W. S. Rockwell Co., 50 Church St., New York, N. Y. This furnace is of the rotary type, provided with a grooved helical lining which feeds the material through from end to end of the furnace, as the latter revolves on the supporting rollers provided for it. The oil or gas used as a fuel is injected directly into the chamber in a direction opposite to that of the travel of the material. The machine, as will be seen, is of the continuous-action type, constantly receiving fresh parts, and delivering them at the front with the heat treatment properly applied.

Grinder for Sharpening Threading Dies: National Machinery Co., Tiffin, O. This machine grinds the chasers for belt cutter dies in such a way as to give them the proper bevel and clearance, enabling each chaser in the set to do an equal portion of the work. This results in better threads and in lengthening the life of the die. It will sharpen any size or type of threading chasers on the market. A suitable chart is furnished for making the necessary settings for various diameters, and it is an easy matter to change from one size to another.

Quick-Acting Tool-Makers' Vise: Mutual Machine Co., Hartford, Conn. This vise comprises a movable jaw, sliding on longitudinal rods seated in the fixed jaw, and adjustable thereon by a screw working in an adjustable yoke. The position of this yoke on the rods may be quickly changed by turning a locking disk out of engagement with ratchet-shaped teeth cut on the inner sides of the rods. This constitutes the quick-adjustment feature. All the parts are finished and hardened. The jaws measure 3 by 1¾ inches, and open out to 2 inches in width.

Simplex Multiple Spindle Automatic Screw Machine: Boston Bolt Co., 40 Farnsworth St., Boston, Mass. This is an automatic screw machine designed and built in England, of which a number have been sold in this country. It is to be built here by the Boston Bolt Co. It is of the multiple spindle type, in which the turning tools are carried in a stationary head and the work spindles are mounted in an indexing drum. A feature of the machine is an adjustable feed cam by means of which the movement of the tool slide may be varied to exactly suit the dimensions of the work being turned.

Electric Pyrometer: Leeds & Northrup Co., Philadelphia, Pa. This pyrometer is of unusual construction, in that it combines the functions of an instrument of the deflection measurement type, with the accuracy and constancy of the Wheatstone Bridge method of measurement. The current used in measuring is obtained from any direct current system, and is practically independent of voltage fluctuations. A regular stock ammeter without shunt is used. The operation of measuring consists in balancing the bridge for about the desired temperature (within 200 degrees) and then reading the finer calibration on the ammeter dial.

Large Traversing Head Boring Machine: Beaman & Smith Co., Providence, R. I. This machine is of the type in which the spindle is carried by a vertically adjustable saddle on a horizontal adjustable column or head, the work being clamped

to a suitable floor-plate. The machine is particularly interesting from its size. The spindle is 6½ inches in diameter and has a 72-inch feed. The vertical adjustment is from 2½ to 10½ feet above the table. A revolving work-table is provided, having a working surface of 6 by 8 feet. This table is revolved by a 5 horse-power motor which is also used for its adjustment lengthwise in the bed.

"Perfection" Wrench: Perfection Wrench Co., Port Chester, N. Y. This wrench provides a combination of quick adjustment and toggle joint grip. In adjusting, the jaws are set to graduations. The force of the grip is controlled by turning a set-screw, which, however, does not need to be altered every time the wrench is changed from one size nut to another. The wrench may be adapted for use in piping work by removing the hardened smooth false jaws, and replacing them by hardened serrated jaws. The tool may be used as a vise also, or as a parallel drill press clamp, being finished to hold the work true on the machine platen.

Horizontal Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. This horizontal boring machine (which is also adapted for drilling and milling) is of the type in which the work-table is adjusted longitudinally and crosswise of the spindle, on an extended knee, which is, in turn, vertically adjusted on the face of the column. The particular feature of the new design is a single pulley drive. All of the feed and speed changes are effected by change gearing. Speeds range from 7 1/3 to 75 8/10 revolutions per minute and the feed changes from 0.05 to 0.115 inch per revolution of the spindle.

Single-Phase Motors for Machine Driving: Wagner Mfg. Co., St. Louis, Mo. This line of motors is particularly suited for direct connection to machine tools. The line includes designs for all frequencies from 25 to 140 cycles, and a wide range of sizes from ¼ to 40 H. P. in either a constant speed or variable speed construction. A feature of the design of these motors is the provision of an automatic governor apparatus for starting the machine with a heavy torque, on the repulsion principle. When speed has been obtained, the action of the governor transforms the rotary winding to the squirrel-cage form, after which the motor operates as a regular induction type machine.

Excelsior Multiple Punch: Excelsior Tool & Machine Co., East St. Louis, Ill. This machine bears no resemblance to an orthodox punching machine, though it performs the same work. It is intended for punching any required layout of holes in sheet iron at one operation. A horizontal die-plate, stripper plate and punch holder is provided for the full size of the sheet, with loose punches mounted in place over the die holes. A heavy and strongly supported roller is passed over the top of the punches, depressing them one after the other, as the roller comes in contact with them. This roller is set at a slight angle, so that it does not have to strike a transverse row of the punches simultaneously.

Releasing Tap and Die Holder: Wells Bros. Co., Greenfield, Mass. This is a tap and die holder of the pull-off or releasing type. It is of unusually simple and effective construction. When threading on the work the tool is driven by a positive jaw clutch. This operates until the movement of the tool-slide stops, when the continued action of the tap or die pulls the jaws of the positive clutch out of engagement, allowing the holder to revolve freely with the work. When the spindle is reversed, a friction roller clutch of simple form takes hold, and withdraws the die, releasing again as soon as the latter starts to work on a new blank. The positive clutches are of hardened steel, securely fastened in place. The use of the friction reverse permits the parts to take hold quickly and quietly and saves the re-engagement of the positive clutch.

* * *

Bids for the construction of a 500-foot steel tower to be used as a wireless telegraph station at Washington have been received. When this station is in operation, it is stated that it will be possible for the Navy Department to be in constant communication with all vessels on the Atlantic seaboard.

TEST ON "STERLING" HIGH-SPEED POWER HACK-SAW.

The "Sterling" high-speed power hack-saw machine, equipped with a 17-inch "Sterling" hack-saw blade (products of the Diamond Saw and Stamping Works, Buffalo, N. Y.), cut off the 6-inch disk of machinery steel shown herewith, in one hour and fifteen minutes. The same blade was then used for cutting six disks from a 5-inch round bar of hammered axle steel, which were completed as follows:

1st cut, 25 minutes; 2nd cut, 28 minutes; 3rd cut, 32 minutes; 4th cut, 34 minutes; 5th cut, 35 minutes; 6th cut, 37 minutes.

After completing this work, the blade was taken out in good condition. The durability of its serviceableness is evident in comparing the slight increase in time required from the third to the sixth cuts. The same saws have been used to cut off sixty-pound steel rails—an operation which can be completed in from six to ten minutes.

A Six-inch Disk of Machinery Steel cut off by a "Sterling" Hack-saw Blade in 75 Minutes.

An important feature of the machine in relation to the durability of the blade, is the provision for placing it in the holder with the teeth either forward or backward, so that after one-half of the blade has been used, by reversing the saw, a fresh portion of the cutting surface is presented, thus saving nearly one-half the blades required for a machine of this capacity. The machine is also provided with a pump and lubricant and suitable draining facilities. This serves to keep the blade cool when running at high speed.

* * *

The United States Steel Corporation announced February 18 that the price of steel so firmly maintained by the company during the past few years would be cut to meet the competition of independent makers, excepting the price of steel rails. It is expected that the price of $28 for rails which has ruled for the past several years will be maintained by the five largest companies by a tacit understanding to that effect. The companies are the United States Steel Corporation, Cambria Steel Co., Lackawanna Steel Co., Bethlehem Steel Co., and the Pennsylvania Steel Co. The announcement of the cut in prices of from $4 to $7 per ton or more is followed by the threat that the wages of employes in steel mills will be reduced in all probability. The reduction of the tariff on steel products, now under consideration by Congress, is probably the reason for the cut in prices and the rumor that wages probably will be reduced.

* * *

The Delaware, Lackawanna & Western Ry. opened a new tunnel to traffic through Bergen Hill, N. J., February 14. The new tunnel contains two tracks which, with the old tunnel, makes four tracks through the hill. The new tunnel is interesting from an engineering point of view in that it is lined throughout with concrete and the rails are laid on creosoted wood ties imbedded in concrete with creosoted blocks for ballast, also laid in concrete. The tunnel is seven-eighths of a mile long.

PERSONAL.

James Duguid, machine shop foreman of the Grand Trunk Railway, Stratford, Ontario, has been promoted to the position of general foreman of the Toronto shops.

Charles Geldart, toolmaker in the Grand Trunk Railway shops, Stratford, Ontario, has been promoted to machine shop foreman, succeeding Mr. James Duguid.

John B. Guthrie has been appointed representative of the Carpenter Steel Co., Reading, Pa., in the Pittsburg district, with office in the Columbia Bank Building, Pittsburg, Pa.

John P. Cosgro has been appointed district manager of Allis-Chalmers Co., with office in El Paso & South Western Building, El Paso, Texas.

A. L. Lovejoy, formerly treasurer of the Becker-Brainard Milling Machine Co., is now manager of the sales department of Pratt & Whitney Co., New York.

J. J. Keefe, well known to the pneumatic tool trade, has entered the employ of the Independent Pneumatic Tool Co., Chicago, Ill., as sales manager, with headquarters in Chicago.

John Edgar, formerly machine tool designer with the Becker-Brainard Milling Machine Co., is employed by the Everett-Metzger-Flanders Co., Detroit, Mich., designing special machine tools for the manufacture of automobiles.

Mrs. Frances A. W. McIntosh, formerly advertising manager of the Buffalo Forge Co. and associated companies, has resigned that position and opened an office at 103 Anderson Place, Buffalo, N. Y., where she will prepare catalogues, advertising copy and general advertising literature.

Fred A. Mitchell has been appointed foreman of the tool room of the New Departure Mfg. Co., Bridgeport, Conn., succeeding Mr. Leland Nelson. Mr. Mitchell served an apprenticeship with the Pratt & Whitney Co., Hartford, Conn., and later worked for the Veeder Mfg. Co., of Hartford. He has been with the New Departure Mfg. Co. for about five years in the capacity of model-maker and foreman of the model department, which he still will supervise.

Prof. H. Wade Hibbard has resigned his position as head of the railway engineering department of Sibley College, Cornell University, to fill a similar position with the University of Missouri. Prof. Hibbard began teaching in the University of Minnesota in 1895, where he was professor of machine design and locomotive engineering. In 1898 a fund became available in Cornell University for the development of a railway engineering department, and Prof. Hibbard became a member of the faculty and developed the course.

J. E. Woodwell of the firm of L. B. Marks and J. E. Woodwell, New York City, has been retained by Messrs. McKim, Mead & White, architects, as consulting engineer for the entire mechanical and electrical equipment, including the heating and ventilation, electric lighting and power, mail handling devices, etc., of the new U. S. Post Office to be erected at the Pennsylvania Terminal Station in New York City. The automatic mail handling machinery will be a special feature of the building.

Ethan Viall, whose contributions on machine shop practice have made his name familiar to our readers, has joined the editorial force of MACHINERY to act as western traveling representative, with headquarters at Decatur, Ill. Mr. Viall is an expert with the camera and his contributions will be profusely illustrated with half-tone views, as in the past, showing shop operations, machines, tools, kinks, and the thousand-and-one devices that American manufacturers are continually bringing forth to facilitate production and reduce cost.

John S. Considine, of Columbia, Pa., has been made assistant track supervisor of the Pennsylvania Railroad Co. This promotion is important as it marks the departure of the company from a long standing rule, that ordinary track laborers could not be promoted to positions higher than track foreman, they not being considered eligible for the higher positions. The company, heretofore, has employed graduates of technical schools for official positions in maintenance-of-way and mechanical departments. Hereafter an employe not having the advantages of a college education, but who displays extraordinary ability, will be considered eligible for higher positions.

OBITUARY.

J. S. Spencer, head of the J. S. Spencer Machinery Co., Springfield, Mass., died January 18, aged fifty-eight.

Herbert Burroughs, treasurer of the Builders Iron Foundry, Providence, R. I., died suddenly at the Fort Pitt Hotel, Pittsburg, Pa., January 2, aged forty-five.

William C. Stimpson, who was head instructor in forging and foundry work at Pratt Institute, Brooklyn, N. Y., for several years, died at his home in Milford, Conn., January 13.

Otis Eddy Wood, who died in January at his home near Ithaca, N. Y., at the age of seventy-seven, is said to have been the first Morse telegraph operator who learned to read messages by sound.

Ephriam K. Smith, one of the founders of the Diamond Match Co. and maker of the first safety match produced in the United States, died in Philadelphia, Pa., February 16th, aged sixty-nine years.

George W. Shotwell, whose death was mentioned in the February issue of MACHINERY, was not president of the Diehl Mfg. Co., Elizabethport, N. J., but a member only of the family of the president, Mr. Burnett C. Kenyon.

Louis J. Atwood, president of the Plume & Atwood Mfg. Co., Waterbury, Conn., died February 22, aged eighty-two years. He was one of the pioneer manufacturers of the Naugatuck Valley and the inventor of many devices.

John F. Russell, an inventor of national reputation, died in Springfield, Ohio, February 14, aged seventy-one years. Mr. Russell was associated with William N. Whitely in the development of the modern reaper. He took out many patents including improvements on harvesting machinery, steam locomotives, etc.

Edward M. Twiss died at the Dickinson Hospital, Northampton, Mass., February 4, aged sixty-three. For many years he had been foundry superintendent of the Florence Machine Co. of Northampton, and was a very successful iron foundryman, having held important positions in other foundries.

Carroll D. Wright, president of Clark College, Worcester, Mass., died February 20th in his sixty-ninth year. Mr. Wright was noted as a statistician and for his work as United States Commissioner of Labor. He was commissioner of labor for twenty years, his term dating from 1885 to 1905.

Prof. Benjamin Franklin Clarke, Professor Emeritus of mechanical engineering at Brown University, died December 29 of pneumonia at his home in Providence, R. I. Prof. Clarke was born in Newport, Me., in 1831, and since his graduation from Brown University in 1863 has been connected with the faculty. He was twice acting president of the university.

Joseph Wharton, one of the largest individual iron manufacturers in the United States, founder of the Wharton School of Finance and Political Economy of the University of Pennsylvania, president of the American Iron and Steel Association, writer on financial, industrial and scientific subjects, died at his home in the suburbs of Philadelphia, January 11, aged eighty-three years.

W. C. Young, vice-president of the W. C. Young Machine Co., Worcester, Mass., builders of machine tools, died at his home in Worcester, January 30, in his sixtieth year. Mr. Young was well known in Worcester, having lived there for more than forty years. He had served on the city council and on the school board. The business of the company will continue as before.

David E. Harding died at his home in Mansfield, Mass., February 3, in his eighty-third year. He was born on a farm in West Mansfield, his father being one of Massachusetts pioneers, who had settled in Mansfield in 1775. In 1881 he entered into partnership with S. W. Card who was then making taps and dies. The business prospered and in 1891 it was made a stock company of which he was elected treasurer, and which office he held at the time of his death.

Edward F. C. Young was buried December 9. He was born near Morristown, N. J., in 1835 and was educated in the public schools of Jersey City. Mr. Young had been active in politics and was a director in street railway corporations and banking institutions. He is succeeded in the presidency of the Jospeh Dixon Crucible Co. by Mr. George F. Smith, vice-president. Mr. Wm. H. Corbin, counsel for the company, has been elected vice-president.

Alexander Beaudry, president and secretary of Beaudry & Co., Inc., Boston, Mass., died suddenly February 10 at his residence at Weymouth Heights, aged seventy years. He invented the first Beaudry hammer, early in the seventies, and embarked in the manufacture of it in 1880. Since then he has brought out many types of hammers and presses, having twenty-eight patents on tools of this character. The business of the company will be conducted the same as heretofore, as Mr. Beaudry's death will not in any way affect the conduct of the business. He had taken no active participation in it for the last few years.

Jose F. DeNavarro died of heart disease on February 3 at his home in New York, aged eighty-six years. He was born in Spain, graduated from the Spanish Royal Naval Academy and came to America as a teacher in the Jesuit College at Baltimore, Md. He afterward became interested in banking and transportation enterprises, and one of his most notable works was the building of the Manhattan Elevated Railroad, New York. He was the constructor of the first apartment house in New York, and was largely responsible for the establishment of the Portland cement industry in the United States, using the rotary kiln process.

WALTER M. ALLEN.

Walter M. Allen, works manager of the Warner & Swasey Co., died at his home in Cleveland, Ohio, February 8, in his forty-third year. His parents lived in Bristolville, Ohio, where he was born, and his father became engaged in the lumber business in Cleveland, but died when Mr. Allen was seven years old. Upon his father's death, his mother and three children returned to her early home in Cherryville, Me., and his early education was acquired there in the local schools. As a boy he showed great aptitude for things mechanical, but the small shops of that coast town—a box factory and a few boat works—did not satisfy his ambition. When only sixteen or seventeen years old he frequently went to the nearest railroad station, a distance of thirty miles, to study and make drawings of the locomotives that passed. When eighteen he was apprenticed to the machine trade in the works of the Warner & Swasey Co., and throughout his apprenticeship displayed great earnestness, ability and integrity. In 1891 he was made head of the drafting-room in which department he had displayed unusual ability, and during the next two years the details of design and construction of the 26-inch telescope of the Naval Observatory, and the 40-inch instrument of the Yerkes Observatory, were very largely developed under Mr. Allen's direction. In 1893 he was in charge of the firm's exhibit at the Columbian Exposition, Chicago, and on his return, when scarcely twenty-seven years old, was made superintendent of the works, which position he held with general satisfaction during the next six years. In 1904 he was made works manager, which position he held at the time of his death. The position involved not only general oversight of the works, but an active part and general responsibility in the business management as well. Mr. Allen ranked high as a designer of machinery and tools, being a man of quick perception and good judgment. He was well informed on engineering subjects generally and took an active part in planning and constructing the present new shops. He was a member of the American Society of Mechanical Engineers, Cleveland Engineering Society, Cleveland Chamber of Commerce, The Colonial Club of Cleveland, and the Automobile Club of Cleveland. He is survived by a wife and two sisters.

EDWIN REYNOLDS.

Edwin Reynolds, one of the most distinguished American mechanical engineers, died at his home in Milwaukee, Wis., February 19. Mr. Reynolds was born on a farm and learned the machinist's trade in Connecticut. In his early years he entered the employ of George H. Corliss, Providence, R. I., then the most prominent engine builder in America, and finally became general superintendent. He left the Corliss company to take charge of the E. P. Allis Co.'s works in Milwaukee, which at the time was in the hands of a receiver, to put it on a paying basis. He succeeded in doing this to a marked degree through his improvements in engines and mining machinery. The Reynolds-Corliss engine became famous as an engine of close regulation, high speed, and low steam consumption, and the works prospered. In his early career with the Allis works he took a contract for a 20 by 42 engine for the Trenton Iron Works which was required to run at 160 revolutions per minute. This high speed required a special valve gear and large ports, and the leading Corliss engine builder, George H. Corliss, would not consider the order. Reynolds built the engine successfully, and it was a great advertisement for his company. His most notable achievement, so far as the general public is concerned, was the design and construction of the great 8,000 horizontal and vertical compound engine for the Manhattan Elevated Railway power station in New York about 1900. The general features of the design of these engines were worked out by Mr. Reynolds on a railway train going to Milwaukee after having secured the contract in New York. The requirements were for great power and close regulation, and the ordinary design would have made necessary cylinders so large that it would have been very difficult to cast them without flaws and other serious defects. Mr. Reynolds conceived the idea of connecting high- and low-pressure cylinders to one crank pin and putting the generator between two sets of cylinders, the crank-pins standing 135 degrees apart. The result was a great success, as the world knows. A notable achievement in mining engineering made by Mr. Reynolds was the substitution of solid for flexible foundation under steam stamps. It had been the general practice to erect mine stamps on a springy foundation, and the result had been unsatisfactory. Mr. Reynolds very sensibly pointed out that the steam stamp was made to crush rock and that it was very poor engineering to mount it on a "feather bed," as he called it, and it was simply a matter of a solid foundation in order to get the very best effect of the blow. He took the responsibility of erecting the first steam stamp with a solid foundation, and the efficiency and durability were much increased. Mr. Reynolds was president of the American Society of Mechanical Engineers 1901-1902. He was consulting engineer of the Allis-Chalmers Co. at the time of his death.

* * *

The United States naval fleet of sixteen battleships anchored in Hampton Roads, Va., February 22, thereby completing the famous round-the-world cruise begun there December 16, 1907. The fleet doubled South America, passing through the Straits of Magellan, proceeding thence to Valparaiso, Magdelena Bay, San Francisco, Hawaii, Samoan Islands, Australia, Yokohama, Cheefoo, Suez Canal, Gibraltar, and Hampton Roads. The total distance traversed by the fleet was over 42,000 miles, and the vessels are said to be still in fit condition for further service, but, of course, they will go into dry-dock for cleaning and general repairs.

* * *

The Cunard Line steamer *Mauretania* beat all records for a day's run from Sunday noon until Monday noon, February 7-8, when she logged 671 nautical miles, making an average of 26.84 knots for the twenty-five hours.

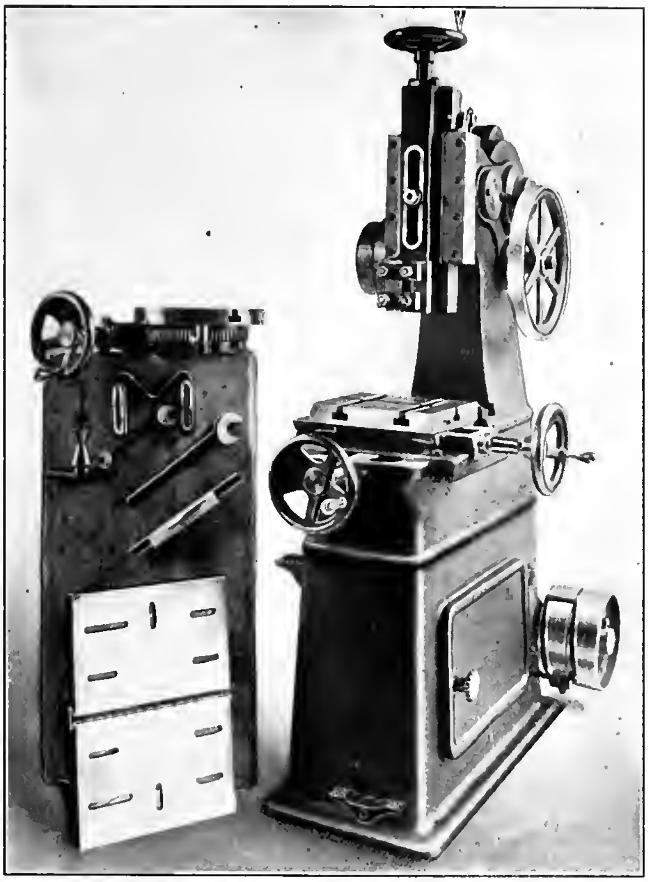
AN ENGLISH SLOTTING MACHINE.

JAMES VOSE.

The accompanying engraving illustrates a small slotting machine designed for rapid handling of the many jobs which are best dealt with on a vertical planing machine. The points of easy manipulation and large capacity have been kept in mind by the designer—Mr. A. Haworth—who has had extensive workshop experience with leading British concerns.

Though having so short a maximum stroke as 5 inches, a quick return motion is provided. The length of the guiding area of the ram is ten times its breadth. No counter-shaft is required, apart from that integral with the machine, which provides for two cutting speeds, and can be driven direct from the line-shaft. A flywheel is provided, placed at the side of the machine, so that the workman may easily adjust the position of the ram when setting work. The ram is adjustable within a range of 7½ inches by a hand-wheel and screw, while the machine is in motion.

The top slide of the table may be set central with the ram by means of a spring-backed plunger, and an attachment, shown at the left, allows work placed on the table to be self-centering. The tools supplied with the machine—for slotting keyways—are of a special nature, do not require forging, and are held central in a tool-holder which fits in a central groove in the face of the ram. An adjustable dead-stop enables quantities of pieces to be duplicated. A circular attachment is supplied and is provided with an index dial of 360 divisions. A spring plunger gives 2, 3, 4, 6 or 8 divisions without necessitating the use of the index dial. This attachment is extremely useful for cutting square, hexagonal, etc., internal or external shapes, in addition to circles or combinations of circular and rectilinear outlines. An auxiliary table 20 inches long and 14 inches wide is another useful extra, enabling work of a bulky outline to be clamped down for machining. A positive belt shipping arrangement, absolutely preventing self-starting, conduces to safe working by the operator.



An English Slotter for Toolmaking and Similar Work.

Some of the leading capacities and dimensions are given as follows: Stroke, zero to 5-inch; depth admitted under head, 12½ inches; traverse to or from body, 14 inches, and transverse travel, 14 inches. Pulleys, gears, etc., up to 24 inches diameter can be keywayed. The surface of the top-table is 15 x 12 inches. The driving pulley is 20 inches diameter for 3-inch belt and has a speed of 240 revolutions per minute. The machine weighs about 1,230 pounds. It is built by A. Haworth & Co., Luton, England. As giving some indication of British prices for tools built in fair-sized lots, the machine illustrated, including the circular table and work-centering attachment, but not the extra table, is marketed here at about $180.

* * *

AMERICAN ANTI-ACCIDENT ASSOCIATION MEETING.

The American Anti-Accident Association held its first meeting February 11 at 215 West 23rd St., New York, with Thomas D. West, Sharpsville, Pa., presiding. The meeting was held in two sessions, the program being as follows:

Afternoon Session.—"The Fundamental Features Involving Work for the American Anti-Accident Association," by Mr. Thomas D. West; "Hoodlumism in Holiday Observance," by Mrs. Isaac L. Rice, President of the Society for the Suppression of Unnecessary Noise, New York City; "Fire Wastes Through Carelessness," by Mr. C. M. Goddard, President of the National Fire Protection Association, Boston, Mass.; "Our Shameful Lead in Railway Accidents, and the One Sure Method of Checking It," by Edward Bunnell Phelps, Editor of the *American Underwriter*, New York City; "The Child, and Accidents of our Unbridled Laxity," by Thomas D. West, President of the American Anti-Accident Association, Sharpsville, Pa.

Evening Session.—"Museum of Safety and Sanitation," with lantern slides, by Dr. William H. Tolman, Director of the American Museum of Safety, New York City; "Industrial Accidents and the Inventors," by Joseph J. O'Brien, Member of the International Congress of Inventors, Washington, D. C.; "Safety Devices in the Machine Shops and Manufacturing Plants," by Prof. John E. Sweet, Syracuse, N. Y.; "An Analysis of 5,500 Machine Shop Accidents," by Mr. L. P. Alford, Member of the Editorial Staff of the *American Machinist*, New York City; "Wage Workers' Accident Insurance and Compensation Fraternity," also Municipal Anti-Accident Boards, by Mr. Thomas D. West. The association extends a general invitation to government and municipal officials, professional men, commercial travelers, manufacturers, managers and superintendents, merchants, labor leaders, mechanics, factory inspectors, fire and life insurance officers, teachers and all other citizens to become interested in the work. The organization is due to the president, Mr. Thomas D. West, who for many years has been greatly interested in the prevention of accidents. He believes in the theory of teaching workmen to take care of themselves and to cooperate with manufacturers in the use of all devices intended to lessen the maiming and death roll in manufacturing and transportation.

* * *

The expert knowledge required to properly adjudicate patent causes, due to the growing complexity of the art, has made the need of a special court of last resort to decide patent cases, keenly felt by all concerned in such litigation. A bill has been introduced in the House of Representatives and favorably considered, for providing a special court of appeals consisting of two judges, assigned permanently, and one federal district judge, with salaries of $6,000 a year each. It is to be hoped that the bill will be passed and the special court established.

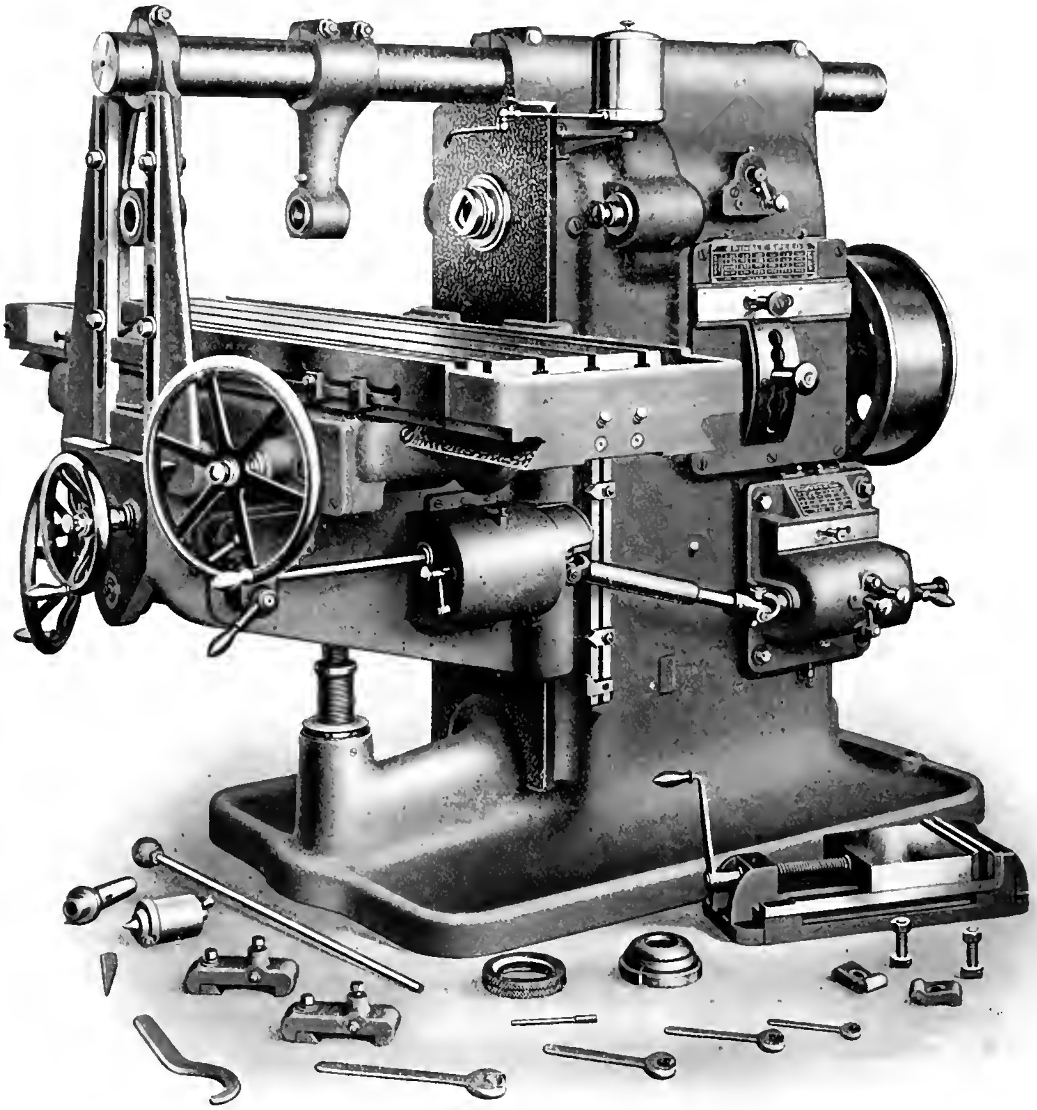
* * *

The torpedo boat destroyer *Tartar* of the English navy, using liquid fuel and steaming under war conditions, exceeded, on January 15, 38 knots an hour, thus beating her official trial record. The trial record was made in December over the official course of the Admiralty between Southampton and Maplin Sands, when the speed attained was between 35 and 36 knots an hour. Previous to this official trial, the *Tartar* made almost 36 knots an hour, beating, at that time, all records for ships of her type. The *Tartar* has been in service since April, 1907, and is a sister ship of the *Mohawk*, which also uses liquid fuel. These boats are 270 feet long, and have engines of 14,500 horse-power.

Brown & Sharpe Mfg. Co.,

The Quality and Quantity

of Work Turned Out on the B. & S. Constant Speed Drive Milling Machine is a Forcible Example of the Rigidity of its Construction.



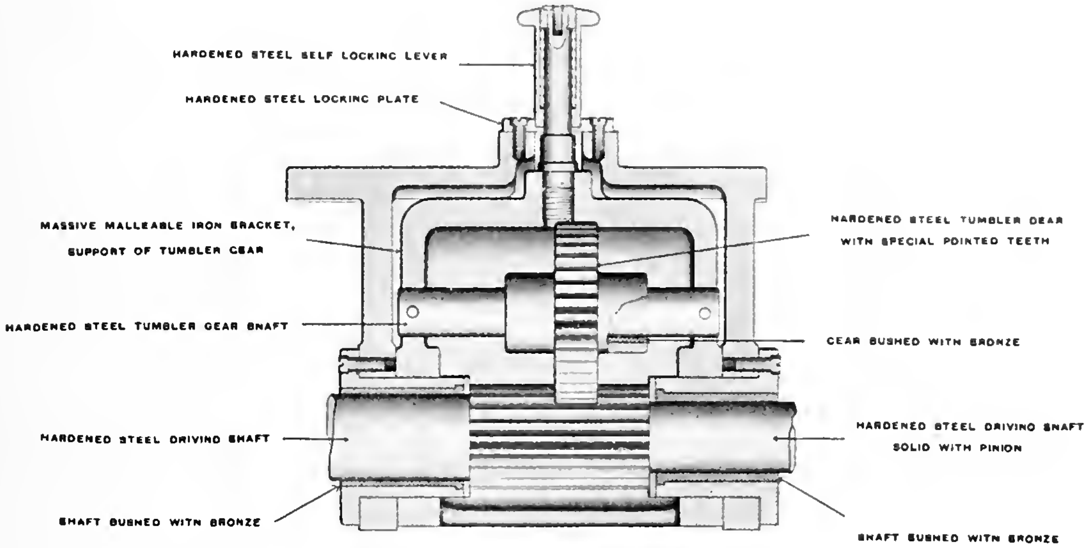
No. 5-B HEAVY PLAIN MILLING MACHINE
(SHOWN ABOVE)

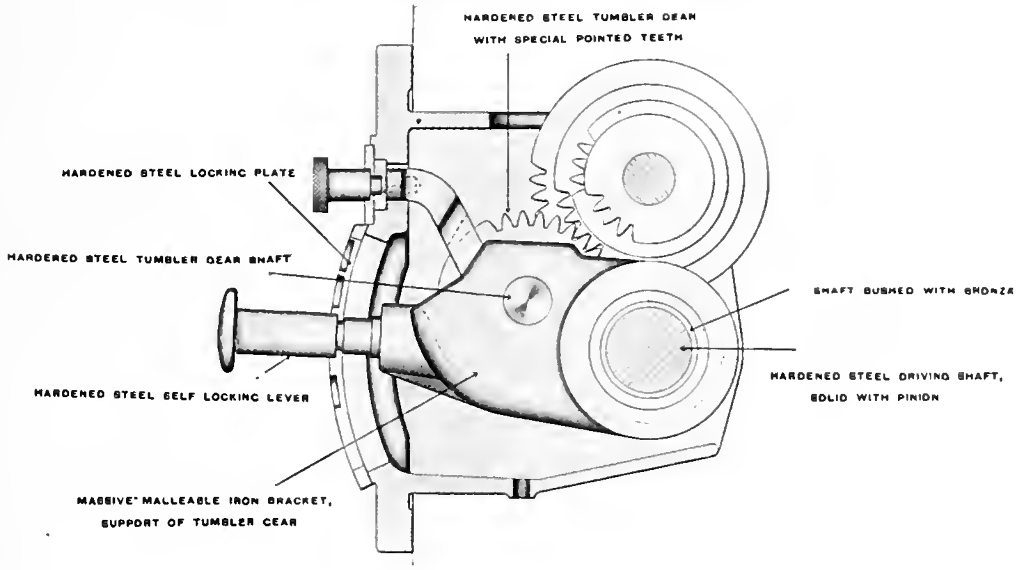
THE entire line of Constant Speed Drive Milling Machines is designed for heavy service and as a whole is a striking illustration of solidity in construction. The rigid control of the moving parts as the table, saddle and knee, together with the quietness of the running gears when the machine is under heavy service show that the design is correct and solidity has been attained.

Providence, R. I., U. S. A.

Tumbler Gear Mechanism

—a Vital Part in the Construction of a Milling Machine, the Design of which is being Daily Demonstrated Mechanically and Practically Correct.





STUDY carefully the above cuts. Note the compactness and heavy proportions of the supporting parts. All shafts are rigidly supported close to where pressure is applied. The tumbler gear itself is strongly supported in a massive malleable iron bracket trunnioned around two heavy stationary bushings, thereby resisting all twisting and cramping strains. It is locked by a heavy hardened steel self-locking lever in a massive hardened steel plate.

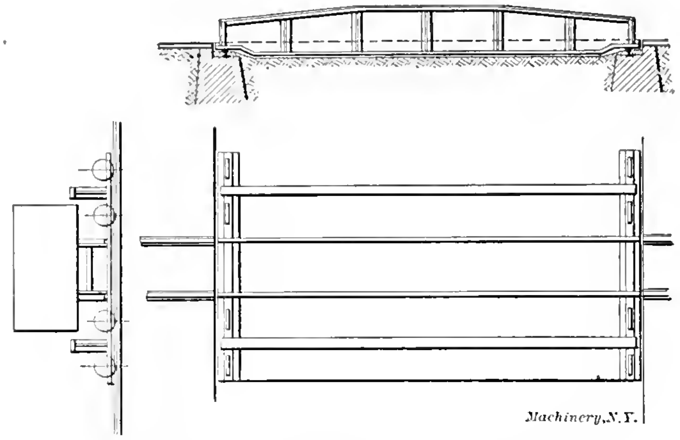
WANTED, PUBLISHED DESCRIPTION OF TRANSFER TABLE.

A reward of forty pounds sterling is offered by Messrs. Harris & Mills, 23 Southampton Buildings, London, W. C., England, to the first person handing them a public paper containing a description of a traverser of the form shown in the accompanying illustration, which complies with the following conditions:

1. The paper must have been published during the last hundred years.

2. The paper must have been published earlier than July 28, 1908.

3. It must be a public paper; according to the Patent Law of Germany any printed paper, printed book, printed lecture or printed report becomes a public paper when it has been exposed at a public library, or if it could have been bought at a bookseller's. Even a printed catalogue or printed prospectus is considered a public paper when forwarded to more than a thousand persons.



"Traverser with raised main girders on the outer side of the profile of the vehicles, moving on a track consisting of only two rails."

4. The description of the traverser, given in the said public paper, must be sufficiently clear to have enabled experts to make use of the idea to construct a similar traverser.

5. The paper must be handed in to Messrs. Harris & Mills before 3 P. M. on March 15, 1909.

6. The traverser must be like a bridge on rollers; the traverser must have raised main girders on the outer sides of the profile of the vehicle, as represented in the drawing.

7. The traverser must move on a track consisting of only two rails.

8. It is not essential whether the traverser has a pit or not. It is, however, more probable that there will be a pit.

9. The traverser may, just as well, have only four rollers instead of the eight rollers represented in the drawing.

* * *

IMPROVED HIGH-SPEED STEEL.

On another page of this issue will be found an account of an English high-speed steel that is claimed to be far superior to the other high-speed steels in general use. In the note Professor Arnold is reported as stating that in all probability every high-speed steel manufacturer in England would soon be making the same steel as the secret could not long be kept. It appears that this prediction was a fact at the time as at least one other maker was then making a water-hardened steel. We understand that "Ultra Capitol" steel, a new high-speed steel, for which George Nash & Co., New York, are the American agents, can be hardened in water and has a capacity of five to eight times the best standard high-speed steel now on the market. It is not claimed for the new steel that it will largely displace the regular grade of high-speed steel, including "Capitol" steel, because the present limitation of machine tools, makes it impossible to realize its full capacity, but it is probable that it will be used for some time to come for work that requires extreme durability of cutting edge. Of course this and other water-hardened high-speed steels will have a very marked effect on machine design, and the efforts of machine tool builders will be to develop lathes, planers, milling machines, etc., to realize the full possibilities of the new product.

CONSOLIDATION OF CINCINNATI MACHINE TOOL COMPANIES.

The Cincinnati-Bickford Tool Co., Cincinnati, Ohio, was incorporated last month for the purpose of manufacturing a full line of metal-working drilling machinery, with the following officers: August H. Tuechter, president; Sherman C. Shauer, vice-president and general manager; W. H. Shafer, secretary; George P. Gradolf, treasurer; and H. M. Norris, engineer.

This company is a combination of the Cincinnati Machine Tool Co. and the Bickford Drill and Tool Co.; and the officers of the new concern are well known in the trade, having been for many years connected with the two concerns represented in the combination, which will undoubtedly prove a potent factor in the machine tool trade as it contains all the elements of strength and progress.

* * *

The *Brass World* gives the following composition (patented by Wm. J. Leddell of Summit, N. J.) for use in making castings in metal molds: Zinc, 90 pounds; aluminum, 5 pounds; copper, 5 pounds. In cases where a harder alloy is desired, for bearings, etc., the proportions of aluminum and copper may be increased: Zinc, 87½ pounds; aluminum, 6¼ pounds; copper, 6¼ pounds. These alloys are said to have the characteristics of low shrinkage, ability to run into metal molds with sharpness, and freedom of crystallization. In addition, they have the important recommendation of being inexpensive. Where a greater fusibility is desired for castings of extreme sharpness, or where thin shapes are to be cast, the inventor advocates the use of one-half per cent or less of cadmium in the mixture. The use of metal molded castings is increasing, as many parts may be cast so accurately as not to need machining.

* * *

SOCIETY NOTES AND COMING EVENTS.

AMERICAN PEAT SOCIETY held a meeting in New York February 13, at the Chemists' Club, 108 West 55th St., New York, at which papers were presented on the value of peat as a fuel and the condition of peat production in the United States. Thousands of acres of peat lands await development which will be veritable mines of calorific value when people learn of their potential possibility.

THE AMERICAN SOCIETY OF HUNGARIAN ENGINEERS AND ARCHITECTS has been organized with the object of bringing into closer touch engineers and architects of Hungarian extraction living in this country, to give moral support and information to newcomers, and to encourage the exchange of engineering, technical and industrial information between the technical men of Hungary and of the United States. The president is A. Henry Pikler, manager of the transformer department of the Crocker-Wheeler Co., and secretary, Zoltan de Nemeth, of the New York Edison Co. The business address of the society is P. O. Box 103, New York.

March 11-12.—Annual convention of the New England Hardware Dealers' Association in Springfield, Mass. S. H. Thompson, Lowell, Mass., president.

March 27-April 3.—Mechanical and Electrical Exhibition, under the auspices of the Worcester County Mechanics' Association, in Mechanics' Hall, Worcester, Mass. The exhibition will include machinery in the operation of manufacturing goods, and is under the direction of Mr. H. F. Campbell, superintendent, room 6, Mechanics' Hall, Worcester.

May 12-14.—Annual meeting of the National Supply and Machinery Dealers' Association, at the Fort Pitt Hotel, Pittsburg, Pa. Secretary-Treasurer A. T. Anderson, 41 Wade Building, Cleveland, Ohio. The association has a membership of 141 manufacturing concerns.

September 25-October 2.—Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the Tribune Building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett, secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

May 18-20.—American Foundrymen's Association convention. Cincinnati, Ohio, Hotel Sinton, headquarters. Richard Moldenke, secretary, Watchung, N. J.

June 16-18.—Annual convention of Railway Master Mechanics' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 16-23.—An exhibition of machinery, tools and supplies for the railway supply trade will be held under the auspices of the Railway Supply Manufacturers' Association in connection with the railway conventions at Atlantic City, N. J. Membership dues in the association are $25 per year and carry one badge only. Additional badges may be obtained by members for $5 per badge. Contracts have been let for the erection of exhibition structures covering 59,000 square feet, exclusive of aisles. The charge to exhibitors will be 40 cents per square foot, to cover the cost of erection, etc. The association has prohibited the distribution of souvenirs. Application for space should be made immediately to Mr. Earl G. F. Smith, secretary, 345 Old Colony Building, Chicago, Ill.

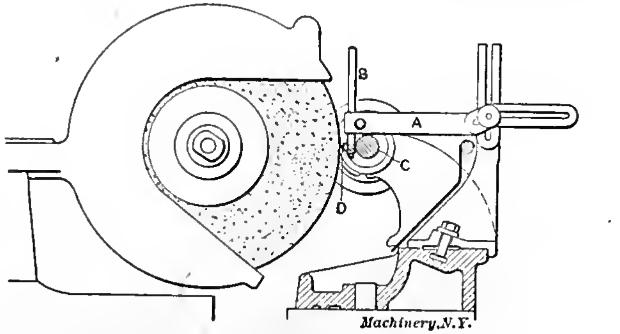
June 21-23.—Annual convention of the Master Car Builders' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

Supplement to MACHINERY, April, 1909.

Operations for the Article in this number entitled "Machine Shop Practice—Cylindrical Grinding.—I."

SHOP OPERATION SHEET NO. 94.

Paul W. Abbott. MACHINERY, April, 1909



Grinding a Hardened Mandrel—Truing the Wheel.

1. Clean the platen of the grinder (in this case a Landis) carefully and set the head- and tail-stocks far enough apart to take the mandrel to be ground between their centers. Be sure that there are no particles of dirt or emery under the head- and tail-stocks, so that they may be clamped down firm and true.

2. Test the head-stock, tail-stock, and wheel spindles to see if there is any play in the bearings. All lost motion in these parts should be eliminated by the means provided to prevent chatter marks and inaccurate work.

3. Select an emery wheel ½ or ⅝-inch wide, of medium grade (60M Norton grading being about right), and mount it upon the spindle. The hole through the center of the wheel should be large enough to be a sliding fit on the spindle, and it is desirable to have either rubber or leather washers between the wheel and the flanges.

NOTE.—When selecting a wheel, the material to be ground, the amount to be removed, and the quality of the finish desired should be considered. More complete information on this subject will be found in the Machine Shop Practice article in this issue.

4. Revolve the wheel by hand and see if the sides run true. A 10-inch wheel should not run out sideways more than 1/64 inch.

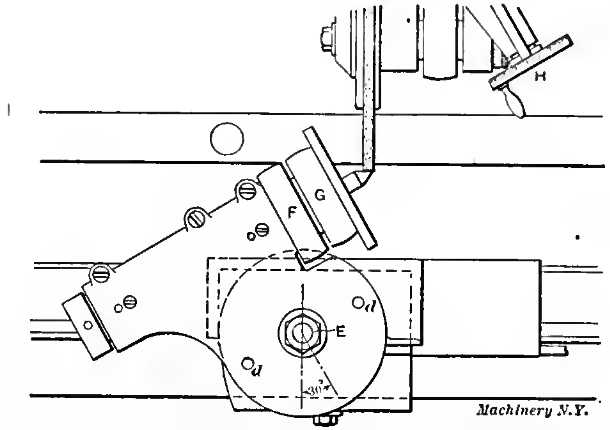
5. Place a piece of work, or an arbor, between the centers, and clamp a truing fixture to the table of the machine as shown in the illustration. Adjust the arm *A*, which holds the stud *B*, until both of these parts are against the piece *C* between the centers, to obtain the required rigidity.

6. Start the machine and set the dogs which regulate the stroke so that the diamond *D* will pass by the wheel on each side about ⅛ inch. Bring the wheel, which should revolve at the speed required for grinding, into contact with the diamond *D* and take light cuts, using water. When taking finishing cuts let the wheel pass by the diamond a few times without advancing it.

NOTE.—The number of times that the wheel has to be trued, depends on the character of the work and the kind of wheel used. When it is necessary to remove considerable stock, the wheel must be trued each time a piece receives a finishing cut.

SHOP OPERATION SHEET NO. 95.

Paul W. Abbott. MACHINERY, April, 1909.



Grinding a Hardened Mandrel—Truing the Centers.

NOTE.—The degree of accuracy to which work can be finished in a grinder, depends partly upon the condition of the machine centers and the corresponding condition of the centers in the work. The illustration shows the head-stock of a universal machine swiveled to an angle of 30 degrees in order that the centers may be accurately ground.

1. Remove the head- and tail-stock centers, which are made interchangeable, and insert the latter in the head-stock. Loosen the nut *E*, remove the dowel pins from the holes *d*, and set the head-stock to an angle of 30 degrees. The angle may be determined by the graduations found on the side of the head-stock.

2. Set the pin used for locking the spindle when grinding on "dead" centers, so that the spindle can revolve, and shift the belt to the pulley *F* which drives it. Start the machine and adjust the traverse dogs, as described in Shop Operation Sheet, No. 96, so that the wheel will overlap the center being ground about ⅛ inch on each side.

3. Bring the wheel into contact with the center by the handle *H*, and take a sufficient number of cuts to true it, using a copious supply of water. Test the angle to which the center is ground with a 60-degree gage; if a slight adjustment is necessary, move the platen by the fine adjustment provided for it. The center should be ground to conform exactly to the center gage.

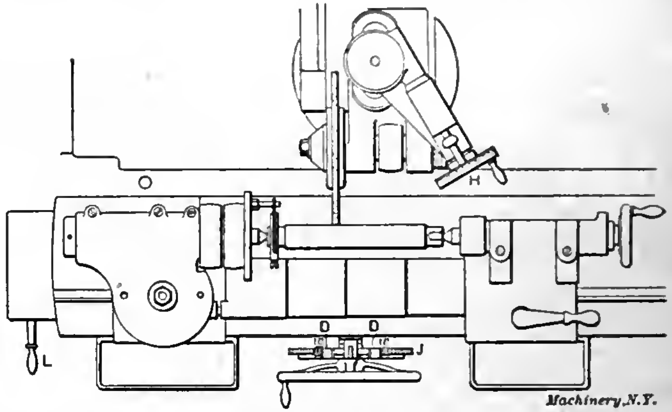
4. Remove the center and place it in the tail-stock. Insert the head-stock center in its spindle and grind the center true, allowing it to remain in the spindle.

5. Loosen the nut *E* and return the head-stock to the zero position. By the insertion of dowel pins in the holes *d*, the head-stock spindle is brought into accurate alignment with the platen.

6. Lock the head-stock spindle and shift the belt to pulley *G* which is for driving the work on dead or stationary centers. Work is ground on dead centers to secure accuracy, for then errors in the machine are not reproduced in the work.

SHOP OPERATION SHEET NO. 96.

Paul W. Abbott. MACHINERY, April, 1909



Grinding a Hardened Mandrel—Grinding.

NOTE.—It is assumed that the center holes were lapped true after hardening the mandrel.

1. Fasten a dog to one end of the mandrel and place the latter between the centers which should be perfectly clean and well oiled.

2. Start the machine and adjust the dogs *D* around the periphery of the wheel *J* until the grinding wheel overlaps the arbor body about ¼ inch. Fine adjustments of these dogs may be obtained by turning the worms *w*, but when they are to be moved some distance these worms are lifted out of engagement with the wheel *J*.

3. By the means provided in the counter-shaft above the machine, adjust the peripheral speeds of the work and wheel to about 25 and 5,000 feet per minute, respectively.

4. Adjust the traverse of the wheel by the lever *L*, until it moves about ¼ inch for each revolution of the work.

5. As the arbor should have a taper of 0.0005 inch to 1 inch, set the swivel table over slightly, using the fine adjusting screw provided.

6. Bring the wheel into contact with work and take one or two roughing cuts. Measure each end of the mandrel with a micrometer for size and taper, and, if necessary, adjust the table. Continue to rough grind, using the automatic feed and removing about 0.002 inch at each cut, until the mandrel is within 0.003 inch of the finished size. A liberal supply of water should be used

7. Change the wheel traverse until it is about ⅛ inch per revolution of the work, and again true the wheel, using the diamond. Take finishing cuts removing 0.0005 inch at each cut. Continue grinding until the small end of the mandrel is from 0.0005 to 0.001 inch under the nominal size, this depending upon the size of the mandrel.

NOTE.—Back rests are used on grinding machines for supporting the work in order to secure accuracy and at the same time permit heavier cuts and more rapid feeds and speeds. No rests are shown in the illustration but one or two should be used, even on short stiff work, to absorb the vibrations.

TABLE OF HORSE-POWER OF GASOLINE ENGINES.

Table I. Horse-Power of Gasoline Engines.

Bore	Stroke								
	Bore + 0	Bore + ¼"	Bore + ½"	Bore + ¾"	Bore + 1"	Bore + 1¼"	Bore + 1½"	Bore + 1¾"	Bore + 2"

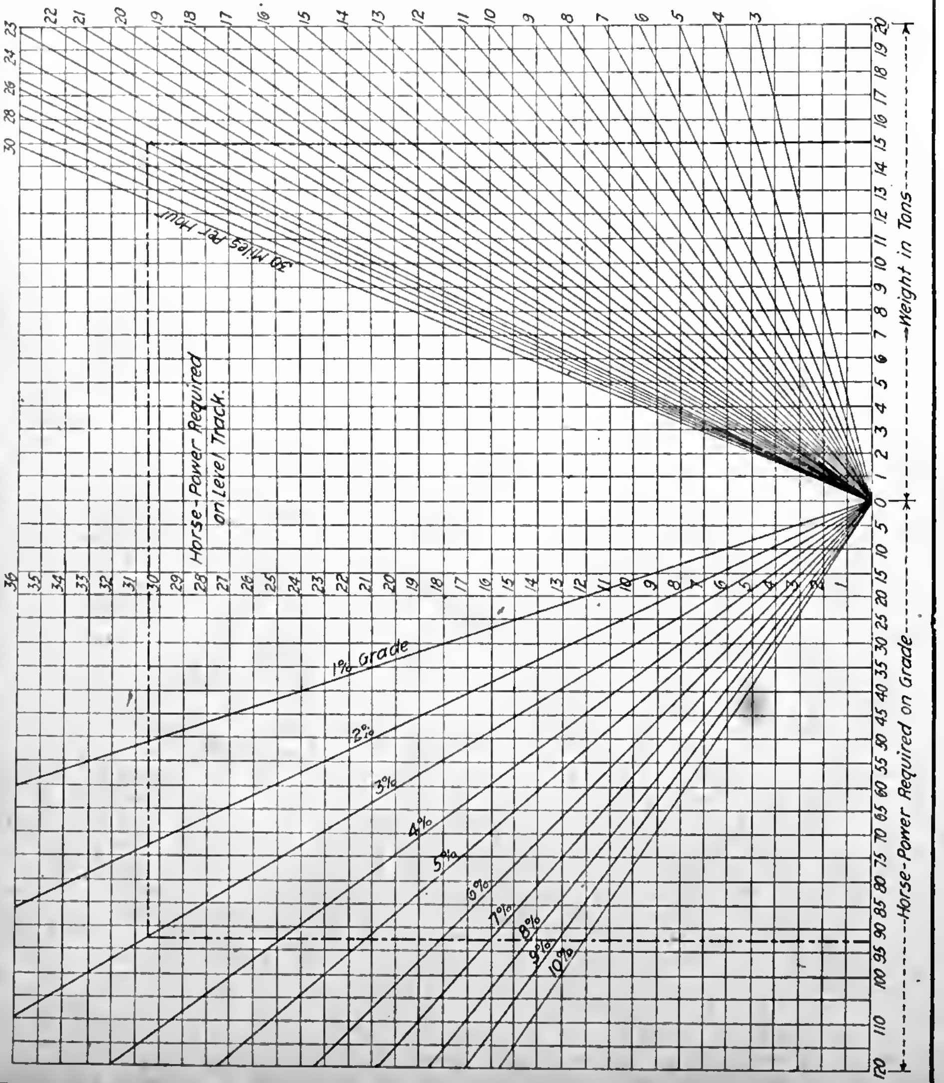
HORSE-POWER REQUIRED FOR MOVING CARS.

Example:— Find Horse-Power required to move a car weighing 15 tons at a speed of 25 miles per hour, both on level track and up a 3 per cent grade.

Find weight in tons, 15, on right-hand vertical scale; follow horizontal line from this point to intersection with line for 25 miles per hour speed. From this intersection follow vertical line to scale for Horse-Power required on level track, reading off 30½ H.P. Follow the same vertical line further to intersection with 3 per cent grade line. From the intersection follow the horizontal line to the right-hand vertical scale, finding 93 H.P.



Contributed by Morris A. Hall.

I.—DIMENSIONS OF CRANE HOOKS.

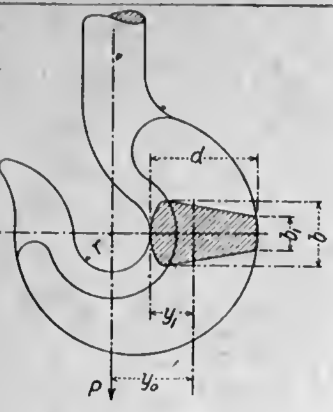


Fig. 1.

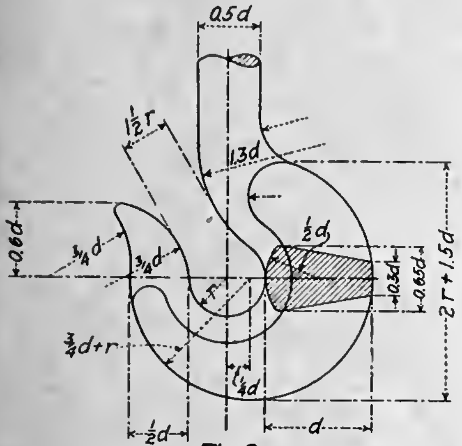

Fig. 2.

Formulas for Crane Hooks.

A = area of section shown in the illustration, in square inches,

f = allowable fiber stress in pounds per square inch

P = load in pounds,

R^2 = square of the radius of gyration in inches.

For b, b_1, d, r, y_0, and y_1, see Fig. 1.

$$\frac{P}{f} = \frac{A}{1+\frac{y_1 y_0}{R^2}} \qquad A = \frac{b+b_1}{2} \times d$$

$$y_1 = \frac{b+2b_1}{b+b_1} \times \frac{d}{3} \qquad y_0 = \frac{b+2b_1}{b+b_1} \times \frac{d}{3} + r$$

$$R^2 = \frac{(b^2+4bb_1+b_1^2)\,d^2}{18(b^2+2bb_1+b_1^2)}$$

Assume $b = 0.65d$, and $b_1 = 0.3d$; then

$$\frac{P}{f} = \frac{d^3}{7.2d + 11.615r} = \text{constant in table.}$$

Directions for using Table for Crane Hooks.

P, f and r are assumed, to suit the requirements; f may be assumed to equal from 16,000 to 25,000 pounds per square inch. Divide P by f and find the quotient in the column headed by the required radius r in the table. Then follow the horizontal line from this quotient to the left-hand column headed d. The figure in this column gives the required width d of the crane hook, and all the other dimensions are found from Fig. 2 as functions either of d or r.

Contributed by H. J. Mastenbrook.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—4.

BRAKES AND BRAKE MECHANISM.

R. B. BROWN.

BRAKES for electric cranes may be divided into two types, viz., solenoid, or magnetic brakes, and mechanical brakes. Electrical or magnetically operated brakes are generally ordinary strap or clamp brakes, which are held off by the action of a magnet or solenoid, electrically connected with the motor in such a manner that when the current is cut off from the motor from any cause, the magnet releases the spring or weight, as the case may be, and allows the brake to come into action. The solenoid commonly in use consists of a coil of wire connected in series with the motor, and a plunger working inside the coil as shown in Fig. 9, which represents, in a general way, the form of solenoids manufactured in several sizes by various electrical firms.

Solenoids should be so proportioned that their action is not delayed when the current has been cut off, due to residual magnetism. On the other hand, a too rapid application of the brake is to be avoided, since it has occasionally bent armature shafts; to effect this end the solenoid forms in itself a dashpot, the air being throttled in the small hole at the top of the body. Arrangements are usually made in the winding of the solenoid to enable it to lift off the brake when the controller is on the first contact, otherwise the motor would drive against the brake.

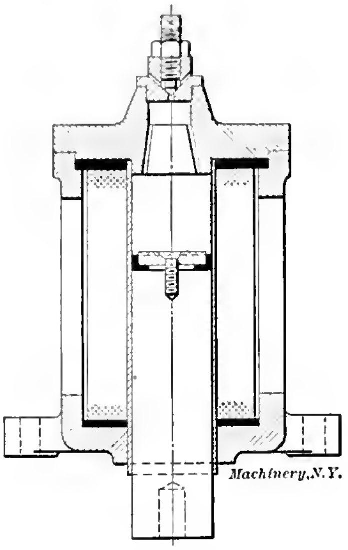

Fig. 9. Solenoid used to Operate Brake for Electric Cranes.

For cranes above five tons capacity the solenoid brake is applied principally as a means of stopping the motor quickly, to facilitate rapid reversal, and it should, of course, always be powerful enough to hold the full load in the event of the mechanical brake failing. The disadvantages of relying entirely on a solenoid brake are due to the fact that it does not permit of steady lowering, since, when the motor is reversed, the brake lifts entirely off and consequently allows the load to run down unchecked until the current is cut off again. This arrangement has been found fairly satisfactory for cranes under five tons (and is, in fact, often used on larger cranes), one reason being that the friction of the crab itself helps to retard a light load to some extent. A better method of lowering for small cranes is shown in Fig. 10, where an ordinary solenoid brake is used which can be released and controlled by a foot treadle for lowering.

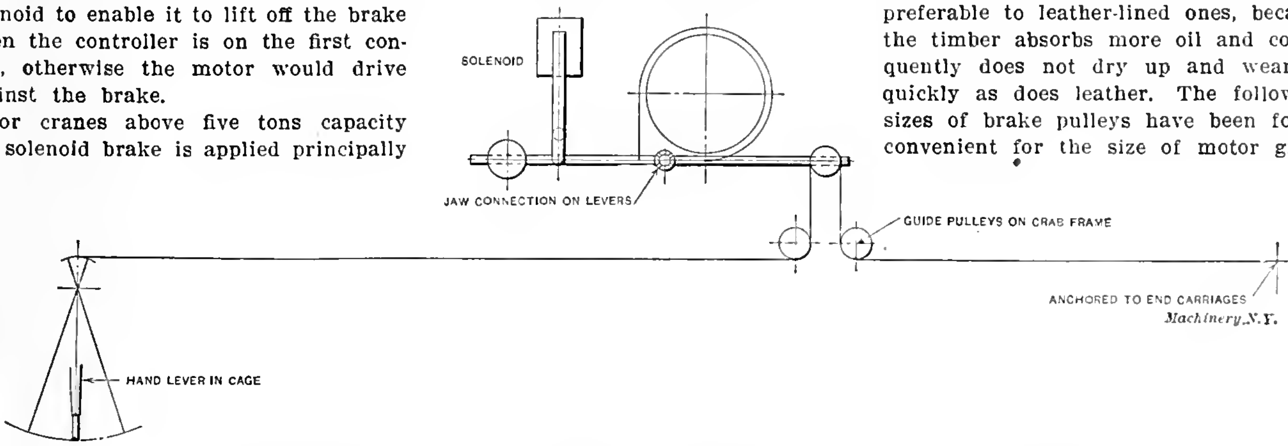

Fig. 10. Solenoid Brake, which can be released and controlled by a Foot Treadle for Lowering the Load.

When a crane is fitted with both a solenoid brake and an automatic mechanical brake, the principal function of the solenoid brake, as already stated, is to absorb the momentum of the armature and gear and stop the motor rapidly, and since this action must take place with the motor running in either direction, the clamp type of brake has been found the most suitable, although the ordinary type of strap brake is frequently used. The solenoid brake is most conveniently applied on the armature shaft itself, since the momentum is more readily absorbed at that point and a smaller solenoid can consequently be employed; but it is a mistake to cut the size of the solenoids too close.

For convenience, motors are sometimes made with the shaft extended at both ends, so that the driving pinion can be fixed on one end and the brake pulley on the other; this arrangement obviates the necessity of coupling a short shaft to the motor and providing an extra and somewhat expensive outer bearing. Brake pulleys are made of cast iron, and, while they should be as large as possible, in order to reduce the tangential force, at the same time the peripheral speed should not, if possible, be more than 2,000 to 2,500 feet per minute, or an inconvenient amount of heat will be produced. In any case, they will, of necessity, become more or less heated, a fact which makes timber-lined brakes preferable to leather-lined ones, because the timber absorbs more oil and consequently does not dry up and wear so quickly as does leather. The following sizes of brake pulleys have been found convenient for the size of motor given below, the full load speed being limited to 750 revolutions per minute for motors up to 20 B. H. P., and 500 revolutions for those above.

Brake Horse-power.	Diameter, inches.	Brake Horse-power.	Diameter, inches
5	10	30	18
10	12	35	18
15	12	40	21
20	15	45	24
25	15	50	24

A compact and typical design of a clamp brake is shown in Fig. 11.

The calculations for all types of clamp brakes are identical, and the horse-power of the motor being given, it is necessary in the first place to find the size of the solenoid. Take for example a 20 B. H. P. motor running at 500 revolutions per minute. If the brake pulley is 15 inches diameter, the tangential effort will be

$$\frac{20 \times 33{,}000 \times 12}{500 \times \pi \times 15} = 335 \text{ pounds.}$$

The [illegible] coefficient of friction for greasy wood on iron is 0.3; therefore, the force required at the center of the blocks will be [illegible] 0.3 = 100 pounds.

The ratio of the levers depends on the stroke of the magnet. Suppose the stroke, in the present case, to be limited to 2 inches, and the blocks are adjusted to lift off ⅛ inch, the ratio will be 2 : 0.25 = 8 to 1, and, consequently, the weight required to stop the motor will be 100 ÷ 8 = 12.5 pounds. It is always advisable to allow for a little extra weight, say 25 per cent, in practice, to cover the momentum, etc., so that in the present example it would be better to provide a 15-pound weight. A small adjusting weight is added to make up the difference between the weight of solenoid core and the actual weight required.

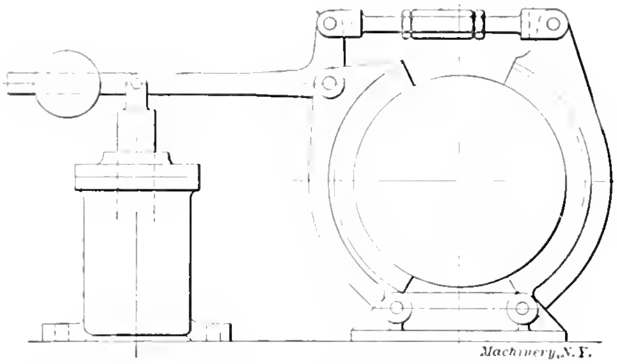

Fig 11 Typical Design of Compact Clamp Brake for Electric Cranes.

Several electrical firms supply an armature brake complete and self-contained on the motor, in which case the weight is generally replaced by a spiral spring.

When a strap brake is more suitable, as in the case shown in Fig. 10, the calculations are somewhat different. The size of the pulley remains the same as given in the previous table, and, as in the case of the clamp type, wood-lined straps are the most serviceable. Having found the tangential effort on the pulley, as before, it is necessary to proportion the levers to give the required pull on the strap. The quantity depends on the proportion of the pulley enclosed by the arc of contact of the strap, the value of coefficient of which will be found in Table VIII. In the diagram over this table it will be seen that if the tangential effort on the brake due to the load is acting in the direction shown by the arrow, the fixed end of the strap will be at F and the slack end, that is the end attached to the lever, at x. To find the pull on the slack end it is only necessary to multiply the tangential effort P by the value opposite the angle θ and under the coefficient μ. For example, the brake for a 10 H. P. motor running at 500 revolutions is 12 inches diameter. The tangential effort

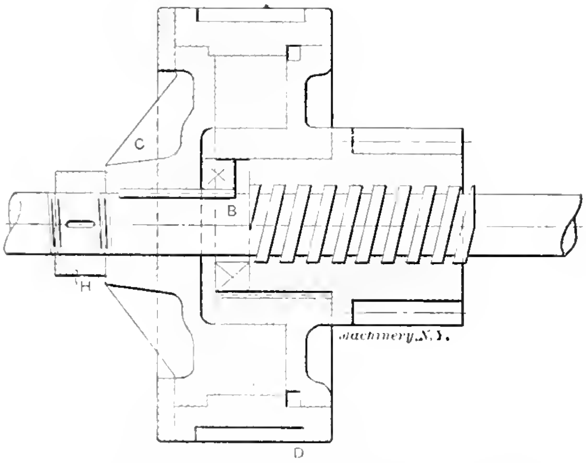

Fig 12 Automatic Screw Brake for Overhead Electric Cranes.

$$P = \frac{10 \times 33{,}000}{\pi \times 1 \times 500} = 210 \text{ pounds.}$$

If $\theta = 210$ degrees, the value of $x = 0.5$ for wood blocks on an iron pulley. Therefore the pull at $x = 210 \times 0.5 = 105$ pounds. The pull on the fixed end can be found from the table in a similar manner, although a table is hardly necessary, since it will readily be seen that the pull at F will equal $x + P$, or the pull on the slack end plus the tangential effort.

The above coefficient may be found independent of the table by calculating the ratio of the tension $\frac{T}{T_1}$ in fast and slack ends of strap from the following formulas.

$$\frac{T}{T_1} = 2.718\ \mu\ \frac{L}{R}.$$

Where μ = coefficient of friction (0.3 for wood on iron).
L = length of contact in inches.
R = radius of pulley in inches.

For example, take the preceding case; then

$$2.718 \times 0.3 \times \frac{22}{6} = 2.99 = \frac{T}{T_1}.$$

$$P = T - T_1;\ \text{but}\ T = 2.99\ T_1.$$

Therefore $P = 2.99\ T_1 - T_1 = 1.99\ T_1$, or $T_1 = \frac{P}{1.99}$.

Since $P = 210$ pounds, $T_1 = \frac{210}{1.99} = 105$ pounds.

And $T = P + T_1 = 210 + 105 = 315$ pounds.

The short lever should be given about half an inch travel, to allow the strap to lift as clear as possible of the pulley; therefore, if the magnet has a stroke of two inches, the ratio of leverage will be 4 to 1, and the pull required 105 ÷ 4 = 26 pounds, showing that this type of brake requires a larger magnet than the clamp type.

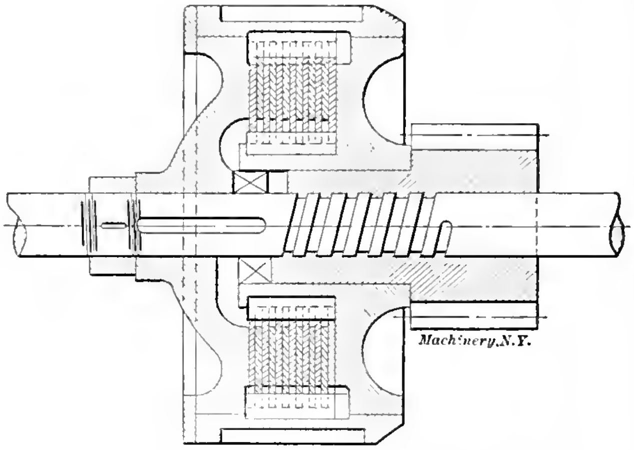

Fig 13. Friction Brake with a Number of Friction Disks.

Brake straps should be made of a good quality mild steel or wrought iron; they can then be stressed up to 5 tons per square inch in the net section, and consequently kept light and pliable.

There are several forms of automatic mechanical brakes used on overhead travelers, foremost among which is the screw brake, as shown in Fig. 12. This brake consists of a pinion of phosphor bronze, or steel, bushed with gunmetal, mounted on a thread which is cut in one of the intermediate driving shafts B. The steel or iron casting C is fixed to the driving shaft by means of a key which allows the necessary lateral movement for the adjustment, regulated by the nut H. The ratchet D, which is cored out to hold oil, and bushed with gunmetal, runs loose on the boss formed by the jaws. All working faces are preferably lined with gunmetal. One or two pawls, according to the size of the brake, engage with the ratchet, being thrown out of gear by a suitable arrangement.

The action of the brake is as follows: When lifting the load, the resulting pressure on the pinion due to the screw holds it hard up against the ratchet face and, the pawls having been lifted out of gear, the whole brake revolves together without resistance. As soon as the lifting ceases and a slight reverse has taken place, the pawls fall into gear, and the load is held secure by friction. In order to lower the load, the motor must be reversed and run on light power, this having the effect of reducing the pressure on the friction faces and allowing the load to slip steadily.

Some makers employ several friction disks in place of the two faces in the form just described. This design is shown in Fig. 13. This type is more powerful in proportion to its size than the other design, but is preferably enclosed in an oil bath to ensure complete lubrication between all the faces. The two jaws in both types are necessary to prevent the pinion backing from the face when the load is too light to keep them together, as when lowering the empty hook.

To calculate the size of the brake shown in Fig. 12, it is necessary to make the diameter such that, allowing for the lowest possible coefficient of friction, it is always in excess of the reaction from the pinion at the radius to the center of the pressure of the frictional surface.

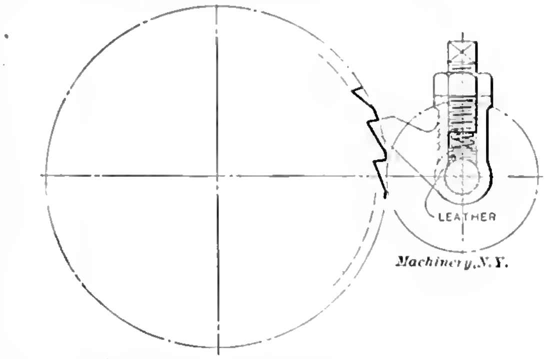

Fig. 14. Arrangement for Releasing Ratchet when Load is Lifted.

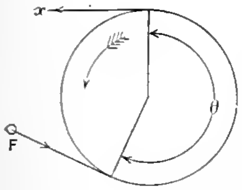
If r = radius of pitch circle of pinion = 6.2 inches,
W = load on teeth,
R = radius to center of pressure of disks = 8.7 inches,
p = pitch of thread,
μ = minimum possible coefficient of friction = 0.04,
N = number of frictional faces.

Then $\frac{W r}{R}$ must equal $\frac{N W \times 2 r \pi}{p} \times \mu$.

Take for example the brake shown in Fig. 12 and let it be necessary to find the maximum safe load it will sustain at the pitch line of the pinion.

TABLE VIII.



μ = coefficient of friction = 0.2 for iron to iron, 0.3 for wood to iron, 0.4 for leather to iron. P = pull on brake rim. x = strain on loose end of brake strap. F = strain on fast end. θ = arc embraced by strap (in degrees). Table gives tension on brake straps when P = 1.

θ	Value of x.			Value of F.		
	μ = 0.2	μ = 0.3	μ = 0.4	μ = 0.2	μ = 0.3	μ = 0.4
30°	9.09	5.89	4.29	10.09	6.89	5.29
45	5.89	3.76	2.71	6.89	4.76	3.71
60	4.29	2.71	1.92	5.29	3.71	2.92
75	3.35	2.08	1.45	4.35	3.08	2.45
90	2.71	1.66	1.14	3.71	2.66	2.14
105	2.26	1.37	0.93	3.26	2.37	1.93
120	1.92	1.14	0.77	2.92	2.14	1.77
135	1.66	0.98	0.64	2.66	1.98	1.64
150	1.45	0.84	0.54	2.45	1.84	1.54
165	1.29	0.73	0.47	2.29	1.73	1.47
180	1.14	0.64	0.40	2.14	1.64	1.40
195	1.03	0.56	0.35	2.03	1.56	1.35
210	0.93	0.50	0.30	1.93	1.50	1.30
240	0.76	0.40	0.23	1.76	1.40	1.23
270	0.64	0.32	0.18	1.64	1.32	1.18
300	0.54	0.26	0.14	1.54	1.26	1.14

The maximum permissible pressure per square inch on the area of the two friction faces, to agree with a coefficient of friction of 0.04, is 600 pounds, which agrees with average practice.

The area of the two friction faces = 126.2 square inches.

Total resistance at center of pressure of faces = 126.2 × 600 × 0.04 = 3,029 pounds.

The reaction on the pinion teeth to correspond with this load $= \frac{3{,}029 \times 8.7}{6.2} = 4{,}250$ pounds

It has been shown above that the axial pressure required on the faces to sustain the load is 126.2 × 600 = 75,720 pounds, and having the load on the pitch line the purchase of the screw will have to equal $\frac{75{,}720}{4{,}250} = 17.8$.

The circumference of the pitch circle of the pinion is 19.6 inches, therefore the pitch of the screw will be $\frac{17.8}{19.6} = 0.9$, or, for practical purposes, 15/16-inch pitch.

Some arrangements must be adopted for the pawls in order to release the ratchet when the load is being lifted, otherwise an objectionable noise will be made. One common arrangement is shown in Fig. 14 in which there are two pawls, one of which is set at half the pitch of the ratchet and mounted on a shaft which is driven through light spur gearing from the brake shaft, as shown. The pawls are moved by this shaft through the friction due to the leather pads which are pressed onto the shaft by a spring.

Another, and somewhat simpler, construction is that shown in Fig. 15. In this arrangement the weighted pawl *A* is thrown in and out of gear by the hinged friction clips *B*, which are adjusted by means of the spring bolt *C*. In either of the above designs the pawls should always be so constructed that in the event of the friction drive failing they will fall into gear with the ratchet.

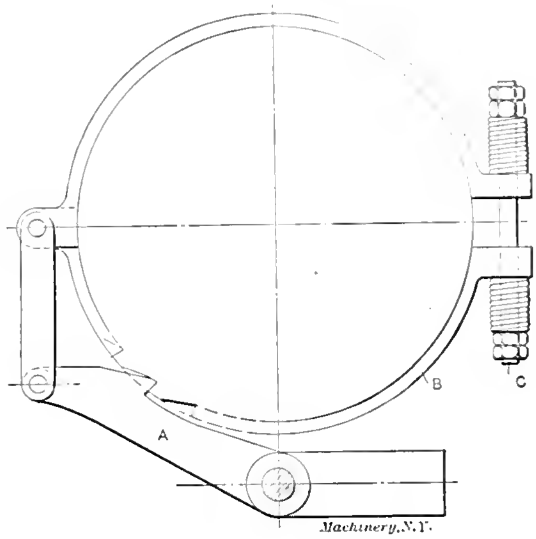


Fig. 15. Another Arrangement for Releasing Ratchet when Load is Lifted.

Shafts and Bearings.

Very little of more than a general nature can be said about the shafts and bearings for overhead cranes, since they possess no individual difference to those used for any other type of machinery. Although the calculation of the shafts is a simple matter in itself, it is no uncommon thing to find shafts stressed abnormally high, due to the fact that the size has been guessed at and not checked by calculation. A weak shaft is an annoyance, because, quite apart from the fact that breakage may take place, the deflection causes heating and binding and a consequent heavy loss of power. The forces due to the combined bending and torsion should always be considered in the ordinary way, and the diameters so proportioned that the stress does not exceed 6 tons per square inch for large shafts and axles, or 5 tons for small shafts.

No definite rule can be given for the limiting stress, it being rather a question of practical consideration and discretion. For example, if a heavy shaft is carrying its load near the bearing, it is safe to subject it to a stress that would not be permissible for a light shaft carrying a gear at some distance from the bearing, as for instance a shaft carrying a number of gears.

Overhung wheels should be avoided where possible, but where such have to be adopted the stress in the shaft ought

to be kept low, more especially if subjected to constant reversal, as for instance the pinion on the end of a motor shaft. Double keys placed at right angles are preferable for fastening gears on high speed reversing shafts.

Ordinary cast iron plummer blocks are generally used for steel framed crabs, and should as far as possible be standardized, in order to permit manufacturing to stock. Bearings should be fitted with split brasses and adjustable caps where practicable, in order to allow of ready inspection and repair. One of the principal objections to the plate-sided crab lies in the fact that several of the shafts have to be carried in solid bearings. Large and substantial grease or oil lubricators should be fitted to all bearings.

The calculations and general details given above apply to all types of crabs, irrespective of the frame formation, or general design. The principal variations are in the type of brakes, due to the fact that certain makers have patents or particular designs of their own, the bulk of which are nevertheless only modifications of the two principal types mentioned.

The type of crab shown in Fig. 2 (January issue) which, it may be remarked, has only been shown for reference purposes, is subject to considerable modification when the number of ropes exceeds four, and it generally takes the form shown in the outline diagram Fig. 16.

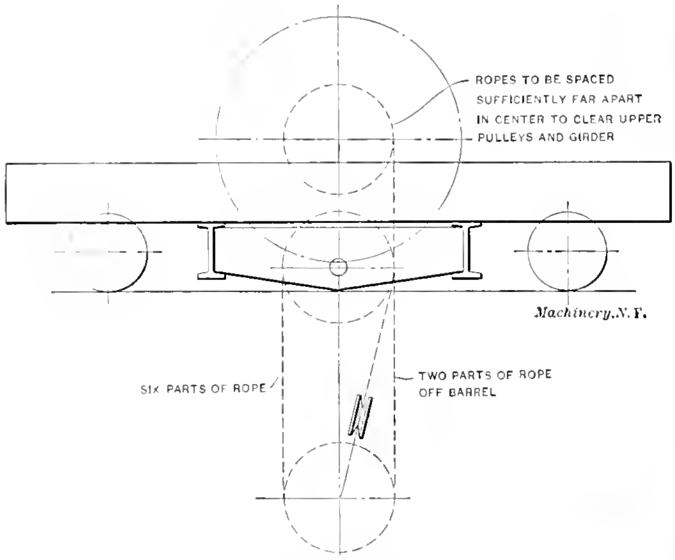

Fig 16. Modification of Crane Crab when the Number of Ropes exceeds Four.

Many makers use four ropes for cranes up to 50 tons, six up to 75 tons and eight up to 100 tons, or in other words limit the load off the barrel to 25 tons, and these quantities may be takèn as a maximum.

* * *

In a large watch factory there is a considerable force of men constantly emplcyed, called "bug hunters," to discover obscure defects in watch movements, which have developed in the regular tests for time-keeping to which the movements are subjected. With any practicable system of inspection of jigs, fixtures and product, there will be, on work of so delicate a nature as a watch, certain parts passed which contain defects not discovered, and scarcely discoverable. When the movements are assembled containing such parts, the discovery of the cause of the irregularity in the time-keeping is not easy. The men detailed to inspect the defective movements and clear up the trouble belong to a peculiar class and have what might be called a sixth sense, which enables them to almost instantly, in the majority of cases, tell the cause, no matter how obscure. When once located, the remedy is easy. It is in the matter of location that the ability of these men lies, more than in their mechanical skill. It is difficult to account for this sense, because it cannot be consistently attributed to a latent sense of hearing, sight or feeling. In the case of large machinery defective operation will make itself known to the operator by sound, manipulation, or sight, but in the case of a delicate watch movement, these senses can be used to a limited extent only, to locate defects.

IMPROVEMENTS MADE BY MOTOR-DRIVEN TOOLS IN A REPAIR SHOP.

The illustrations, "before and after taking," strikingly show the improvement of conditions of a typical belt-driven repair shop and the same shop re-organized and re-arranged for motor-driven tools. The photographs were taken in the repair shop of Peter Doelger's Brewery, New York City, and Fig. 1 shows the shop as equipped just before the change. The machinery was driven by shafts, counter-shafts and belts, including right-angle transmission and mule pulleys. Fig. 2 illustrates the same shop after the plant had been equipped throughout with motor-drive and two new motor-driven machines had been installed.

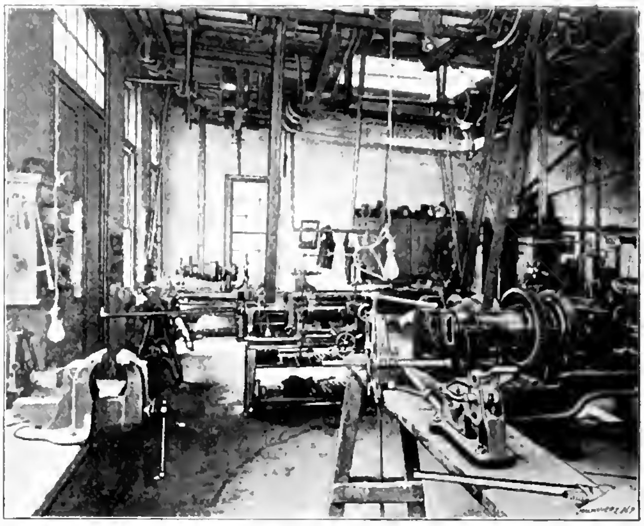

Fig. 1. Old Repair Shop in Peter Doelger's Brewery, showing Complications of Line-shafts, Counter-shafts, and Transmission Belts.

The shop now contains a 36 x 36-inch Hamilton planer, driven by a 5-horse-power motor, the motor running at 1,000 R. P. M.; 9-inch pipe threader, driven by a 5-horse-power 1,000 R. P. M. motor; 2-inch pipe threader, driven by a 1-horse-power 1,200 R. P. M. motor; drill press driven by a 2-horse-power 1,100 R. P. M. motor; 18-inch Hamilton lathe driven by a 4½-horse-power variable speed motor, having a speed range from 580 to 1,740 R. P. M.; and a small 1-horse-power portable saw.

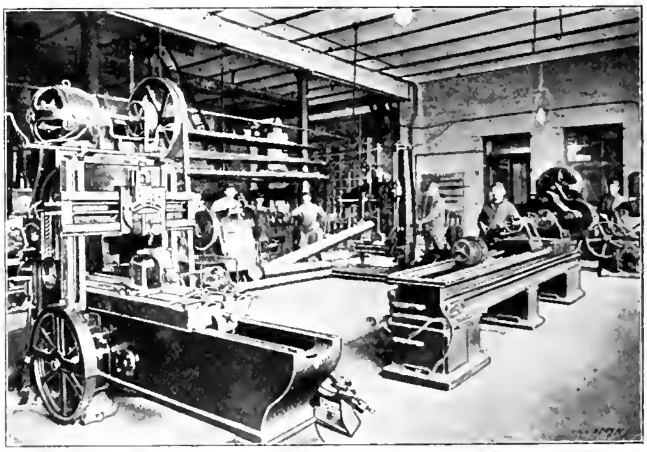

Fig. 2. Reorganized Repair Shop in Peter Doelger's Brewery, showing Motor-driven Machine Tools.

Neither the planer nor the 18-inch lathe were in the old shop, but even without these tools the transmission system was complicated. It will be noted in Fig. 1 that a quarter-turn belt and several reversing belts were necessary. The machines were much crowded, and it was impossible to handle work of considerable size, owing to lack of space. In the new shop the machines are arranged without reference to the line shaft or counter-shafts, being placed exactly where wanted and to facilitate the handling of the work. Each machine has plenty of space around it.

All the motors driving the various machines illustrated were built by the Crocker-Wheeler Co., Ampere, N. J., to whom we are indebted for the photographs and data.

SPECIAL TOOLS AND DEVICES FOR AUTOMOBILE FACTORIES.*

ETHAN VIALL.†

The shop practice at the factory of the E. R. Thomas Motor Co., Buffalo, N. Y., is equal to that of any other concern engaged in automobile work, although the growth of the concern has left it somewhat cramped for room. As in most shops, much of the work is done in the regular, or what might almost be called standard, way, but here and there are interesting, original or unusual devices that attract the attention of the mechanic.

One of the first things to attract the writer's notice was the device, shown in Fig. 1, for holding the rear axle while turning the spindles. The reason why these axles cannot be turned on centers, is that the spindles are not in line, but are bent at an angle in order to give the wheels the proper inclination when in place. In the fixture shown, the axle is bolted securely to the cross pieces in the long, slotted drum or sleeve in such a way that the spindle to be turned is in line with, and supported by, the tailstock center. With this arrangement the spindles are accurately machined in the least possible time. This device, as well as most of the other special tools, was designed and made by Lucien Haas, tool designer, and C. B. Buxton, assistant superintendent.

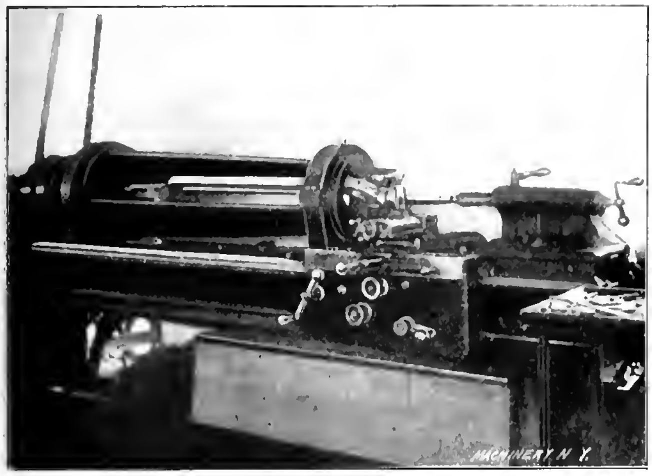

Fig. 1. Fixture for Holding Rear Axle while turning Spindles.

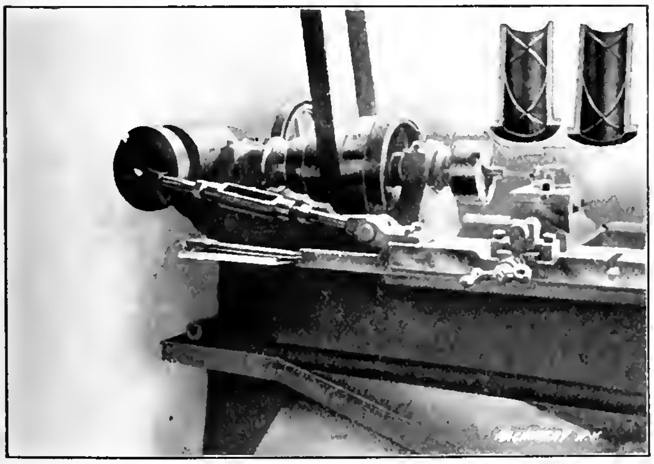

Fig. 2. Machine for Grooving the Inside of Brass Bushings, and Sample of the Work Done.

The cutting of oil grooves on the inside of brass bushings is a difficult problem, and until the machine shown in Fig. 2 was made, all brass bushings used in the construction of the Thomas machines were grooved by another firm, making a specialty of this work; but since the old lathe was made over as illustrated, the bushings have been both double- and single-grooved at less than one-fourth of the previous cost. In the upper right-hand corner of the half-tone, is shown a bushing which has been split in two in order to show the way in which the machine does its work. The principle of this simple, effective machine will be readily grasped by inspecting the illustration.

Another old lathe which has outlived its usefulness as such, and has been made into a special machine, is shown in Fig. 3. This machine is used for facing or counterboring various automobile parts, the old tailstock having been replaced by a special sliding stop operated by means of a hand-lever and accurately set by a micrometer screw adjustment; so that once set for a given stroke, any number of pieces may be machined exactly alike. The live spindle is fitted with a special chuck having a hardened and ground spring collet, and the shanks of all the counterbores and facing tools used in this machine are also hardened and ground in order to eliminate as much as possible the errors caused by warped or untrue shanks.

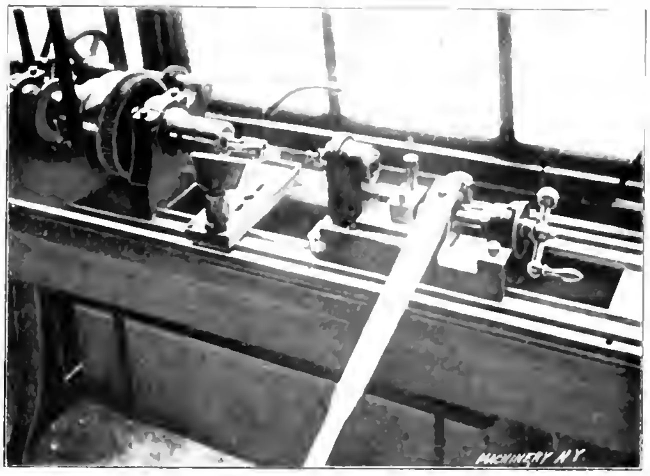

Fig. 3. Facing and Counterboring Machine, with Micrometer Stop.

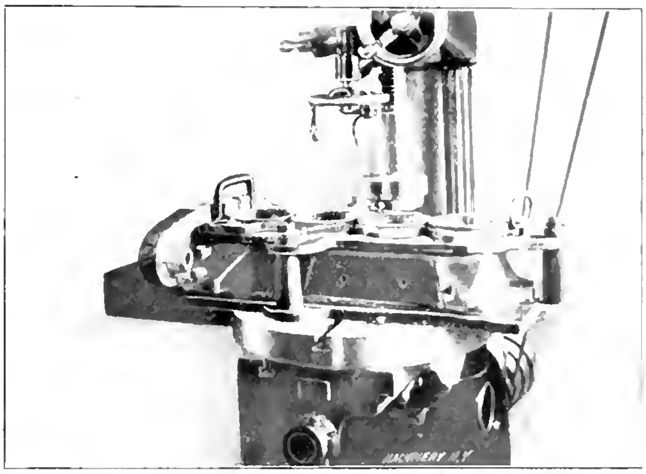

Fig. 4. Jig and Boring Tool for Boring out Cylinder Holes in Crank Case.

Fig. 4 shows the way the cylinder holes in the upper half of an aluminum four-cylinder crank-case are machined. The manner in which the boring tool cutters are guided in the jig bushings by the hardened and ground shoulder on the tool, is very plainly shown. Handles are placed on the top of the jig for convenience in handling, when putting it on or taking it off.

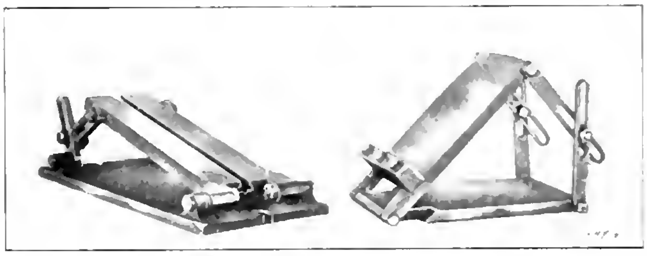

Fig. 5. Adjustable Angle-plates for Milling Machine and Drill Press

Toolroom Kinks.

In the toolroom are a number of interesting things, not the least of which are the adjustable angle plates for the lathe, drill-press and milling machine; those for the two last-named machines being shown in Fig. 5. In Fig. 6 are shown some special removable-pin racks for holding gangs of milling cut-

---

* See also MACHINERY, March, 1909, engineering edition: "Organization and Equipment of an Automobile Factory."

† Associate Editor of MACHINERY.

ters. As the illustration shows, the whole gang may be lifted off the board and taken to the milling machine without unnecessary handling of the individual cutters. The ends of the pins are drilled so that cotters may be inserted if wanted. This is the best scheme for keeping small gang mills together that the writer has ever seen.

Limit gages for inside work are made of heavy tubing with pins run through crosswise near the ends, as shown in Fig. 7. The method of writing the sizes of the gages on cards which hang close to them, is a good one, as it not only makes it easy, in the first place, to find the gage wanted, but also to replace it correctly after use. The size is, of course, stamped on the gage itself in the usual way, but as everyone knows who handles tools of this kind, the figures are too indistinct, even when rubbed with chalk, to be easily read. The holes for the pins in these gages, as well as the holes for the handles of all sizes of socket wrenches, are drilled in the jig shown in Fig. 8. This jig is an improvement over the usual jig of this character and Mr. Haas has so designed it that it will center accurately and hold firmly anything that will go through the hole in the clamping-slide which carries the drill bushing, three sizes of which are shown. These drill bushings are hardened and ground and then lapped to fit the stationary bushing in the clamping-slide. The knurled nut that draws the slide down onto the piece to be drilled has a coarse thread and, after the jig is set for any particular size, a pin placed in one of the holes in the nut makes a very effective locking-lever, as a quarter turn will tighten or loosen the clamp.

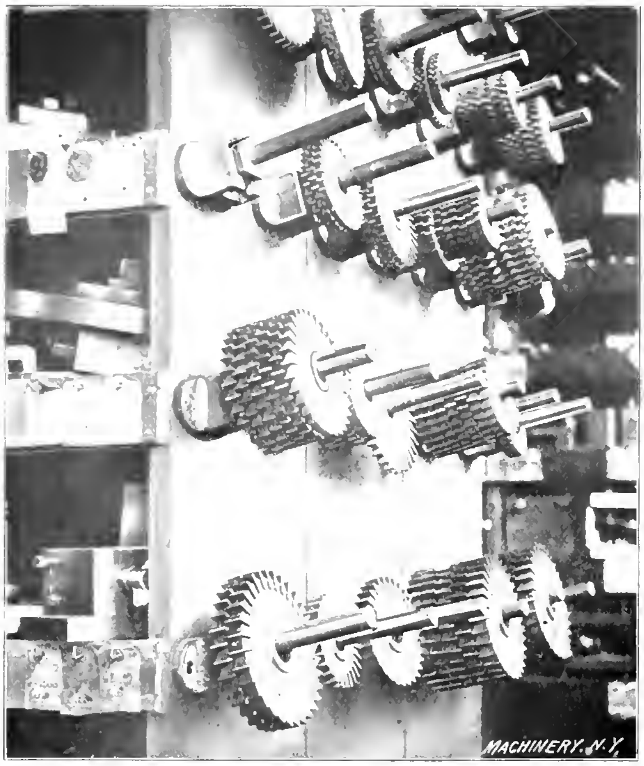

Fig. 6 Gang-mill Removable Storage Pins.

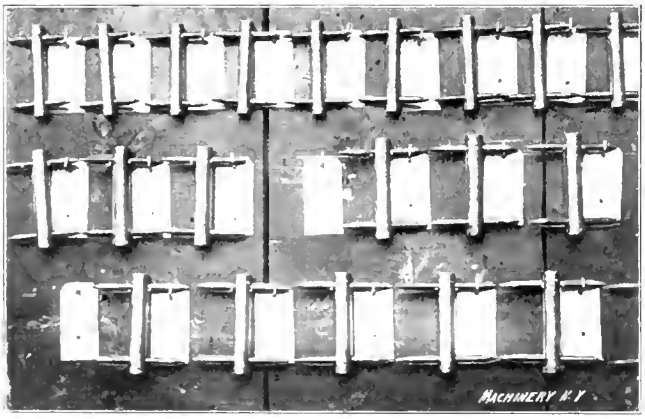

Fig. 7. Cheap Limit Gages with Size Cards.

The tool-chart shown in Fig. 10, a copy of which is kept in the various departments, enables the different foremen to order exactly the tools wanted, and also makes it easy to keep up the supply in the tool storage bins, for as soon as the tools of any type begin to run out an order for a new supply of that particular kind is given to the blacksmith foreman, who refers to his chart and makes up the tools wanted as soon as possible.

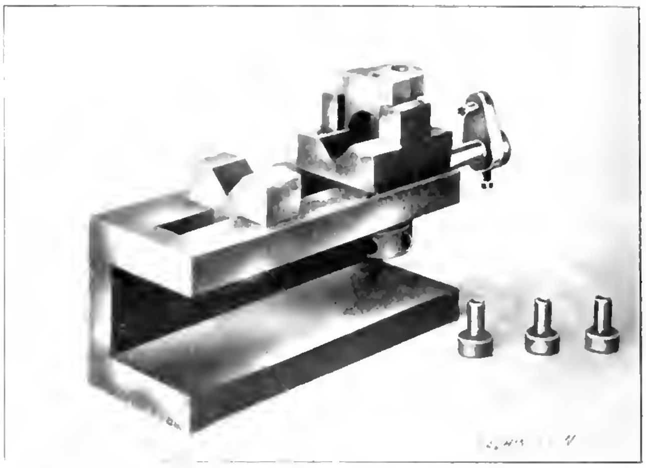

Fig. 8. Jig for Holding Round Bar Stock while drilling Cross-hole.

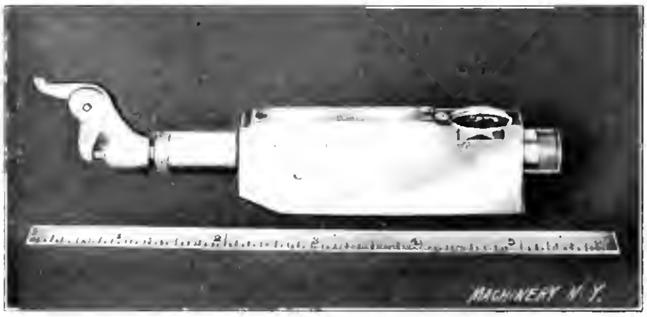

Fig. 9. Home-made Dial Indicator.

Fig. 9 shows an indicator made by Mr. Buxton when he was working as a toolmaker ten or twelve years ago; the dial is about 5/8 inch in diameter and the whole device is less than 5½ inches in length, as shown by comparison with the 6-inch scale in front of it.

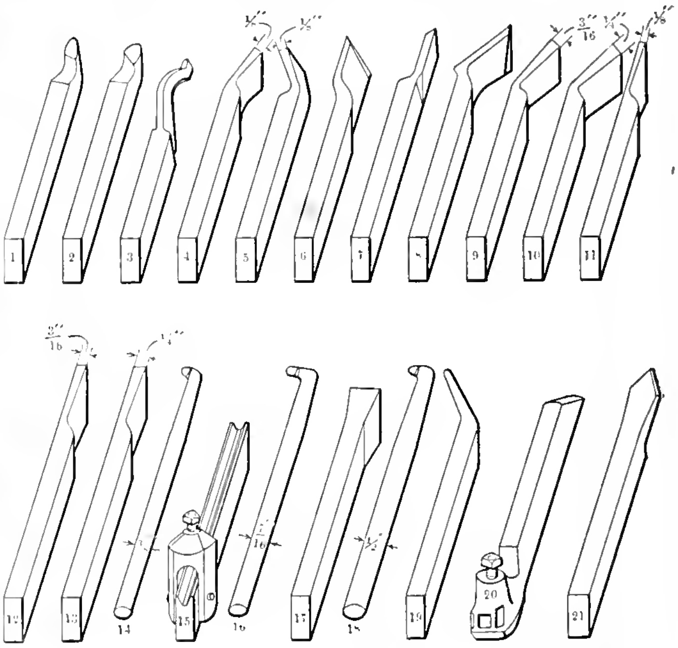

Fig. 10. Chart of Standard Lathe Tools which are ordered by Number.

During 1908 15,413 automobiles were registered in New York State, this being an increase of 1,446 over the number registered the previous year.

SAFETY VALVES.

At the meeting of the American Society of Mechanical Engineers, February 23, a paper on Safety Valves was presented by Mr. Frederic M. Whyte of the New York Central Railroad. In the opinion of the author, the engineering profession in general has been somewhat ignorant of the principles of safety valves, their relative capacity, and the capacities required for various conditions of steam generation. In marine work, certain formulas have been devised for calculating the sizes of safety valves, which have been more or less blindly accepted; but in locomotive work even a greater uncertainty prevails, although there is promise that the present unsatisfactory condition may be improved. The general practice in locomotive work has been to determine in an off-hand way the size and number of safety valves to be used, and former practice has entirely guided the designer. The capacity of the valve has been indicated in an unsatisfactory manner, being expressed as a "size," meaning the diameter of something more or less uncertain, while the other dimension, the lift, which is necessary to give an indication of the capacity, has been entirely ignored. It should be remembered that to know even the capacity of available valves is not sufficient; the important factor is to know how much steam is to be released, and in what length of time it should be released. In view of these various factors the suggestion was made by the author of the paper that instead of indicating the capacity of a valve in a rough way, by the diameter of some opening, the method be adopted of expressing the capacity in pounds of steam at certain pressures.

Another important factor in safety valves is the reliability of the spring, and the effect of the heat upon it. It should be possible to make adjustment easily, and at the same time the valve parts should be so arranged that it would be practically impossible for the valve to get out of adjustment.

On the question of the relation of valve capacity to steam generating capacity, the fact should not be ignored that in locomotive work the total valve capacity has not in the past been made as great as the maximum steam generating capacity, and this may be considered as ample proof that so great a valve capacity is not necessary. The reason for this is, of course, that on account of using the exhaust steam for producing the forced draft, when the demand for steam from the boiler is reduced or entirely cut off, the forced draft is also automatically reduced or cut off, and the generating capacity is reduced so that it is not necessary that the safety valve release the full generating capacity. Probably it is largely a question of opinion what percentage of the total generating capacity the valve ought to provide for, but it is likely that if attention is centered on this question, some fairly definite solution may result. The author concluded the paper by inviting discussion of these particular subjects in relation to safety valves.

During the discussion of the paper many different views were expressed. Mr. Philip G. Darling, of Manning, Maxwell & Moore, who has for two years past conducted extensive experiments on safety valves, presented a contribution, illustrated with lantern slides, on Safety Valve Capacity. He started from the premises that safety valves must have a relieving capacity at least equal to the boiler evaporation, as otherwise the boiler pressure will continue to rise, although the valve is blowing. Thus, with the exception of mechanical reliability, the most important factor in a safety valve is its capacity. Mr. Darling then proceeded to show an apparatus and describe the methods employed for determining safety valve lifts; he gave the results of tests made with this apparatus upon different valves, analyzed a few of the existing rules governing valve sizes, and finally proposed a definite rule, giving the results of the tests on which it is based.

Two factors in a safety valve geometrically determine the area of discharge and hence the relieving capacity: the diameter of the inlet opening at the seat and the valve lift. The former is the nominal valve size, the latter is the amount the valve disk lifts vertically from the seat when in action. In calculating the size of valves to be placed on boilers, rules, which do not include a term for this valve lift, or an equivalent, such as a term for the *effective* area of discharge, assume, in their derivation, a lift for each size valve. Nearly all existing rules and formulas are of this kind, rating all valves of a given nominal size as of the same capacity.

To find what lifts standard make valves actually have in practice and thus test the truth or error of the assumption that they are approximately the same for the same size valve, an apparatus was devised and tests upon different makes of valves conducted. With this apparatus the valve lift can be read to thousandths of an inch at any moment, and an exact permanent record of the lift during the blowing of the valve is obtained which is somewhat similar to a steam engine indicator card in appearance, and of a quite similar use and value in analyzing the action of the valve.

A portion of this apparatus, showing the safety valve and the gage for reading off the valve lift, is illustrated in the accompanying engraving, Fig. 1. The valve, during tests, is mounted on the boiler in the regular manner, and a small rod is tapped into the top end of its spindle; this rod connects the lifting parts of the valve directly with a circular micrometer gage, the reading hand of which indicates the lift upon a large circular scale or dial. The rod through this gage is solid and continues upward, maintaining a direct connection to the pencil movement of the recording gage above it, previously referred to. The experiments undertaken showed that with the exception of a small preliminary simmer, which some of the valves have, they open abruptly to a full lift, and close almost as abruptly when a certain lower lift is reached. Different makes of valves of the same nominal size are of greatly different capacity. Of seven 4-inch stationary safety valves, the lowest lift at the opening was 0.031 inch, and the highest 0.137 inch, while the lowest lift at the closing was 0.017 inch, and the highest 0.088; of six 3½-inch muffler locomotive valves tested, the lowest lift was 0.040, and the highest, 0.140 inch at the opening; while the lowest lift was 0.023 inch and the highest 0.102 inch at the closing.

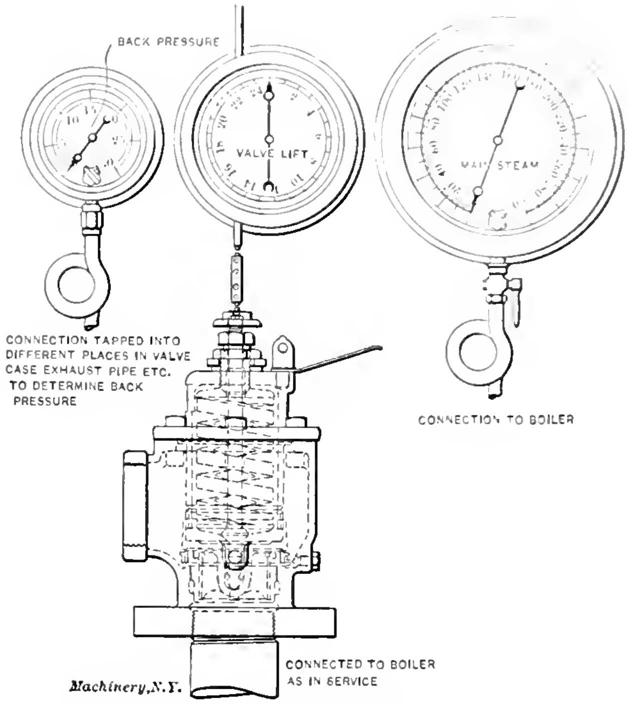

Fig. 1. Apparatus used in Tests for Determining Valve Lifts

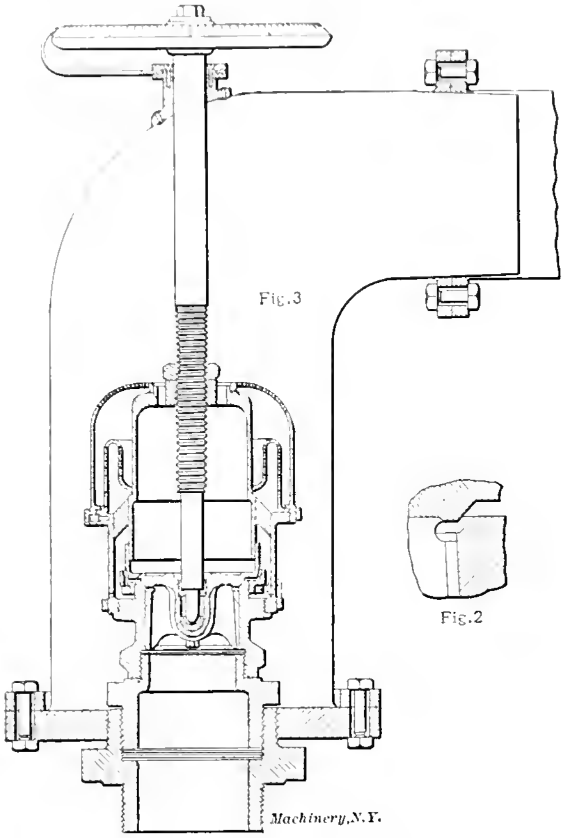
The valves tested all had 45-degree bevel seats. The four wings of the valve probably reduce the flow slightly from what it would be if the theoretical area of opening is calculated, but as the wings are cut away at the seat, as shown in Fig. 2, a definite correction of the existing areas is impossible.

"The great variation—300 per cent—in the lifts of these standard valves of the same size," said Mr. Darling, "is startling, and its real significance is apparent when it is realized that under existing official safety valve rules, these valves, some of them with less than one-third the lift and capacity of others, receive the *same* rating and are listed as of equal relieving value."

That the lift of a safety valve is the true measure of its capacity, other things being equal, has long been recognized. As early as in 1875, a committee reporting to the U. S. Board of Supervising Inspectors stated as the result of its investigations that the diameter of a safety valve is not an infallible test of its efficiency, but that the lift which can be obtained in a safety valve, other conditions being equal, *is* the test of its efficiency. The rules followed in safety valve design, have not, however, taken full cognizance of this, and the result is shown by the variation in capacity of valves of nominally the same size. Existing rules are, therefore, not safe to follow, and Mr. Darling proposed the following formula:



Figs. 2 and 3. Cross-section of Valve Opening and Arrangement for Measuring Capacity of Valves.

$$E = 105 \times l \times D \times P,$$

where E = steam evaporation in pounds per hour,
l = valve lift in inches,
D = valve diameter in inches,
P = steam pressure (absolute).

Transposed, the formula becomes:

$$D = 0.0095 \frac{E}{l \times P}$$

Modifications are given for locomotive practice, where,

$$D = 0.055 \frac{H}{l \times P}$$

in which H = total heating surface in square feet.

For cylindrical multi-tubular, vertical and water tube stationary boilers the formula becomes

$$D = 0.068 \frac{H}{l \times P},$$

and for water tube marine and Scotch marine boilers

$$D = 0.095 \frac{H}{l \times P}.$$

In order to determine the constant or coefficient of flow at different lifts and how it is affected by variation in valve design and adjustment, an extended series of tests was recently undertaken at the Stirling boiler department of the Babcock & Wilcox Co. at Barberton, Ohio. The feed water of the boiler was measured, and the entire steam discharge of the boiler was through the valves being tested. The valves were all previously tested and adjusted on steam; and without changing the position of the valve disk and ring, the springs of these valves were removed and solid threaded spindles inserted, as shown in Fig. 3. At the top of these spindles a graduated disk was placed, by means of which the lift could be exactly determined.

Mr. Albert C. Ashton of the Ashton Valve Co., stated that it did not seem to him that what is most needed to-day is valves of greater capacity, "but rather a better understanding of the proper proportioning of safety valves to boilers, for which no universal rule has been recognized and adopted." He stated that high-lift valves, under some circumstances, may even be considered dangerous, and if high-lift valves were a decided improvement over the best standard makes, manufacturers of safety valves could easily change their design to make nothing but high lift valves; generally speaking, a lift of 1/8 inch is excessive, though valves with a lift a little higher than the standard, say 1/16 inch, would have some advantages.

A presentation of the subject of safety valves, as it appears to the locomotive builder, was contributed by Mr. F. J. Cole of the American Locomotive Company; he referred to the practice both in this country and abroad, and cited several reasons in explanation of the apparent disregard of definite rules governing the application of safety valves to locomotives

Mr. Garland P. Robinson, State Inspector of locomotives, referred to the fact that his experience indicated that no rule is generally followed in determining the size of safety valves for locomotive boilers; he believed that a formula based on the heating surface and providing for 50 per cent of the maximum evaporation of the boiler would give satisfactory results for locomotives. Using the notation above, he gave the formula (applicable to locomotives):

$$D = 0.05 \frac{H}{l \times P}$$

In view of the fact that some of the tests referred to in the discussion have been conducted by manufacturers of valves themselves, Mr. Carhart, of the Crosby Steam Gage & Valve Co., emphasized that "the actual lift or discharge area of valves should be determined and reported upon after impartial tests conducted by competent and disinterested engineers, * * * and not from reports of tests conducted by any one manufacturer without the knowledge of other makers whose valves are tested, and where the one measurement noted has been, in many cases, purposely limited by the manufacturer for special reasons."

HORSE-POWER REQUIRED FOR MOVING CARS.*

MORRIS A. HALL.

It is a rather complicated problem to determine the power required to move a railroad car of known weight at any known speed over a level track, or up a known grade. A diagram, or graphical chart, however, can be prepared, from which the power required may be obtained practically at a glance if the quantities, speed, weight and grade be known. Such a diagram is presented in the accompanying Supplement. Suppose, for an example, that the car weighs 15 tons, or 30,000 pounds, and assume further that we wish to move this car at a speed of 25 miles per hour over a level track. Find first on the right-hand vertical scale the point marked 15 tons (the weight of the car), and follow the horizontal line from this point to the intersection with the oblique line marked 25 miles per hour and from this intersection follow a vertical line downward intersecting the horse-power scale for level track at 30½ H. P. Suppose that the car must also climb a grade of 3 per cent somewhere on the line. In order to find the horse-power required for this, follow the same vertical line, already found, until it intersects the oblique grade line marked 3 per cent grade, and then follow the horizontal line from this intersection point to the right-hand vertical scale, where we find the required power for climbing the grade to be 93 H. P. As will be seen, the diagram can be used for cars weighing up to 20 tons, for speeds from 3 to 30 miles per hour, and for grades from 1 to 10 per cent.

DESIGN AND CONSTRUCTION OF METAL-WORKING SHOPS–6.

CONSTRUCTION PERIOD.

WILLIAM P. SARGENT.*

The previous articles of this series have covered the engineering work in connection with the planning and developing of projects of plant improvement from the conception of the idea to the beginning of the actual work of construction. At the beginning of the construction period the engineering control of the project takes on the function of supervision, and if this supervising is not efficient the best and most thorough planning will be fruitless as far as obtaining a high degree of excellence of construction and the completion of the project on the predetermined date is concerned.

Miscellaneous Notes on Construction Work.

Many of the following commentaries may belong more properly to the planning of the work, but they are brought to mind by the consideration of the construction period, and therefore are presented in connection with the discussion of the carrying out of the plans.

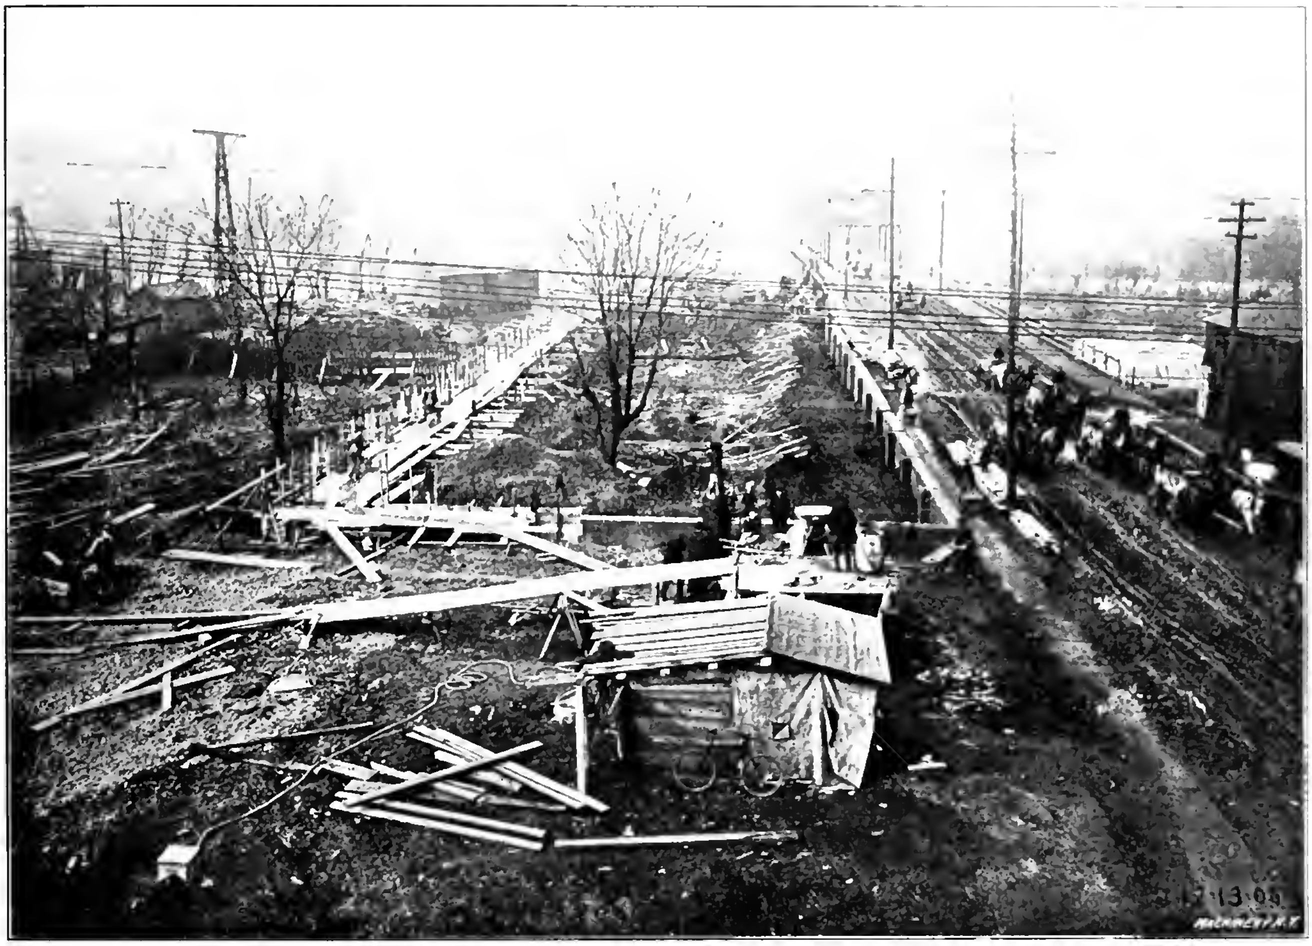

Fig. 37. A Job on which the Contractor put in a Bill for 1,000 Extra Cubic Yards of Excavation The Photograph Helped to settle the Bill for Something like 100 Yards.

The good-will and personal regard of the contractor and his foremen for the engineer in charge of construction work is a stronger factor in securing good work than the strictest supervision and inspection. This holds true in general with the building trades, but one cannot go to an extreme in guarding against unintentional errors and omissions in the laying out of the main working lines of a project and other points that cannot be remedied easily and cheaply. A contractor loses profit and an owner loses time when slips occur in the early part of building operations, so this part of an engineer's care is very important.

Oftentimes such work as trackage, sewers, power-house, water supply, etc., cannot be laid out and contracted for satisfactorily in advance of the awarding of contracts for the buildings. It is then necessary to organize a working force controlled directly by the engineer in charge or by a foreman who receives instructions from, and reports to, the engineer. The writer, in a general way, would advocate that all work should be done by outside contractors, under specifications, whenever possible to plan ahead and give definite directions. If the concern is of such a size as to have at all times on its payroll men of the various building trades, such as masons, carpenters, yardmen and others who will be responsible for the repairs on the new plant in the future, it is advisable to handle all underground work directly. By adding to the plumbing force, for instance, the sewer work can be done cheaper and better in this way, and the head plumber not only has the opportunity to familiarize himself with the drawings, but also sees the work go in, and he cannot afterwards lay the blame for avoidable troubles onto anyone but himself. In the sewer work, for example, changes will often be necessary in the layout almost as soon as work is started, on account of surface drainage or draining excavations. A site is selected because of its being level, but surface water cannot be carried away by means of open ditches without interfering with the rapid transfer of materials, and it pays well to keep the site dry and avoid the seas of mud so often in evidence about new buildings. Then again, tees and other branches can be placed wherever there is the possibility of future need and their location noted on the blueprints, and afterwards on the record drawings, if the work is done by the owners. With a contractor doing work so liable to changes, bills for extras are sure to result, and furthermore the additions and changes will seldom be followed up and recorded on the drawings.

The importance of inserting extra branches at intervals should not be passed over lightly, as the labor required to either cut a hole in tile pipe or set in branches by means of sleeves will pay for these extra branches a dozen times over. Holes can be cut in tile pipe when the pipes are hard rammed full of sand and the pipe is on the ground, but the difficulties arising from the necessity of doing this cutting at the bottom of a trench and with the sewer running nearly full can well be imagined. The branches should be carried up to within two or three feet of the floor level and have

---

* Address: 1528 Arch St., Philadelphia, Pa.

pl[illegible] It is also a wise precaution to cover these [illegible] with a close woven fabric as soon as possible [illegible] debris from getting in and clogging the [illegible] case it is advisable to use cast-iron soil pipe [illegible] of the buildings, and in the vertical branches [illegible] there is a probability of excavating and damaging [illegible] pipes. All branches for future use should be marked by [illegible] stake and they should be located definitely on the record drawings. If branches must be set in a line of finished tile sewer the split tile mentioned in a previous article of this series should be used, as a section of straight pipe can be broken out and the lower half of the new branch rocked into place and cemented and inspected before closing in with the top half.

The main runs of pipe should invariably be made large enough to provide for the extension of the plant buildings

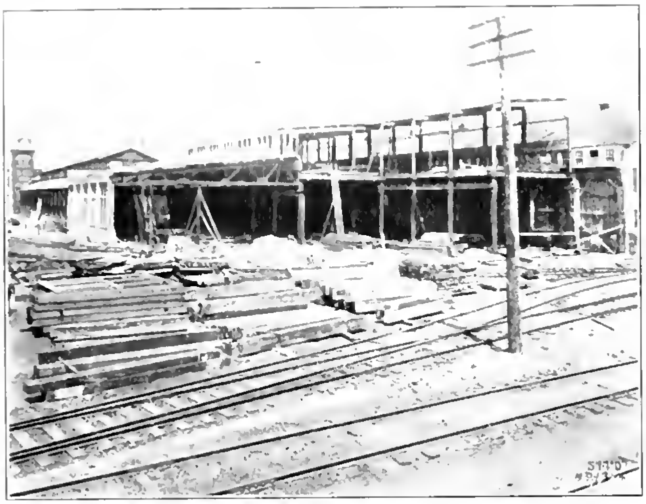

Fig 38. Shop Construction held up in the Condition shown for nearly Two Months because of Lack of Railway Trackage.

The end of every run of pipe, either main or branch, should finish either with a curve of long radius or with a manhole to permit of flushing with a hose or starting obstructions by means of wires.

Grades of Sewers.

There is any amount of information extant concerning the proper amount of fall that should be allowed for sewers, but very little that will help in determining the *very least* that can be used. The problem is often whether the slope that can be easily obtained is sufficient or not. Nearly every engineer has to depart from the recommended practice at times, and precedents are then more valuable than theory. There was a description of a sewerage system in the *Engineering News* of February 6, 1906, in which the slope was given as one-tenth of 1 per cent or approximately 5 feet per mile for an 18-inch sewer; and about 4 feet of head was all obtainable with this slope, and this head had to operate a septic system. A septic system will be a necessary part of nearly every large plant built in the future, as the pollution of streams will not be tolerated. Many of the large railroad shops have septic systems, and one large industrial plant saved over $1,800 per year on its water bill by such an installation. The cost of a septic tank and filters approximates $5.00 per man. The above mentioned article is one of the most concise descriptions of a septic system published.

The predetermined slope of a pipe sewer can easily be obtained in construction by excavating nearly to the desired depth and driving stakes. The tops of the stakes represent the undisturbed bottom of the trench and should be set with an instrument. The bottom can be graded to the stakes, and by digging out for the bells of the pipe, the barrel of the pipe rests on solid ground. *Salt glazed* tile should always be used to secure strength and freedom from porosity.

In making layouts of sewers, a small scale is naturally used and the details of branches, etc., are often too small to be well shown. A method of numbering the branches and [illegible] data of lengths, sizes, location of traps, in marginal [illegible] similarly numbered is recommended. The branches on [illegible] side of the main line should be numbered odd and on the [illegible] side numbered even, beginning at one end of the system. This method of numbering aids in listing material and checking off the work as finished.

Drainage of Pipe Tunnels and Basements.

It is seldom possible to lay drains for underground chambers and tunnels that will clear them of seepage water by a gravity flow. It is hardly possible to thoroughly waterproof the side walls of concrete without excessive cost for excavating to afford room for men to work between the sheeting and the wall after the forms are struck. For these two reasons, sump pits should be installed below the floor level, and steam syphons or other forms of pumps put in to raise the water to the level of the gravity drainage system. There are a number of compounds on the market which are intended to be mixed with the cement to prevent seepage. These have been efficacious in some instances, but failures have occurred that suggest the advisability of providing for the removal of seepage, even if a compound is used.

Whitewashing of the interior wall surfaces should be deferred until either seepage is evident or a certainty of a dry chamber is assured. One very good way to handle seepage is to localize the leakage by drilling holes in the walls at the points of greatest leakage, and by means of small pipes laid in channels cut in the concrete, leading the water to the drain and sump. Porous agricultural tile laid outside the wall near the bottom will often take care of the surface drainage and prevent seepage, and such tile should be laid even when the interior drains and sumps are provided. The roofs of tunnels are generally waterproofed with a multi-ply felt roofing laid with pitch as on buildings.

There is one most important point in planning pipe tunnels that is often neglected—the exact location of branches of piping which cross over and lead into buildings. It is often necessary to carry a branch back of the interior wall line, then up and through a raised chamber, in order not to unduly restrict the free opening of the tunnel. As these recesses cannot be put in after the tunnel is built it is obvious that most careful study and laying-out of the piping should be done before making the final drawings of the tunnel.

Wrought Iron Piping.

The use of galvanized pipe where laid unprotected underground is strongly advocated. The deterioration of black pipe has been noted by nearly every engineer who has watched excavation around old buildings, and the recommendation of galvanized pipe made here is based on the experience of an old engineer in the Middle West, whose work for nearly 40 years had been mainly in connection with pumps and water-works. This same engineer has noted the deterioration of black pipe when used inside of shops for compressed air and states that galvanized pipe has a much longer life than black pipe when used for this purpose.

Fig. 39. An Illustration of the Opportunity for carrying on Work Inside when Masons work on Outside Scaffolds.

Concrete Work.

Great stress is often placed on the testing of cements and concretes irrespective of the nature of the work. It is hardly practical to specify a different mixture for each par-

ticular mass of concrete, so an experienced foreman is apt to judge the concrete by the color and to vary the mixture according to the need for a rich or lean mixture. It would be unwise to arouse the antagonism of the construction foreman by insisting on a rigid compliance with the specifications for the "mix" for concrete to go in the bottom of masses and in unreinforced members on which there is little load.

Let the foreman know that the concrete will be tested with a pick after the forms are struck and the concrete is set and aged, and that defective work must then be replaced. It will not then be necessary to place a watch over the mixer, for if the foreman is competent the quality of the work will be satisfactory even if the contractor does save a few dollars.

There is a great difference of opinion as to the effect of freezing on concrete. Nobody maintains, however, that freezing helps concrete, and concrete which has been frozen and can be broken with the toe of one's shoe is certainly unfit for anything. It is believed generally that concrete can be safely put in at any temperature as long as it is protected from freezing by means of hay, straw, etc., until it has set. The writer is informed by an engineer of the Pennsylvania R. R. that concrete has been put in at zero temperature without any freezing. The following rule is believed to be safe for the permissible minimum temperatures: Concrete may be put in down to 35 degrees with a falling thermometer and at 28 degrees with a rising thermometer.

Many methods and expedients are used in the attempt to obtain a good surface on concrete. Even if the surface is to be bush-hammered afterwards it is the better if made as uniform as possible when being placed. The thin-edged square-end spade so often recommended does not always force the aggregate back sufficiently, and paddles of wood ½ inch or more thick are better. The proper thickness can be found by watching the effect on a section from which a form board can be removed. Of course, tongued and grooved lumber will make a better surface than plain boards. Nothing less than 2-inch plank, with uprights on a 2-foot center, should be used in order to prevent bulging. With the uprights on 2-foot centers, stock lengths of lumber can be used without waste.

Fig. 40. Inside of Shop shown in Fig. 42, during Construction.

It is difficult to obtain a uniform level for the tops of piers and pilasters where columns are to be set. This cannot be done by attempting to flow the concrete to a line. It is better to keep the concrete an inch or more below the line and build up to the line with a rich cement mortar trowelled on. The common way of levelling up columns is to grout in under the column footplates, pushing the grout in with a paddle. This does not, with any degree of certainty, provide an even bearing on the concrete. The best way is to leave 2-inch holes in the footplates and pour the grout in until it shows all around the plate, confining the grout with a dam of clay or putty.

It is obvious that the forms for foundation walls will not be built on the entire outline of the building at once, but that sections of concrete will be put in up to the floor level and the forms then built up for the next section, using the lumber from the completed section as fast as the forms can be struck. This necessitates vertical joints These stop-offs will not do material harm if the old and new sections are bonded securely. Undoubtedly the strongest and best method is to use steel reinforcement, letting the steel run into both sections about 2 feet.

The "V" joint commonly used has but little strength, as dependence is placed upon cohesion alone A square tongue and grooved joint is stronger in both directions. The "V" joint often leaves an unsightly fissure in the face of the wall at the feather edge. If either joint is used to take care of strains in the direction perpendicular to the wall, reinforcement should be invariably used in addition. The surface of all parts of older work should be scratch-brushed before placing fresh concrete. Many contractors content themselves with washing the surface with a little water or throwing on a little dry cement. Reports of recent tests indicate the advisability of cleaning and scratching and brushing with a cement grout.

Fig. 41. Inside of Same Shop as shown in Fig. 40, at a Later Period of Construction.

A frequent cause of differences between the engineer and the contractor is extra concrete and excavation. It is very easy to avoid trouble on this score by having the bottoms level, the footings uniform in thickness and then taking measurements from the top of the wall to the footings after striking the forms. These measurements should be taken by the engineer and a representative of the contractor jointly. Records of these measurements should be made in duplicate and signed by both parties. This precaution will tend towards amicable relations.

Fig. 37 shows a job on which the contractor put in a bill for 1,000 extra yards of excavation. On account of measurements taken as above, and the photograph, this bill was settled for, within five minutes, on a basis of something like 100 yards, and the contractor was satisfied.

Grading and Filling.

For filling in the deeper portions of holes, almost any material will do; but as the floor level is approached care must be exercised to get the material so placed that the voids in the coarser material will be filled by the fine dirt, which is best done by using water from a fire hose. Twenty-five dollars worth of water will accomplish more than a hundred dollars expended for tamping. Ashes, cinders and gravel are all good for filling for the inside of buildings, and in some sections of the country locomotive front-end cinders are used as a substitute for concrete. This does not make such a solid floor as concrete but is all right for subsidiary buildings. The filling inside of buildings which are to have other than dirt floors, should be started as early as possible, so that low spots may be discovered and filled, and thus a firm substructure for the concrete secured. When grading for future trackage, make certain that the surface is kept low, as it is difficult to depress a track. Section men will often raise a relatively long stretch of track rather than depress a short length.

Track Work around Industrial Works.

In the following notes it is assumed that it is permissible in practice in track work for a large private plant to consider the factor of future repairs as very important, and that a first cost is justified which is greater than often expended for private corporation trackage.

Ballast should be at least 8 inches deep under the ties. The ties should be 6 x 8 or 7 x 9 inches, and may be spaced on 21 inch centers to make a solid track. With a regular spacing of 21 inches on straight track, the spacing will be about 19 inches at the mouth of the frog, and about 22 inches at the points of 15-foot switches and decrease to 19 inches at the heels. Tie plates will add about 15 cents per lineal foot of track, but they will lengthen the life of the ties 50 per cent. A 70-pound rail is probably the most economical section to use about a plant building heavy machine tools or large engines, because of the heavy switching. Such a rail will last longer than a 60-pound rail or the "re-lay" rails which are generally used. The first wear of a rail is well worth the added cost over old rails.

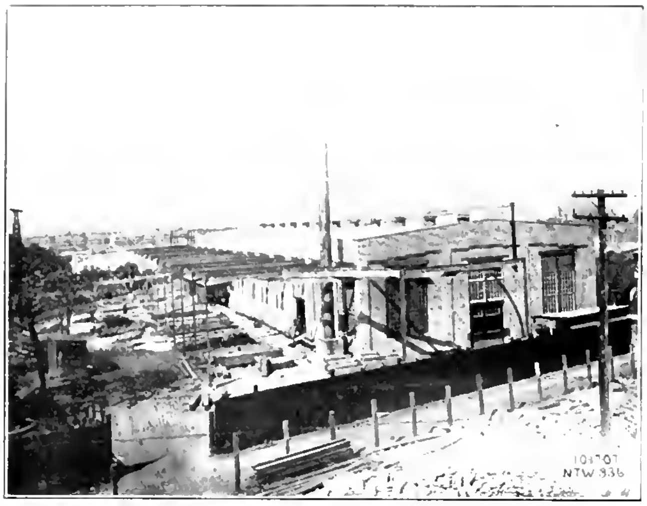

Fig. 42. Outside of Shop Illustrated in Figs. 40 and 41.

Suspended joints should always be used, and angle plates rather than fish-plates. The "pumping" of a tie at a supported joint is certain to cause excessive wear of the rail ends and to make low spots in the track. In laying out tracks remember that railroads are often "sticklers" about any track over which they may be called upon to operate, and even if the works is to do its own switching the curves and grades should be such that a railroad cannot consistently refuse to operate in the event of a private switch engine being laid up for repairs. The Inter-State Commerce Commission has recently established a minimum permissible curvature of 175 feet radius and a standard frog can be obtained for this curve. A 1 per cent grade should not be exceeded on curves if a small engine is to be used. Low switch-stands with targets cost more than the common ground-throw type, but are much better, as dependence is not entirely upon signals given by a brakeman.

The ideal curve for turn-outs or cross-overs would be one that would give a uniformly accelerated motion in the direction of departure from the principal track. If the frog and switch are made with straight rails and start with an angle less than is generally called for by the curve, an approximation to the ideal curve will be secured. This method starts the curve easy and the radius is gradually shortened as the curve advances.

The gage of the track should be standard except on curves, and even for the 175 foot radius curve a widening to 4 feet 9 inches is sufficient. In laying out curves that lead into buildings, see that the curve does not begin for nearly a car-length outside of the door. This permits of narrower doors than if the curve starts at the wall line. For side clearance on straight track keep all obstructions 6 feet 6 inches away from the center of the track. The safest way to look for interferences on curves is to make a dummy of [illegible] foot car to scale, cutting the corners back on one side to the kingbolt centers. Move the dummy around, keeping the kingbolt centers on the track center line and watch the corners and side for interference with buildings or other obstructions. Keep obstacles at least 4 feet away from the side or corner of the car. Very substantial bumpers of a type that is secured to the rail should be put up at the ends of all tracks. A "Y" in some part of the track system is necessary in order that the switch engine can be turned end for end once every week or two. This distributes the wear over the wheel flanges on both sides of the engine.

As much as possible of the track system should be put in in advance of the building operations to expedite the placing and unloading of material. This will be appreciated by the contractors, and as the tracks have to go in some time, it is as well to get the use of them when time can be saved that will help to get the plant running earlier. The track scales should be put in at the start, especially if the steel work is to be paid for on a tonnage basis. The weights of the bills-of-lading may be right; but if the project is of the size of the model plant previously described, the amounts in question are great enough to warrant extra endeavors to provide a means for securing correct weights.

Fig. 38 shows a building which was held up in the condition shown for nearly two months because of the delay in the track work being done by a railroad company.

Erection of Structural Work.

The unloading of the first car of steel work will indicate for the time being whether or not the fabricating company is really making an effort to erect the material on time. If the first car-loads are made up of columns for the first building wanted, well and good; but if they consist of members for buildings not wanted until later, then a "loud holler" must be made. The securing of material in the proper order is a point where the inspector at the shop can be of great value, if employed by the owner, as through his reports the engineer can know of dilatory work and can endeavor to remedy the trouble when it begins. See that the unloading does not result in distortion of the steel work, especially of the compression members. A goodly portion of the shop coat of paint is apt to be rubbed or scratched off in shipment and such spots should be touched up, at least in places that will be inaccessible after erection.

As a rule steel erectors do their work thoroughly and conscientiously, but there are times when they will get an idea that there are too many rivets, and that a few left out will do no harm. Therefore it is well to look at the places requiring rivets that are hard to get at and make sure that all are in.

Another important point in erection is the final tightening of bracing in the plane of the upper chords of the roof trusses. If not done carefully, distortion of the truss will result, due to the excessive unbalanced tension on the diagonal ties. That the abutting surfaces of the columns are in contact over the full surface at the splices is also important. Full rivet heads should be insisted upon, even though the contention is often made "that a poor rivet is better than a bolt, and a bolt would do." The practice of battering the ends of bolts to prevent nuts loosening at bolted connections is to be discouraged, as it is uncertain in fulfilling its object. The form of lock washers used in erecting traveling cranes is more certain for this purpose.

Work of Various Building Trades.

It is difficult to obtain good work and speed at the same time, and it is useless to expect better work than is the ruling custom in the locality in which the buildings are being erected. There is a tendency in some sections to think that anything is good enough for a shop building. This results from the demand for a minimum of cost irrespective of quality of work. Often one will find mason contractors who think a ¾ inch mortar joint is all right, and whose ideas of a shoved joint are such as to defeat the desired aim of securing a full joint and a solid wall. The bonding of the inner and outer courses should be good, and anchors for tying the brick work to the structural framing should be placed wherever there is a chance of the brick work breaking away at points where the parts of the work are intended to

be mutually supporting. Many hard-burned bricks absorb water slowly, and if such is the case the joints should not be struck until settlement has taken place.

The time taken to lay brick for any building is little, in relation to the entire time consumed in building, but this period can be profitably occupied in doing foundation and underground work inside of the building. To this end the masons must work from outside scaffoldings on single story shop buildings. Many contractors will object to doing this, claiming difficulty in keeping the walls clean and in lining up the outside courses. Their objections are not weighty enough to balance the advantage to the owner, of having the space within the walls available for doing such work as may save much valuable time in the future. Fig 39 shows the opportunity for pushing work when the masons work from outside scaffolds.

Plumbers are not prone to work accurately to drawings in the location of piping, and their work should be watched as to clearances for cranes, sliding and lift doors and any other subsequent work.

Most foremen of the building trades have risen to their positions primarily for their skill, and they are generally more proud of their craftsmanship than they are of their executive ability. The feeling that their skill is recognized and credited by the engineer will lead the foremen to use extra care to prevent things from slipping through that would reflect on them personally and even to suggest slight changes that would be better than the design calls for. This cooperation of the contracting foremen can often be obtained by using tact, and its value is immeasurable.

Methods of Following and Expediting Progress.

The following method of recording the progress of building operations is based on the premise—that of a piece of work requiring ten weeks to complete 70 per cent of it should be done in seven weeks, or a larger force should be put on to make up the time lost. It may not be out of place to state that the keeping of costs on shop work by the use of "average hour rates" rather than distributing every minute of every man's time, is recommended by one of the leading practical supervisors of cost keeping in the metal-working industry.

The application to construction work is very simple, as the different hour rates are fewer than in shop work. The first thing required is the total number of hours or days necessary to complete the work. This total for each branch of the work is obtained from the engineer's estimate of cost, either by summating the number of hours there given in detail or by dividing the cost (pay-roll cost only, refer to fifth article of the series, January issue) by the average hourly rate for that branch of the work, and then by the number of hours to a working day, then by the number of working days in the available time. Thus the average number of men required is obtained. The time actually put in on the work is then easily obtained by counting the number of men at work each morning and afternoon. This can be done without arousing any suspicion that the work is being checked Of course, allowance should be made for the days lost on account of the season of the year, bad weather and holidays The available time and the dates from which records should start are shown by the time charts described in the fourth article, December issue, page 253. The progress can be plotted graphically against a predetermined curve on a chart which shows the dates on the horizontal line, and the cumulative number of man-days on the vertical scale. This method involves the least amount of clerical work and shows very plainly whether or not the work is progressing rapidly enough. The vertical scale can also be marked for percentages, and the chart will give the percentage of completion which should be reached on any date, and when filled in, the curve of actual days worked to date will give the percentage which is actually accomplished at that date. As it is necessary to record the number of men working each day, the desired progress can also be shown by the table indicated by the following headings:

Fig. 43. An Illustration showing the Manifold Duties of the Engineer in Charge of the Large Project of Construction Work.

Date.	Men at Work.	Cumulative Days.	Required Days.	Required Per Cent	Actual Per Cent

This method may not be thought sufficiently accurate for cost keeping for shop work, but it certainly is for construction work,, and is far more accurate than the general estimates of percentage of completion, and has the undoubted value of being based on something more than observation and is strong as a support of a claim that the work is behind, if it becomes necessary to make such a claim to the contractor.

The uncertain factor, the figured labor cost as taken from the estimate, should be checked, as it is only necessary to verify the unit of time required for a unit of work. If it is found that this time varies from the estimated time it is easy to modify the curve on the chart. This chance for verification makes it possible to feel more certain that a large project is going right, or to know just how bad things are if they are not going right.

It is hardly necessary to mention the importance of photographs of construction work as a factor in preventing disputes when settling for extras, but the great value of photographs of details, when other work is to be designed or estimated upon, is only realized by engineers who have these record albums in connection with the complete data of estimated and actual costs and other conditions of the problems. Figs. 40, 41 and 42 show stages of a piece of construction work and the details are certainly the equivalent of many pages of a note-book.

Installing and Moving.

It is important that foundations for new apparatus and machines from the old shops shall be ready when the machines arrive on the ground and that facilities are provided for handling and placing the machines without delay in order that the starting up may be systematic and proceed without confusion. Foundation plans for the new machines are easily available, and the time taken to repair old machines before moving should be made use of in obtaining the location of anchor bolts and whatever measurements are required for pits, etc., which cannot be obtained before. The completion of the foundations must also be rushed on receipt of this information.

This is one of the busiest periods in the work of plant extension, as all the many minor items forgotten or deferred must now be met. The machines, as soon as on foundations, must be leveled and made ready for use. The starting up of the machines, the constant operation of cranes and the demands for lights make it absolutely necessary that the power plant be in good running order, and that such changes be made as develop from watching the operation of new apparatus.

On the presumption that the engineer in charge of the construction of a metal-working plant has to do with the

selections of new equipment both in way of machine tools and equipment for handling and transporting of materials, the erecting and running of new machinery should not be left to the shop people. Especially in shops where the heads of departments have worked up from the ranks, there is often a reluctancy to give new machinery a fair chance or to strive for the most that the machinery is capable of. Therefore, the engineer will work to the best interest of his employers and himself if he renders every assistance to any erecting men or demonstrators from the outside, and follows up and records the performance of machines when they are in the hands of skilled operators. The little "kinks" of handling and time-saving used by demonstrators should be noted, as later on the shop men may so handle machines that the performance is not duplicated, and if the engineer has advocated the machine without the earnest acquiescence of the shop foremen, it will be "up to him" to save an efficient machine from being condemned.

Scope of Construction Engineering.

The reason that the author has placed so much stress on the responsibility of the engineer in charge of a large project of construction work is shown in a way by the range of work going on in the scope of Fig. 43. Below the surface of the ground there is tunneling, plumbing and power piping being carried on. The foundry shown at the right is being worked into running order; the foundations are put in for the boilers at the power house of which the mason work is in progress. In the foreground: excavation, concreting, the placing of capstones and the beginning of the steel erection is in evidence. The planning and contracting for the work shown in this one view was done within six months and involved the expenditure of nearly $400,000. If one will but consider the large number of personalities with whom the engineer must deal, and the mass of details for which he must stand sponsor on a job of this size, the difficulty of securing results that are satisfactory to even a *few* people will be understood. The subject is so broad that to treat it in a general way can only serve to bring out a portion of the many things which have to be considered in this class of engineering.

* * *

CRANE HOOKS.*†

H. J. MASTENBROOK.‡

The tables of dimensions and properties of crane hooks found in hand-books usually apply only to hooks of ten tons capacity and under. They are based largely on the results of practice, and are forged from a rod of uniform cross section for reasons of economy in manufacture. In designing a hook of large capacity the matter of weight is of much more importance than cheapness of production; it is therefore important to distribute the metal in the most economical manner, and obtain the necessary strength with a minimum weight. The shape of the cross section of a hook is such that it does not lend itself readily to exact mathematical treatment. However, approximations may be made that are fairly accurate and which experience has shown to be safe.

Let us first consider briefly the development of a general formula. In the formulas:

A = area of section in square inches,
f = allowable fiber stress in pounds per square inch,
P = load in pounds,
p_1 = stress due to pull in pounds per square inch,
p_2 = stress due to bending in pounds per square inch,
I = moment of inertia of cross section,
R^2 = square of the radius of gyration in inches.

See also the accompanying illustration for the notation used. Then

$$p_1 = \frac{P}{A}$$

$$p_2 = \frac{P y_1 y_0}{I}.$$

For safety $p_1 + p_2$ must equal f; therefore:

$$f = \frac{P}{A} + \frac{P y_1 y_0}{I}$$

which may be reduced to the following form:

$$\frac{P}{f} = \frac{A}{1 + \frac{y_1 y_0}{R^2}}.$$

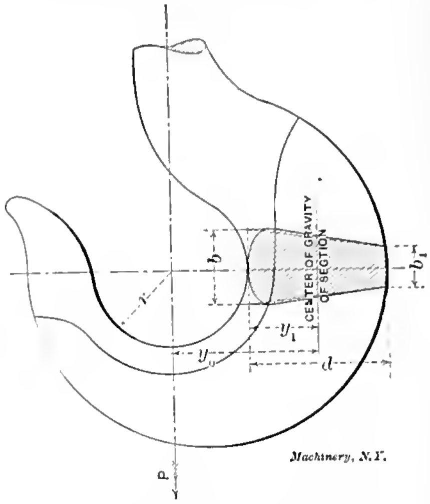
If, instead of the actual section of the hook, we consider the trapezoid as shown by the dotted lines, we then have the following values for the various terms in the formula:

$$A = \frac{b + b_1}{2} \times d,$$

$$y_1 = \frac{b + 2b_1}{b + b_1} \times \frac{d}{3},$$

$$y_0 = \frac{b + 2b_1}{b + b_1} \times \frac{d}{3} + r$$

$$R^2 = \frac{b^2 + 4bb_1 + b_1^2}{18(b^2 + 2bb_1 + b_1^2)} \times d^2.$$



Machinery, N.Y.

Notation for Crane Hook Formulas.

Substituting in the above formulas $b = 0.65\ d$; and $b_1 = 0.3\ d$, we have:

$A = 0.475\ d^2$,
$y_1 = 0.4386\ d$,
$y_0 = 0.4386\ d + r$,
$R^2 = 0.0795\ d^2$.

Substituting these values in the general formula reduces it to

$$\frac{P}{f} = \frac{d^3}{7.2d + 11.615r} = \text{constant in table in Supplement.}$$

To facilitate the work of design, tables giving values of $\frac{P}{f}$ for various assumed values of d and r may be calculated, and such tables are given in the accompanying Supplement. Hooks designed by these tables have been very thoroughly tested in practice and have given entire satisfaction. For ordinary service, a fiber strain of from 16,000 to 25,000 pounds may be used with safety.

When using the table in the Supplement for designing crane hooks, the load P in pounds which the hook will be required to carry is first determined. Then the allowable fiber stress f is assumed, and the quotient $\frac{P}{f}$ obtained. This quotient is found in the body of the table under the value of the radius r required in the hook. When the nearest value to $\frac{P}{f}$ in the table has been located in the vertical column under the radius, follow the line horizontally to the left-hand column which gives the dimension d directly. All the other dimensions are proportioned from the dimension d, as shown in the engraving, Fig. 2, in the Supplement.

As an example, assume that a crane hook for a 50-ton crane is to be designed, that the radius r is required to be 3 inches, and that the allowable unit fiber stress is 20,000 pounds. Expressed in pounds, P = 100,000 pounds. This divided by 20,000 gives us the quotient 5, which is found in the table in the vertical column under 3 inch radius. It will be seen that the nearest value to 5 is 4.75, and following the horizontal line in which 4.75 is found, to the left-hand column for d, we find d = 7.5 inches. All the other dimensions can now be found by inserting this value of d in the formulas in Fig. 2 in the Supplement.

* * *

The movement for increased facilities for technical education is clearly making progress. Even Palestine is to have an institute of technology at Haifa, Palestine. Mr. Jacob H. Schiff of New York, has contributed $100,000 towards it.

AUTOGENOUS WELDING AS A MEANS OF REPAIRING CYLINDERS.*

HENRY CAVE.†

Breakages in automobile cylinders can be divided into three main classes which cover at least ninety per cent of the cases. The majority of these breakages can be satisfactorily repaired by means of the oxy-acetylene flame as carried out by the Autogenous Welding Equipment Co., Springfield, Mass., with their Davis-Bournonville apparatus, the cylinder being as good as new, and better in some cases. Autogenous welding, as the process is called, consists of fusing the metal around the break by means of an acetylene flame, the heat of which is concentrated to a very small area by being burned with pure oxygen in a torch giving a flame temperature of over six thousand degrees F. Additional metal is added where necessary from a rod of the same material, and the process is practically recasting the part locally.

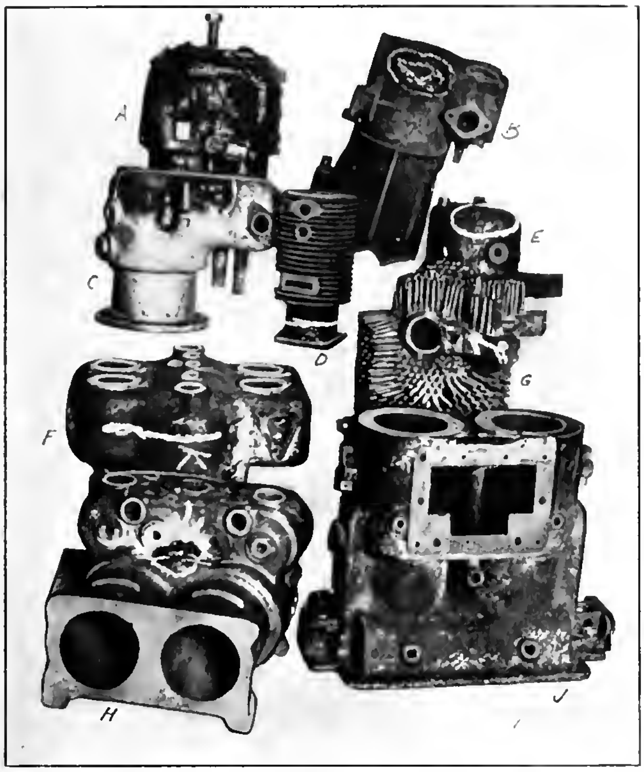

Fig. 1. Group of Broken Automobile Cylinders that were repaired by Autogenous Welding.

Autogenous welding is proving a great boon to those who are unfortunate enough to have their automobile cylinders broken, as they can be satisfactorily welded and in the majority of cases, with a little trimming off, the repairs will not show. This is a particularly valuable feature as some owners wish to sell their cars without the repairs being noticed. Cylinders with cracks are sometimes brazed, but owing to the necessity of heating the whole cylinder to a good red heat to even up the contraction strains, so as not to crack when cooling, the bore of the cylinder is generally warped, and the job requires a lot of finishing as the spelter and flux spread considerably and are hard to remove. Also, owing to the dirt and rust in the crack it is difficult to get the brazing below the surface; the high temperature necessary will sometimes crack the cylinder elsewhere.

Water Jackets Broken by Freezing.

The largest class of cylinder breakages—mainly due to carelessness or misfortune, probably in most cases the former—is caused by allowing the water jacket to freeze, resulting in the breaking of the water jacket wall. This cannot always be termed carelessness, as I have known an automobile to have all its water jackets cracked as early as the middle of October when the owner had no thought of such a thing being possible. I have also known of cars being "hung up" on the road in cold weather, the driver opening the drain cocks before he left to summon help and upon his return finding the water frozen with the usual result. This accident probably is due to too small drain cocks. Also, it has frequently happened that when shipping a car by rail in winter the drain cocks were opened, but due to some pocket in the water system (in some cases very small ones) which did not drain, the cylinders have become fit subjects for the autogenous welder.

Curiously enough the majority of cylinders cast from the same patterns will break in just the same place when frozen. In a number of cases the break causes a piece of the wall of the water jacket to be entirely detached, and the breaks occur so nearly alike, in similar cylinders, that it would be possible to take the detached piece from one and weld it into another, even the smaller irregularities coinciding.

When a break of this nature is autogenously welded, by means of the oxy-acetylene flame, the crack or edge of the broken part is prepared so as to leave a groove nearly through the metal. The whole part is then uniformly heated to about five hundred degrees F. This temperature is not high enough to warp the bore, as has been repeatedly proven by careful measurements before and after treatment. The sides of the groove are fused together and filled from a rod of cast iron. The resulting weld is very neat in appearance; it generally requires no finishing and is as strong as the original wall. As a very small number of heat units are absorbed by the part, owing to the intense heat of the flame fusing the metal before the heat has time to spread, there is seldom any trouble with cracks when the metal contracts in cooling.

Cylinders *A*, *F*, *H* and *J*, Fig. 1, were welded in this manner. The weld on *F* was along the chalk line, and was ground off so that all signs of it were effaced. A piece of the water jacket had been knocked out of cylinder *H* when the casting was being smoothed up ready for painting at the factory; the successful welding, however, saved the cylinder. A crack along the top corner of *J* is shown welded. *A* and *B*, Fig. 2, show common types of breakages which are being satisfactorily welded every day. The crack in *A* is seventeen inches in length. Both cylinders are grooved out ready for welding.

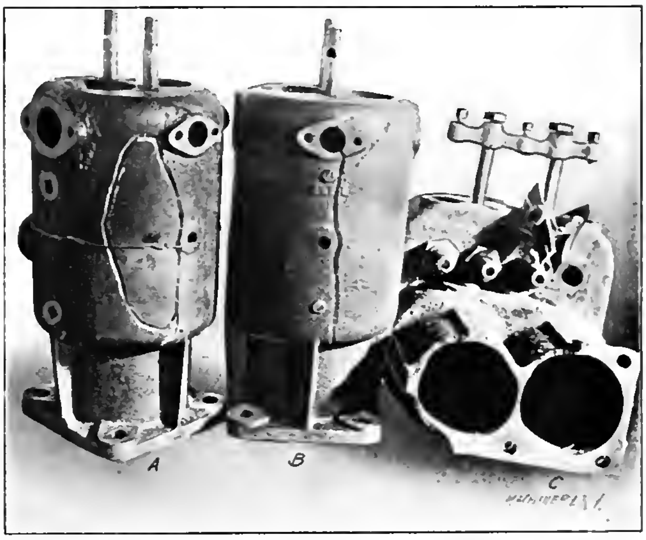

Fig. 2. Two Cylinders with Cracked Water Jackets prepared for Welding
Twin Cylinders with Broken Flanges to be Welded

Cylinder Wall Broken.

The next class of breakages, in order of frequency of occurrence, is that in which the wall of the cylinder, combustion or valve chamber, is broken or cracked. These breaks are, in most cases, due to freezing, but a certain number of them are due to the designer making a large flat surface without adequate ribbing to support the pressure of the explosion.

Another cause is the breakage of the connecting-rod, allowing the piston to strike the top of the cylinder. Serious damage from this cause occurs most frequently in two-cycle engines as the deflector on the piston readily punches a hole in the combustion chamber wall. Fig. 3 shows a cylinder

* For previous articles on oxy-acetylene flame autogenous welding see "The Application of Autogenous Welding to Automobile Repairs" by Henry Cave, December, 1908, and other articles there referred to.

† President of the Autogenous Welding Equipment Co., 92 Hayden Ave., Springfield, Mass.

h[illegible] and Fig. 4 shows the outside after welding. [illegible] break also often occurs due to foreign s[illegible] s the head of a broken valve getting between [illegible] the cylinder head.

[illegible] of breakages is the most difficult to repair, as [illegible] necessary in most cases to cut out a section of the [illegible] to be able to work on the inner wall, the only deviation occurring when the break happens to be opposite a large hand hole. This operation has a singular resemblance to the well-known trepanning operation performed upon the human skull.

It can be readily seen that it is practically impossible to make a repair when the break occurs between two cylinders or behind the valve chamber, as these parts cannot be reached with the small flame.

If the crack occurs in the bore it is necessary to carefully weld to within a sixteenth inch of the bore, or the finished surface will be spoiled; the crack left in this way is of small importance, as sufficient metal can be built on the outside so that there is no doubt about the strength. After welding the break the section of the water jacket which was removed is welded back in place.

As it often is impossible to determine the length or exact locality of the cracks before cutting away the jacket and is desirable to remove as small a section as possible, it often is found necessary to cut additional pieces out, thus necessitating welding a number of small pieces back in place when finishing the job. To restore these pieces sometimes is impracticable, and a sheet steel substitute must be hammered out and welded in place. With care this piece can be shaped so as to coincide with the piece removed, and cannot be detected when welded in place. A case of this kind is shown in *B*, Fig. 1. The part shown cut away was neatly replaced by sheet steel, as shown at *A*, Fig. 5.

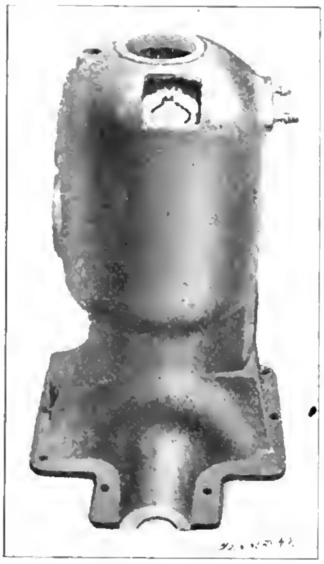

Fig. 3. Cylinder with Section of Water Jacket removed to repair Crack in Inner Wall

Fig. 4. Cylinder shown in Fig. 3, after Welding

The water in freezing will often crack both the water jacket and cylinder wall. The former being readily seen is generally thought to be the full extent of the damage, particularly as it is practically impossible to make a test until the crack is repaired. The work may then have to be cut out to find further defects. This was the case in the cylinder shown at *A*, Fig. 1, the right angle crack being first welded; the break extending from below the hole shown cut out across the other side was welded and the cover replaced. A similar break then being discovered in the other cylinder, the relief cock boss for both cylinders was entirely detached and welded back in place.

The cover plate on the cylinder shown in Fig. 5 was also broken in freezing, at the same time as the cylinder wall was broken, and is shown welded.

Fig. 6 shows a cylinder having a crack eight inches long, located at the corner of the combustion head, that was welded. The part cut out of the water jacket is also shown. It [illegible] noticed that this operation required cutting through a supporting lug. The water jacket part successfully welded back in place is shown at *C*, Fig. 1.

The cylinder shown at *E*, Fig. 1, had a hole to be welded to accomplish which it was thought necessary to remove the section shown chalked. A much larger section, however, had to be cut out so as to take care of a crack running down the side; the two pieces removed were welded together before they were replaced.

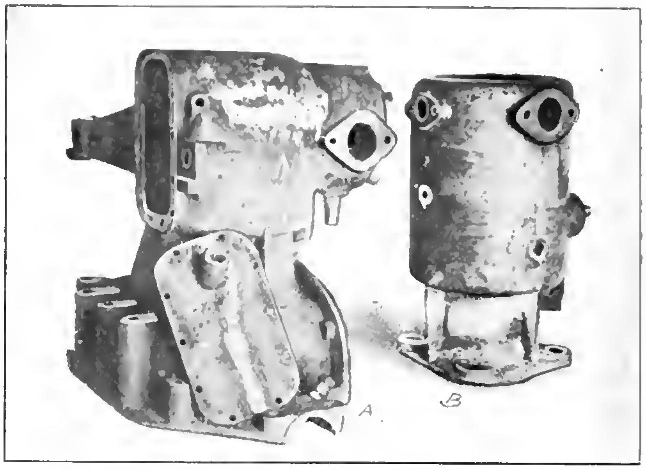

Fig. 5. Cylinder A, (Fig. 1, B) repaired by inserting a Steel Piece, bent to Shape, and autogenously welded in Place.

Broken Flanges.

The next order of breakages in point of number are those in which all, or a portion of the flange, which holds the cylinder to the crank case is broken away, due either to insufficient metal to withstand the strain or, to carelessness in assembling.

These breakages occur in two ways; the wall of the cylinder may be broken away or part of the flange may be cracked off. In the latter case it is an easy matter to make the repair, but when the break runs through into the bore of the cylinder considerable care is required. First it is necessary to consider whether it is desirable to weld in the bore which would then require machining or at any rate filing out, or only groove and weld from the outside to within a sixteenth inch of the bore, sufficient metal being added to the outside to insure strength. The latter method, of course, leaves the crack on the inside, which can, however, be smoothed down and is not objectionable for a repair job; not interfering with the satisfactory operation of the motor in any way.

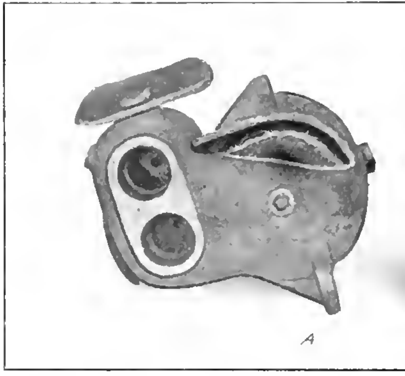

Fig. 6. Cylinder Cracked in Inner Wall, showing Large Section of Outer Wall removed to weld the Crack.

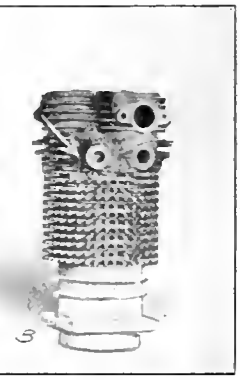

Fig. 7. Air-cooled Cylinder on which Boss for Ignition Plug was autogenously welded.

In addition to these three classes, there is a large variety of other breakages, no two of which are alike, that can be repaired successfully by the oxy-acetylene torch, such as broken inlet and exhaust flanges, holes knocked through the barrel of the cylinder by broken connecting-rods, welding of broken supporting brackets, as shown at *G*, Fig. 1, the bracket or lug shown having been entirely detached.

In addition to this, considerable welding can be carried out for the manufacturer, such as the welding on of additional bosses for dual ignition systems, as shown in Fig. 7, building up bosses that did not "fill" in castings, welding porous spots which show up after machining or adding metal anywhere it may be required.

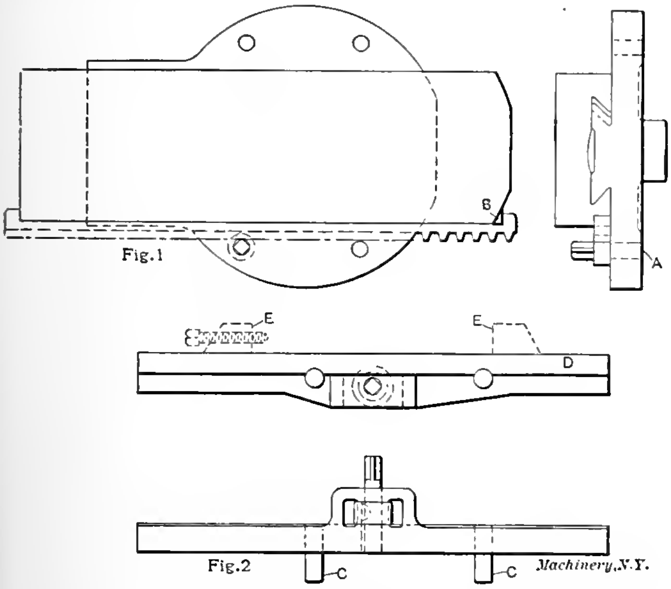
LABOR-SAVING DEVICES FOR SCRAPING OPERATIONS.*

ALFRED SPANGENBERG.†

Alfred Spangenberg.‡

There are a number of elements entering into the cost of scraping operations, other than that of scraping proper, which are always of sufficient importance to merit the closest consideration. In fact, very often it is the lack of attention to these other factors that accounts for much lost time. This is particularly the case in such laborious operations as "straightening out." This operation consists in moving the sliding machine member with the packing set up tightly, over the fixed member, in order to find the bearing on the packing, and finally to feel the "high spots." It is obvious that the packing must be adjusted to make the sliding member pull hard, otherwise it would be impossible to detect any variation in pressure due to inequalities in the machining.

Even on comparatively light work this pulling and pushing, if done directly by hand, involves more labor than is required in the actual operation of scraping. In work of this character, where brawn and muscle are prime requisites, we are dealing with the human elements which may cause a slowing up of production. The principal point to be observed is that a workman has a certain amount of physical endurance, and if the greater part of his energy is concentrated on the productive operation of scraping, a material increase in production will result; because of this fact, it becomes of extreme importance that means be provided for making the task of pulling easier.



Figs. 1 and 2. Device for Pulling Planer Slide back and forth, and Support for Rack and Pinion.

The classifications of work determining the selection of a proper type of pulling device are: (*a*) Planer slides, lathe rest slides and work of a similar character; these are usually pulled directly by hand. For this work a rack and pinion operated by a ratchet wrench is the most convenient type of pulling device; the tight and loose places in the work being easily detected. (*b*) Boring mill rams, shaper rams, milling machine tables and similar work, which is comparatively short and too heavy to be pulled by a ratchet wrench. The type of device suitable for this class of work is a rack and pinion operated by power. The pinion being driven through a frictional device, the slipping of the driven friction member indicates the "high spots" in the work. (*c*) Planer crossrails, lathe beds and work having large dimensions, and where the pull required is long. For this class of work the pulling device takes the form of a power-driven wire rope drum. A tension indicator interposed between the work and the wire rope indicates any variation in pulling force required to move the work.

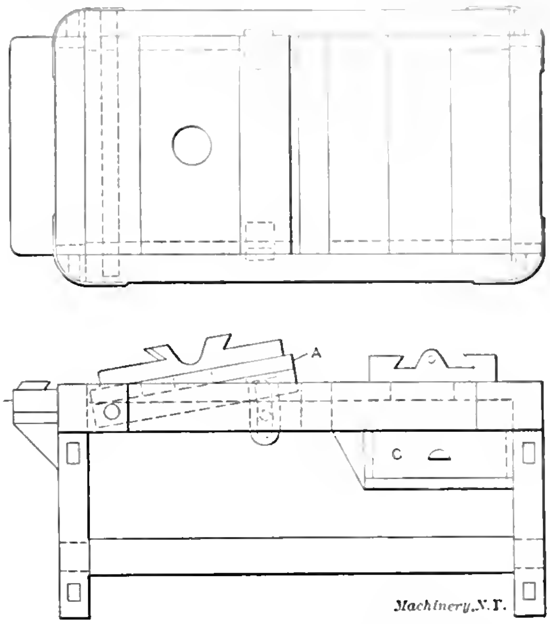


Fig. 3. Bench for Holding Slides and Swivels

Concrete examples of the conditions stated in class (*a*) are illustrated in Figs 1, 4. and 5. Fig. 1 shows the application to a planer slide and swivel, of a rack and pinion operated by a ratchet wrench. In this case, the clamping bolt hole *A* in the swivel is made use of as a bearing for the pinion. A lug is cast on the slide at *B* to provide a square seat for the projection on the rack. The rack is a loose fit endwise on the slide and is easily removed.

When the design of the swivel is such that the clamping bolt hole *A* is too near the slide to be used as a bearing for the pinion, the device shown in Fig. 2 is substituted. The pins *C* fit into the holes in the swivel and hold the device from moving. The surface *D* supports the rack and keeps it in place when the slide is in the extreme positions. The lugs *E*, indicated by the dotted lines, show how the device can be attached to a swivel in which the clamping bolt holes *A* (Fig. 1) are not available for supporting the device.

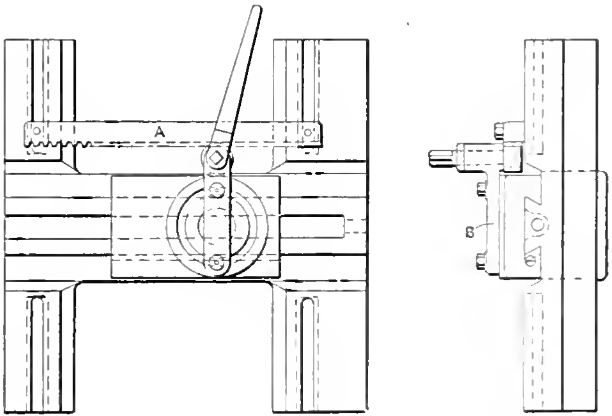

Fig. 4. Method of Attaching Rack and Pinion to a Lathe Rest.

The special bench represented in Fig. 3, while not strictly a pulling device, is shown because it is very useful for holding

† Address: 951 W. Fifth St., Plainfield, N. J.

‡ Alfred Spangenberg was born in Brooklyn, N. Y., in 1876, and received a high school education, after which he completed a correspondence course in mechanical engineering. He served a four years' apprenticeship with the Pond Machine Tool Co., three years of which were in the machine shop and one year in the drawing office. He has been employed by the Hercules Seamless Drawn Tube Co., Garwood, N. J.; National Meter Co., Brooklyn, N. Y.; and the Pond works of the Niles-Bement-Pond Co., Plainfield, N. J., where he is now employed as foreman of the turret lathe erecting department. Mr. Spangenberg has made a specialty of assembling work, and his article on the subject published in the February issue of MACHINERY illustrated a number of practical shop devices for scraping and fitting, which are of his own design.

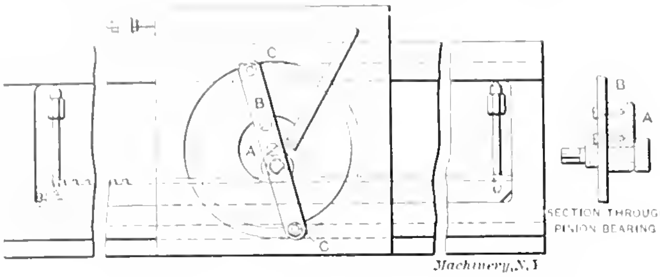

Fig. 5. Rack and Pinion for Pulling a Planer Slide

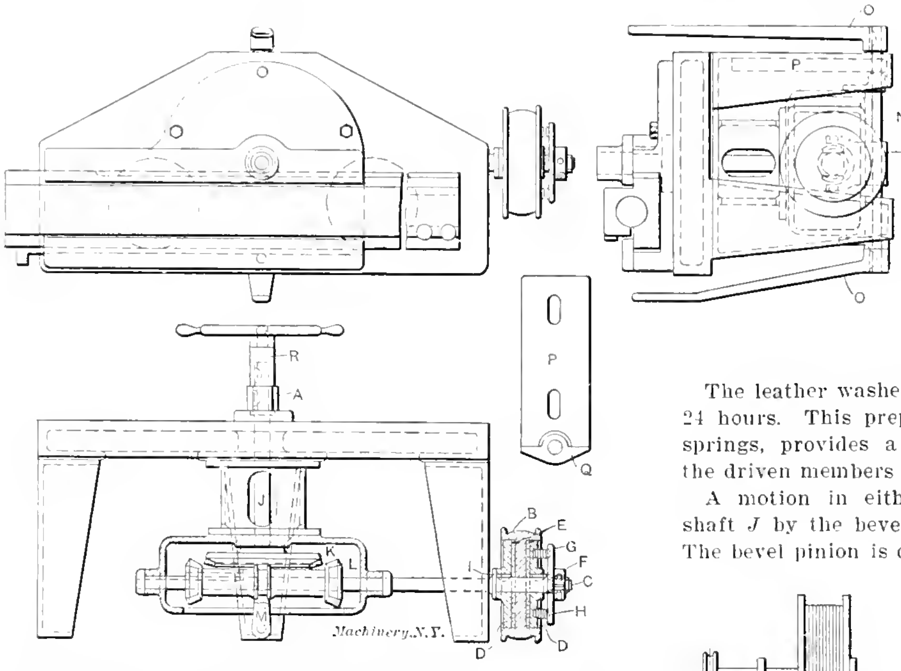

Fig. 6. Machine for Imparting Motion to Boring Mill Rams while Scraping.

slides and swivels and work of a similar character, during the operations of pulling and scraping. The top half of the bench shown tilted is for holding the swivel on an angle, the object being to easily keep the slide against the fitting angle of the swivel while finding the bearing before the packing is fitted. When the packing is being fitted, and during the operation of "straightening out," this swinging top *A* is kept level. The magnetic chuck *B* provides a very convenient means for holding the packing while it is being scraped. A drawer *C* is for keeping the scrapers, oil stone, etc. The bench is made of wood and iron and bound at the corners.

Fig. 4 clearly indicates the method of attaching a rack and pinion to a lathe rest and shoe. The rack *A* is bolted to the rest by means of the T-slots. The pinion bearing casting *B* extends across the top of the shoe and is clamped by two bolts in the circular T-slot. The rack is quickly made parallel with the ways of the rest by placing the shoe, with the pinion clamped to it, in one extreme position and clamping the adjacent end of the rack in proper mesh with the pinion; then repeating the operation with the shoe in the other extreme position.

The method of attaching a rack and pinion to a small planer cross-rail and saddle is shown in Fig. 5; it is practicable to apply this method for pulling the saddles of cross-rails up to sizes of 48 inches. Referring to the illustration, the rack rests on the rough inside surface of the cross-rail, and is held in position by the screw, studs and nuts as indicated. The adjustment of the pinion into proper mesh with the rack is accomplished by making the pinion bearing *A* in the form of an eccentric bushing fitting into the hole in the saddle. The eccentric bushing is clamped by the strap *B* and bolts *C*.

The principles embodied in the design of the pulling machine illustrated in Fig. 6 are adaptable to the work mentioned in class (*b*). This machine is made for pulling boring mill rams; the simplicity of the design is immediately apparent from a study of the three views shown in the sketch. The top and end views show a right-hand ram and swivel in position on the table of the machine. This table is supported on three legs to avoid any tendency to "wind," and the design is adapted to hold either right- or left-hand swivels.

The machine illustrated is belt-driven, although a motor drive could be easily substituted. The mechanism for driving the pinion *A*, which meshes with the teeth of the ram, is clearly shown in the side view. Referring to the sectional view of the friction pulley, the driving member is the flanged pulley casting *B*, having a solid web. This member is a running fit on the shaft *C* and friction disks *D*. The friction disks are the driven members, and are keyed to the shaft *C*. Between these disks and the pulley casting are two leather washers *E*. The amount of friction required is adjusted by means of the split nut *F*, which moves the spring disk member *G* (keyed to the shaft) and compresses the twelve springs *H*. This regulates the pressure on the friction disks, leather washers, and pulley; the thrust is taken by the nut *F* and collar *I* on the shaft.

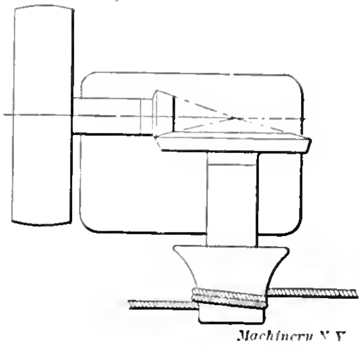

Fig. 7. Winch Superseded by Pulling Machines in Figs. 6 and 8.

The leather washers are prepared by being soaked in oil for 24 hours. This preparation, together with the action of the springs, provides a very uniform and positive slippage of the driven members when the load is excessive.

A motion in either direction is imparted to the pinion shaft *J* by the bevel gear *K* and the double bevel pinion *L*. The bevel pinion is operated by the yoke *M*, shaft *N* and operating levers *O*. The detail sketch of the weight *P* shows its action on the double rocker arm *Q*, which is pinned to the lever shaft *N*. It is obvious that this device keeps the double bevel pinion in a central position when the hand levers are not being operated. The hand-wheel sleeve *R* is a sliding fit on the pinion shaft and its key.

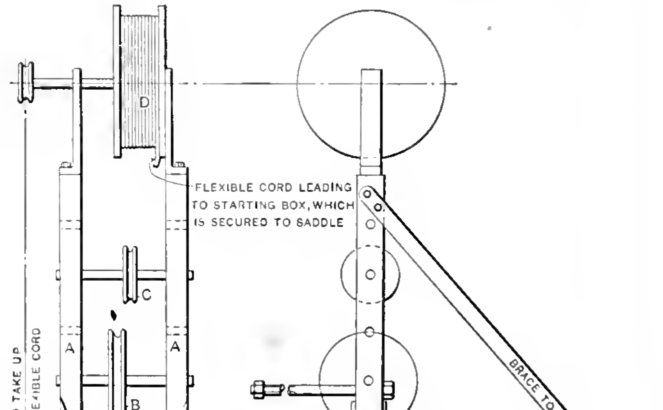

Fig. 8. Pulling Device for Cross-rail Saddles.

In operation, the swivel is centered by its hole fitting the hub cast on the table, and clamped by the bolts as indicated. When the packing and gibs are being fitted, the hand-wheel is left off the machine, and the ram only moved back and forth for a short distance near the center of its travel. After the operation of "straightening out" the ram is completed, the hand-wheel is used to pull the ram by hand (once or twice) to make sure the ram pulls evenly from end to end of its travel. The friction is adjusted so it will just pull the ram when the packing and gibs are set to a rather tight running fit. The "high spots" in the ram are indicated by the friction slipping. The machine is geared to move the ram at about the rate of 15 feet per minute. A modification of this machine is adaptable for pulling any work of comparatively short dimensions, by coupling the sliding work member to a rack supported in suitable guides and driven by a mechanism similar to that shown in Fig. 6.

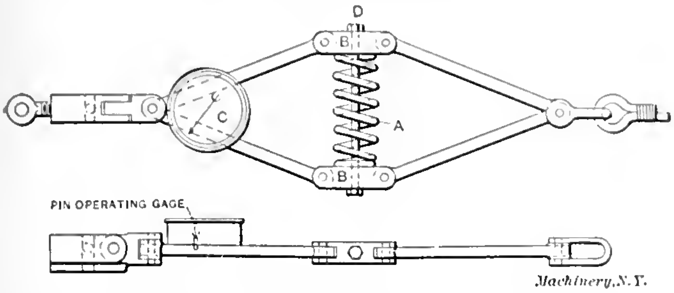

Fig. 9. Indicating Mechanism for Pulling Device.

The type of pulling machine illustrated in Fig. 8 is particularly well adapted to the work mentioned in class (*c*). The general features of the machine comprise a heavy cast-iron base carrying the motor, wire rope drum and driving mechanism. Bolted to the base are two upright steel bars *A*, which are made rigid by the braces as indicated. These bars support the wire rope idler sheaves *B* and *C* and the electric conductor cord drum *D*. The holes in the bars *A* are for carrying the wire rope sheaves at a height to suit the work, it being desirable to have the rope attached to the gage, measuring the pull, as nearly level as possible.

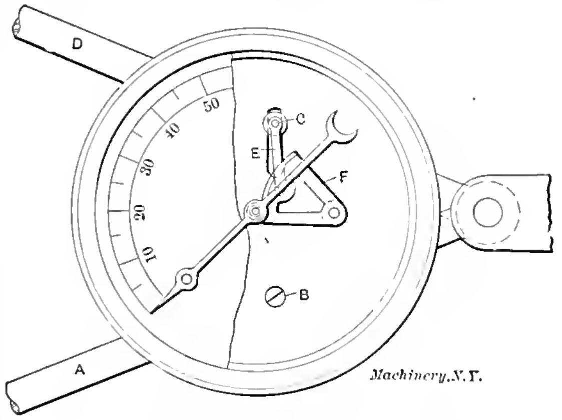

Fig. 10. Detail of Gage shown in Fig. 9.

It will be seen that the machine is self-contained as far as the application of power is concerned. The spur pinion on the motor shaft meshes with the gear on the worm shaft. Between the bearings for this shaft is the worm; this worm drives a worm gear on a cross-shaft. On the cross-shaft are also a sliding clutch and wire rope drum. This drum has clutch teeth cast on one end and is driven by the sliding clutch. The lever *E* is for operating the sliding clutch. The advantage of this clutch is to facilitate the setting of a tension indicator and wire rope onto the work.

The tension indicator illustrated in Fig. 9 and used in connection with the pulling machine just described is essentially a double toggle joint. A force pulling on the wire rope, with the indicator attached to the work, compresses the spring *A* between the two short links *B*. The amount of compression is indicated by the index hand on the dial of the gage *C*. The function of the stud *D* is to limit the outward travel of the lever arms and thus reduce their movement by keeping the spring under a slight compression when there is no load, *i. e.*, there is no movement of the lever arms until the pull is sufficient to move the work. This avoids the tendency of the gage to jump or vibrate.

The construction of the gage is clearly indicated in Fig 10. The body of the gage is pivoted to the lever arm *A* by the screw *B*. A stud *C* screwed into the lever arm *D* passes through a slot in the body of the gage. A shoulder on this stud and the screw *B* keep the gage in place. The link *E* connects the stud *C* with the sector *F*. The teeth on this sector mesh with the pinion on the index hand shaft. There is no stop pin at 0 for the index hand, the return to 0 being controlled by the stud *D*, Fig. 9.

Referring now to Fig. 9, it is evident that since the relative movement of any two levers of the toggle joint is not in direct proportion to the amount of tension applied to the device, compensation should be made in the dial graduations. This refinement is not necessary, however, as the requirements simply are that the gage indicate *variations* in tension and not the *amount* of variation measured in any definite quantity.

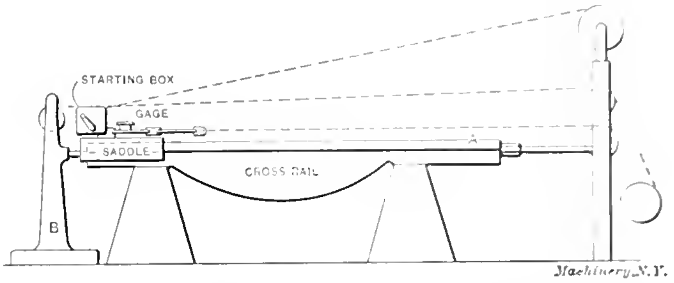

Fig. 11. Pulling Machine, Fig. 8, and Tension Indicator, Fig. 9, in Position for Moving a Cross-rail Saddle along its Ways

Fig. 11 shows the pulling machine and tension indicator in position for pulling a planer cross-rail saddle. The cross-rail is shown lying face up on suitable iron parallels. This is the position for fitting the packings and "straightening out" the angle. When the surface *A* is being scraped, the cross-rail is turned right-side up. In this case the idler sheave shafts are moved up in their supports so as to keep the wire ropes level. The pulling machine is not fastened to the floor; its weight and the braces keep it in position. The same conditions exist in the case of the idler pulley stand *B*.

The wire rope for pulling the saddle back to the starting point is fastened to the eyebolt shown in Fig. 9. The swivel block of the indicator is bolted to the T-slot in the saddle. When the saddle is pulled backwards the packing is left loose.

The starting box and reversing switch for the motor are on a board which is fastened to the saddle. The weight and cord attached to the sheave on the drum shaft, Fig. 8, take up the slack in the electric cable as the saddle moves forward. The rate of traverse is about 10 feet per minute.

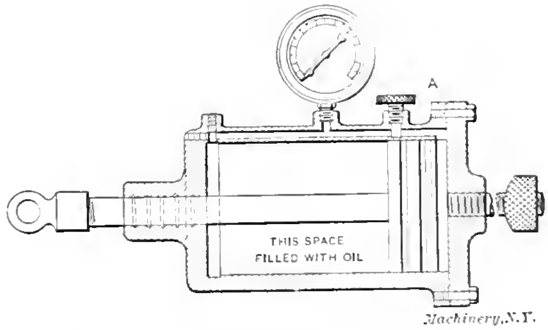

Fig. 12. Tension Indicator which proved a Failure.

In operation, the saddle is moved for a short distance near the center of the cross-rail to fit the packings. During the operation of "straightening out" the cross-rail, the saddle is brought to the position shown in the sketch, the packing is adjusted and the operator starts the motor. By watching the gage, the operator marks on the cross-rail with a piece of chalk the tight places. When the surfaces being tested are parallel with those that have previously been surfaced with a straight-edge, the index hand on the gage will remain fixed from end to end of the cross-rail. The packings are, of course, tightened one at a time.

It will be observed that the gage shown in detail in Fig. 10 consists of parts from a standard pressure gage. The reason for using this was a special one in this case.

When the pulling machine shown in Fig. 7 was designed by the writer a hydraulic tension indicator, illustrated in Fig. 12, was made. The general principles of this indicator are immediately apparent from a study of the line engraving.

Although the piston was grooved, and the cylinder and piston ground to insure their being a good fit, trouble was experienced from the oil leaking past the piston. Provision was made for returning the oil to the front of the piston by opening the valve *A* and pushing the piston-rod back. The principal cause of its failure, however, was the fact that the gage was too sluggish in its action. The sliding members to which the indicator was attached, had to travel quite some distance before the gage indicated the actual tension.

The indicator above referred to was then designed by the writer, using parts from the pressure gage. This type proved to be very simple and efficient.

The engraving, Fig. 7, represents a power-driven winch that was superseded by the pulling machine described in this article. The advantages possessed by the latter type are at once apparent; they are time and labor savers. The principal point to be gained by their employment, however, is the fact that far more accurate results are obtained.

BROACHING AUTOMOBILE PARTS.

ETHAN VIALL.*

There is a decided prejudice in some shops against the broaching of keyways, but where the broaches are properly made, the quickness, ease, and accuracy with which keyways may be cut in almost any metal, is astonishing to those accustomed only to the work of the ordinary keyseating machine. The principal difficulties encountered by those who have only experimented a little with broaches, have arisen from the fact that, as a rule, too few teeth have been cut in them, thus compelling six or seven teeth to do the work at one pass, that would require twenty-five or thirty strokes of the cutter on the keyseating machine. Where too few cutting teeth are used there is not only the strain of the heavy bite, but the cut metal fills up between the teeth and either scores the slot or breaks the broach. In addition to an ample number of well-spaced cutting teeth, a number of full-sized teeth should be left on the broach to insure accuracy, and long life to the tool, for where only one or two sizing teeth are used, they soon wear away under the excessive task and the resulting keyway is undersize and causes trouble. Not only must good judgment be used in the making of keyway broaches, but in all of the other forms as well. Of course there are some classes of broaching work where it is only possible to use a few teeth in the broach, but as a general rule plenty of cutting and sizing teeth, as well as ample chip space, should be put in if the nature of the work and the stroke of the machine will permit.

The hardening of the broaches also calls for the exercise of a great deal of judgment and "horse sense," for with these as with other cutting tools, a careless or ignorant hardener can spoil the work of the most competent designer or painstaking toolmaker.

In many cases the character of the work necessitates the broach being pushed through the metal, but for regular keyways, and wherever possible on other work, the broaching should be done with a drawing cut, the broach being supported by a guide or bushing. Draw-cut broaches that are used to cut double keyways, should have a guiding rib extending their entire length, which accurately fits the slot in the guide bushing. This form of flat broach, stiffened and guided by a rib and running through a slotted bushing, is preferable in many ways to the round-bodied self-supporting form, where close accurate work is desired.

In the construction of automobiles, where the Woodruff system of keying is almost universal, the broaching process is particularly adapted to the work, and at the factory of the E. R. Thomas Motor Co., Buffalo, N. Y., not only are all keyways broached that are usually cut on the keyseater, but this method is used for a number of other classes of work that are generally done in a more round-about way. Much of the broaching work is in direct charge of C. B. Buxton, the assistant superintendent, and his practical experience and ideas, together with those of the tool-designer, Lucien Haas, have done much to simplify the difficulties encountered from time to time, thus placing their broaching practice ahead of a majority of the other shops in this respect.

A good idea of the class and variety of the broaching work done at the Thomas plant may be obtained from Fig. 1, while a few of the broaches are shown in Fig. 2. The broaches *A* and *D* are for cutting double keyways, and the guiding rib is very plainly shown; *C* is a broach for cutting a single keyway, and works in a slotted bushing; *B* is a self-guiding broach for cutting the spring notches in the segments of what is known as the Westinghouse piston ring. All of the larger broaches are of the draw-cut type, while the small ones are pushed through the metal. It will be noted by carefully examining the broaches shown, that the notches between the teeth are not sharp at the bottom, thus lessening the tendency to crack at these places.

The draw-cut work is done on the type of machine shown in the illustration, Fig. 3, where the method of holding the work is well illustrated. The piece being broached has a taper hole, and it is set in the jig at an angle in order to make the keyway parallel with the side of the hole. As the small end of a draw-cut broach must be thrust through the hole in the work and then fastened to the draw-head of the machine, some quick method of locking the broach to the draw-head must be used. For the broach shown at *B*, Fig. 2, a socket and pin are used on the draw-head, but for the broaches shown at *A*, *C* and *D*, a lock shown at *E*, Fig. 4, is used. This lock consists of two parts as shown, which are placed together with the broach and the grooved end of the draw-head between them. The collar *F*, which hangs loosely on the spindle, is then slipped over the parts *E*, thus locking them securely in place, yet allowing a certain amount of floating action. At *G* is shown another style of draw-head lock. The broach end is round and notched on each side, while the shape of the slot in the lock-slide is seen at a glance. The slide is lowered until the end of the broach can be slipped through the round hole *J* at the bottom of the slot, and the broach is then pushed in until the slide drops down into the notches locking the broach to the draw-head. At *H* is shown a guide-bushing for a double keyway broach, while at *I* is a jig for holding small cams while broaching out the keyway, the end of the guide-bushing being shown in the hole.

A turret arrangement for use in broaching to a shoulder is shown in Fig. 5. This device is extremely useful and efficient for doing this class of work. The broaching tools in the turret are not indexed in any way, but are swung around by hand and the pilot inserted in the hole in the fitting which is firmly held in a jig as shown.

HINT FOR LEARNERS OF LETTERING.

An approved method of learning to letter drawings neatly is somewhat like that of learning to walk—a child creeps before it stands, and the learner of lettering soon finds out that he can imitate the approved free-hand style commonly used for legends on drawings much easier if he makes a broad flat letter in the beginning, thus:

When learning to letter make the letters
broad and flat, thus:

This style of lettering represents the creeping period, but after much practice the learner is able to give his letters more height and less base until finally his lettering looks something like this:

As proficiency is acquired make the letters narrower, space
closer and give more height.

Young draftsmen who are troubled by inability to letter neatly and rapidly may find a valuable hint in the above.

JIGS AND FIXTURES—13.

PLANING AND MILLING FIXTURES.

EINAR MORIN *

Fixtures for planing and milling are as essential for interchangeable manufacturing as are drilling and boring jigs. Fixtures of this kind serve primarily the purpose of locating and holding the work, but they are often provided with setting pieces or templets which are made either in one part with the fixture or separate; the cutting tools are set to these setting pieces so that the work is always machined in a cerain relation to the locating means on the fixture itself.

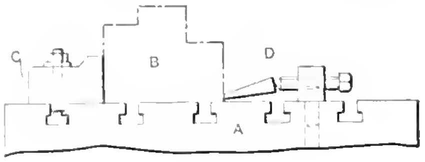

Fig.167

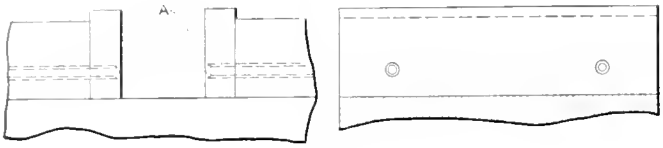

Fig.168

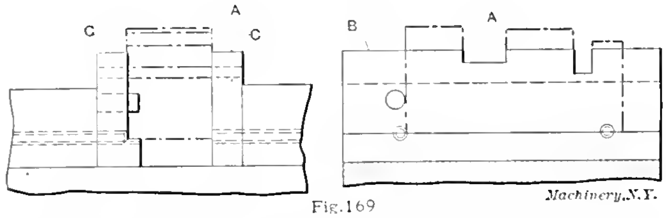

Fig.169

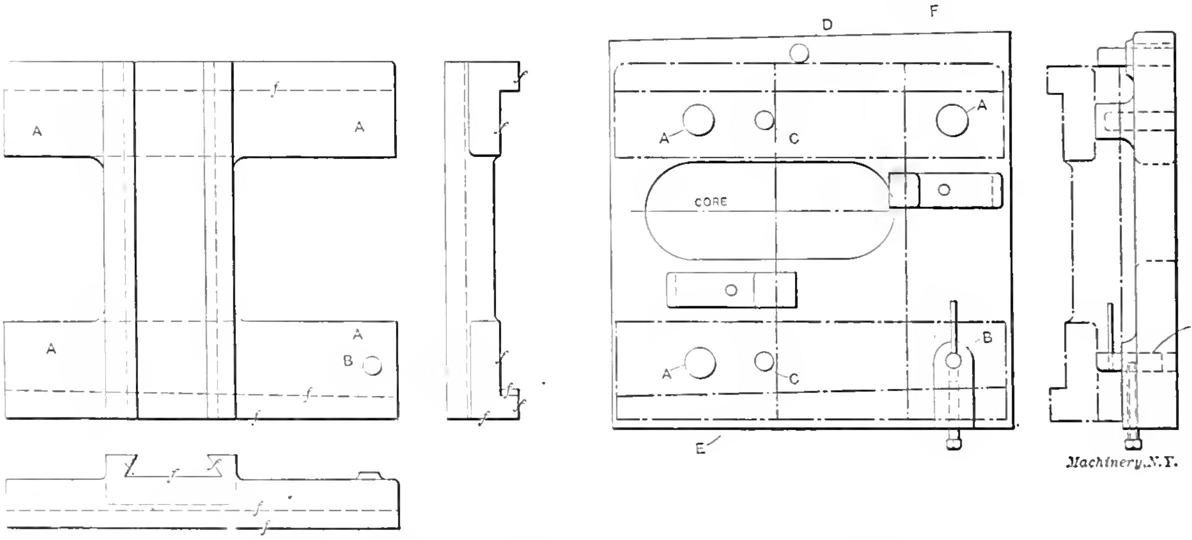
Fig 167 Principles of Fixtures exhibited by Common Method of Clamping Work on the Planer Fig 168. The Common Milling Machine Vise, an Example of Adjustable Fixture of Wide Range. Fig. 169. Vise with False Jaws shaped to the Form of the Work by the Cutting Tools Themselves.

When more than one milling operation is to be performed on the same piece, it is often possible to use the same fixture for the various operations, but it may be, in some cases, of advantage to make up a fixture for each different operation. The designer must in this case be guided by the number of pieces that are to be machined, and the advantages as regards rapidity of handling and operation that may be gained by having special fixtures for every operation, even though the operations may be such as to permit the same fixture to be used, with or without slight changes.



Figs. 170 and 171 Lathe Carriage and Fixture for Rough Planing Ways.

The strength of fixtures should be governed by the kind of operation to be carried out on the work while in the fixture, whether planing, milling, slotting, etc., and how much stock is to be removed. A milling fixture, as a rule, must be made stronger than a planing fixture, because a milling cutter, as a rule, takes a heavier cut than a planing tool.

The principles which have been previously explained in this series for drill jigs govern the locating means of milling fixtures, and the clamping devices of the same general type as described and illustrated in the July and August, 1908, issues of MACHINERY, are used, except that they are usually made heavier than when used for drill jigs and planing fixtures. On account of the irregular form of the work and the necessity for clearing the cutting tools, the clamps of milling and planing fixtures must often have irregular shapes.

An important factor, on which too much stress cannot be placed, is the necessity of having sufficient clearance for the cutting tools so that they do not interfere with some part of the fixture and clamping devices, and also that the fixtures, when located on the platen or machine table do not interfere with any part of the machine, when the table is fed one way or another. As a rule, milling and planing fixtures are provided with a tongue or key in the base, for locating them on the machine table. Suitable lugs should also be provided for clamping the fixture to the platen.

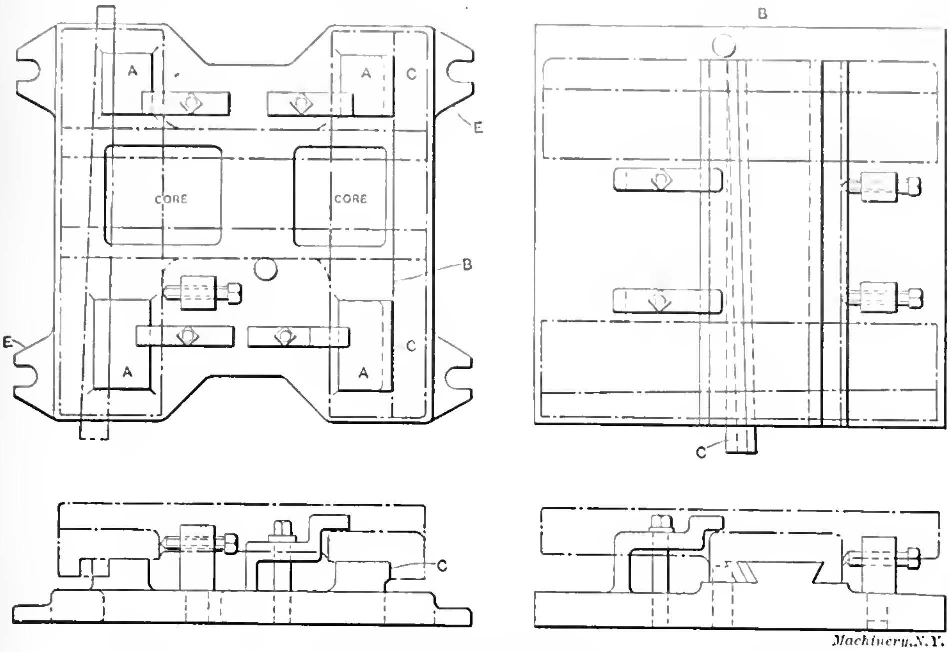
One of the very simplest types of fixture is illustrated in Fig. 167; work being planed is very commonly located and held by the means indicated, and for taking light cuts in the milling machine such an appliance may also be used. In this case, the planer platen *A* forms part of the fixture, and the work *B*, located on the platen, is held up against the bar *C*, which is held down by bolts, and located by a tongue as shown. The lugs and lug-screws shown with the spurs *D* hold the work up against the bar, and press it flat against the table. Instead of using the loose spurs *D* between the screws and the work, it is sometimes possible to let the screws bear directly on the work, in which case the screws should pass through the lugs at an angle with the top of the table, as shown in Fig. 175. The arrangement in Fig. 167 may or may not properly be considered a fixture, but it illustrates the principles of a fixture, as it locates and clamps the work in the simplest manner.

The most commonly used fixture for planing, shaping and milling is the vise. Standard vises are indispensable in planer or milling machine work, and by slight changes they can be used for a large variety of smaller pieces. In Fig. 168 are shown the regular vise jaws *A* of a standard vise. These jaws are often replaced by false jaws, which may be fitted with locating pins and seats, and held to the vise the same as the regular jaws. They are usually left soft, and often the milling cutter is permitted to cut out the jaw to the same shape as required for the work, as shown in Fig. 169. Vises with false vise jaws are especially adapted for milling operations, but vises are not usually employed for long work, special fixtures then being commonly made. While it is difficult to lay down any specific principles for the designing of milling and planing fixtures, it may be said that for most kinds of plain work, finished in the planer, the fixture shown in Fig. 167 is quite satisfactory. When pieces of a more complicated nature are to be machined, particularly in the milling machine, more complicated fixtures will be required.

---

* Address: Borlänge, Sweden.

Assume that a set of planing fixtures for the piece shown in Fig. 170 is required. The work is a slide or carriage for a lathe. The finishing marks given on a number of the surfaces indicate where the work is to be finished. The piece comes rough from the foundry. In the first place, it must be considered which sides to locate from, and how to locate and hold the work without springing it, and in what order the operations should be performed to best advantage. Fig. 171 shows a fixture for roughing out the ways on the bottom. The slide is located on three fixed locating points *A* and the sliding point *B*. This latter is adjustable in order to enable cutting the metal in the slide as nearly as possible to uniform thickness. Sometimes, if the parts *A*, Fig. 170, bevel towards the ends, lugs *B* may be added; these can then be finished and used for locating purposes. The carriage, as shown in Fig. 171, is further located against the pins *C* in order to insure that the cross slide of the carriage will be square with the bottom ways. The slide is brought up sidewise against the pin *D*, and then clamped down in convenient places, the clamps being placed as near the bearing points as possible to avoid springing. The reason for not having the locating point *D* on the opposite side, is that this side must be finished at the same setting; this side, being the front side of the carriage, is finished for receiving an apron.



Figs. 172 and 173. Fixtures for Planing the Dove-tail Slide and for Finish Planing the Ways of Carriage in Fig. 170.

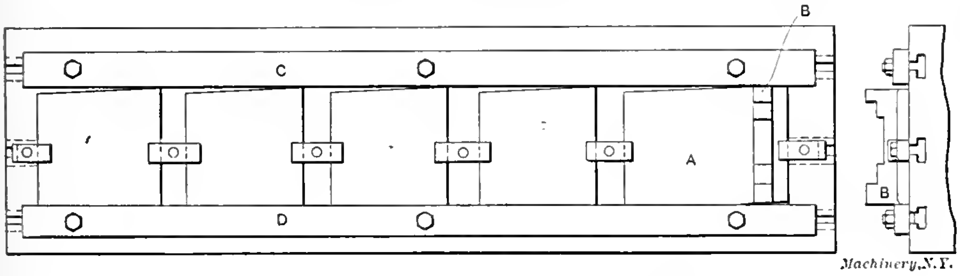


Fig. 174. "String" of Fixtures on the Platen of a Planer.

The sides *E* and *F* of the fixture may be finished in a certain relation to the locating points and each other, and the side *E* be made perfectly square with the locating points so that when it is brought up against a parallel on the machine table, the ways of the machined piece will be square with the ends. The side *F* may be finished on the same taper as required in one way of the work for a taper gib.

The fixture for the next operation is shown in Fig. 172. This fixture is made to receive the carriage and locates it by the now rough-finished ways; in this fixture the cross-slide dove-tail in the work is planed. The slide rests on four finished pads *A*, and the straight side *B* of the ways in the slide is brought up against the finished surfaces *C*. If no other part is available for clamping the fixture on the machine table, lugs *E* are added. If there are no tapering surfaces, the fixture can be located on the machine table by a tongue, as already mentioned, or by placing a finished side against a parallel. The slide or dove-tail is now roughed out and it is usually sufficiently accurate practice to finish it in the same setting, especially as slides must anyway be scraped and fitted to suit the machine on which they are to be used.

The next operation would be performed in the fixture illustrated in Fig. 173. The carriage is here located by the dove-tail and by the pin *B*, and held by a gib *C*, or by straps and screws, as shown. It will be noticed that with the given design, the straps and screws must be removed each time a new piece is inserted, which is an undesirable feature of the fixture. If parts *A* in Fig. 170 project out too far, so that a light finishing cut would cause springing, they are supported by sliding points or other adjustable locating means.

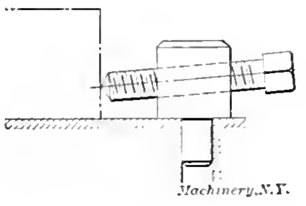

Fig. 175. Clamping Work by Means of Pointed Screw.

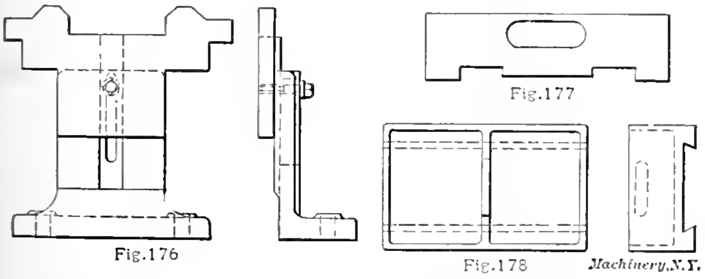
If the dove-tail in the slide had simply been rough-finished in the fixture, Fig. 172, the finishing operation of the bottom ways could have been done as just described in the fixture in Fig. 173, and then, after having finished the bottom ways in this fixture, the work could again have been located in the fixture, Fig. 172, and the dove-tail finished; this procedure may insure more accurate work in some cases.



Figs. 176 to 178. Gages for Setting Tools and Testing Work.

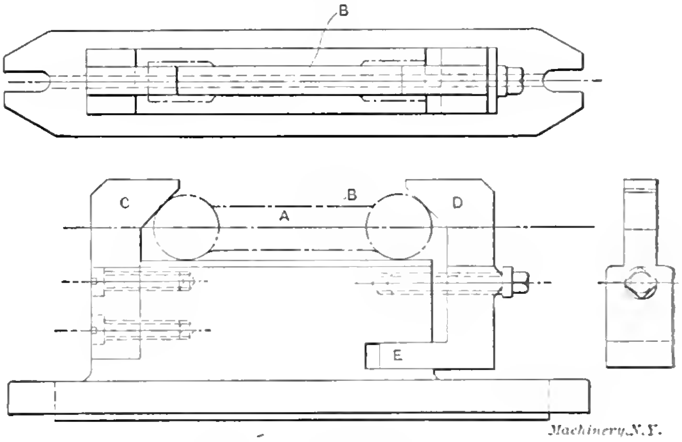


Fig. 179. A Typical Milling Fixture.

In the case just described, the work requires three different fixtures, to be completed. How many fixtures to use in each

case is entirely dependent upon the nature of the work. When there is a large amount of work of the same kind to be done, several fixtures of the same type are made up for the same piece, and when in use these fixtures are placed in a "string" on the table of the machine, as shown in Fig. 174. Each strap holds down two of the jigs, one on each side of the bolt through the strap. The first one of the fixtures, *A*, is provided with a templet *B*, to which the tool may be set. The fixtures are located against the bars *C* and *D*, alternatingly, depending upon whether the straight or tapered side of the slide planed in these fixtures is being finished.

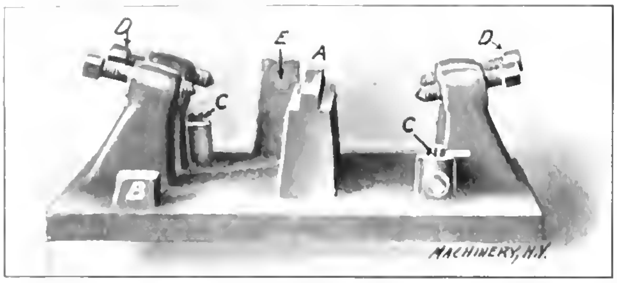

Fig. 180. Simple Type of Milling Fixture.

Templets are often made up separately and are used to determine the machining of both larger and smaller work. A templet may even be made adjustable, as shown in Fig. 176. This templet may be fastened to the machine table either in front or behind the work and the tool set to it, and is used when planing machine beds. Other templets or gages are made for testing the planing. They may not properly be considered as parts of the fixtures, but are usually designed and made at the same time as the fixtures are completed. These gages are made from sheet iron, and the profile or cross-section of the work to be planed or milled is cut into the templet, as shown in Fig. 177. Other testing pieces may be made up more elaborately, as shown in Fig. 178. These latter are also used for testing when scraping and fitting the work. One templet may be made for rough planing or milling and one for the finishing cut.

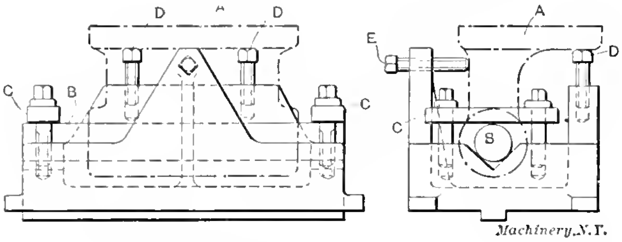

Fig. 181. Milling Fixture in which Work is Located from a Previously Bored Hole.

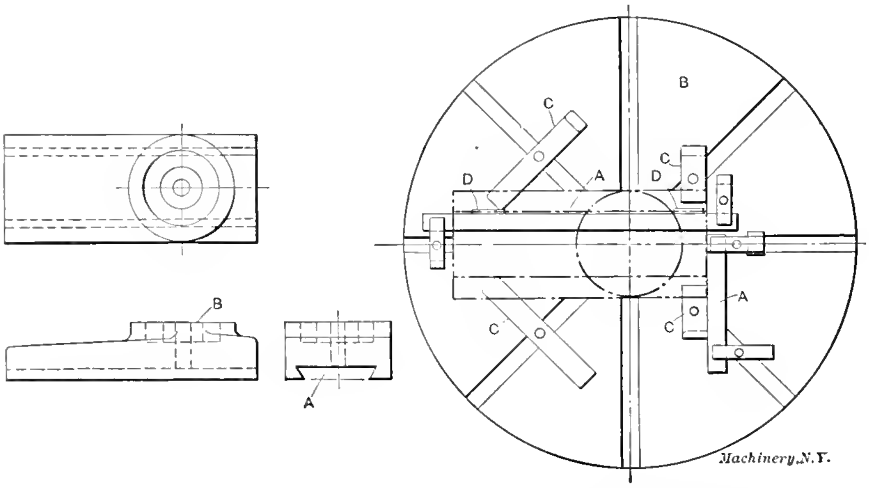

Figs. 182 and 183. Work to be Recessed and Faced and Method of Doing it in a Lathe.

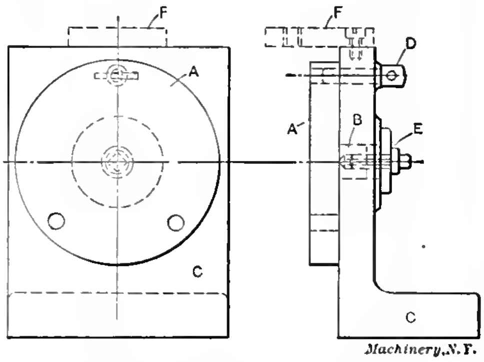

Fig. 184. Simple Type of Indexing Fixture.

A milling fixture of a type commonly used is illustrated in Fig. 179. The work *A* is supposed to be milled on both sides simultaneously. It is located on the fixture base *B*, and is held up against the half V-shaped piece *C*, which is stationary and held to the base by screws; the clamping is done by a clamp *D* which is guided at *F* as indicated, so that it has a tendency to hold the work down well. Both the clamp and the corresponding piece *C* are thinner than the work, so as to allow the straddle milling cutters to pass over the fixture without interference.

In Fig. 180 is illustrated a simple fixture which may be used for both milling and planing. Two pieces are machined at the same setting in this fixture, and are located against the finished seats *A* and *B*, which latter acts both as a seat and as a stop. Another seat like *B* on the opposite side is not visible in the illustration. As the work to be done is of a rough character, sliding points provided at *C* give an adjustable support. The work is clamped by the pointed screws *D*. The tool is set by the lug *E*, which is cast solid with the fixture and which has a top finished to the required height.

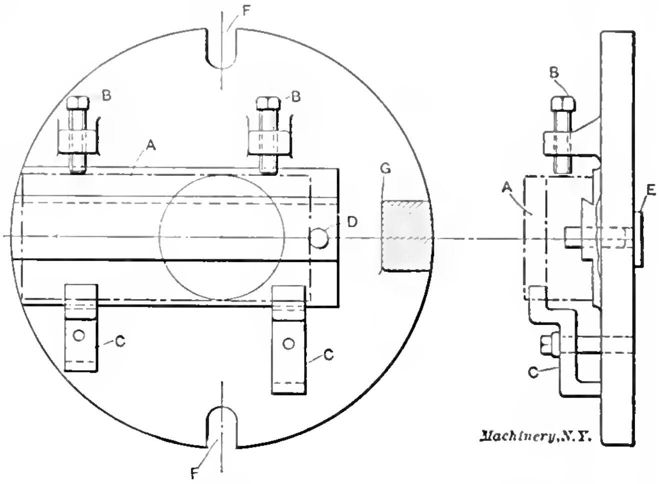

Fig. 185. Fixture for Recessing Work shown in Fig. 182.

It is often advantageous to perform milling operations after the boring and drilling has been done on the work, and then some finished hole may be used for locating the work. An example of this is shown in Fig. 181 where the work *A* is located by an arbor *B* passing through the finish-bored hole in the work, and resting on two V-blocks planed out in the fixture as shown. Two straps *C* hold the arbor down in the V-blocks. The work is further located against the screws *D*, which are adjustable so that the work may be held level. The clamping screw *E* holds the work against the screws *D*.

It is sometimes advantageous to make fixtures for holding work in the lathe. Suppose that a piece to be finished has the appearance shown in Fig. 182. The dove-tail *A* is finished, and the circular seat *B* is to be turned afterwards so that the center of the seat will come in a certain relation to the dove-tail and a certain distance from the end. This operation can be carried out as shown in Fig. 183, by placing parallels *A* on the face-plate *B* of the lathe. These parallels will serve as locating means, and straps *C* hold down the work. If it is required that the seat be in exact relation to the dove-tail, two rollers *D* may be used onto which the slide is hooked; the angle of the dove-tail and the diameter of the rollers are calculated so that the work can be very carefully located.

The work may be turned out properly by this means by a careful man, but there are always chances of moving the parallels and it is a slow operation. If a simple fixture like

the one illustrated in Fig. 185 is used, an apprentice can do the work correctly, provided he knows how to run a lathe. The work *A* is located by a dove-tail in a similar manner as it later on will be located on the machine on which it is to be used. It is held against the dove-tail in the fixture by screws *B* and clamped down on its seat by straps *C*. The pin *D* locates the work in the other direction, and the fixture itself is located on the face-plate by the boss *E*; as this boss has a perfect fit in a recess turned out in the face-plate, it must, by necessity, run true. Slots may be provided for locating the fixture on the face-plate and driving keys inserted. A sufficiently large lug *G* may be provided for counter-balancing.

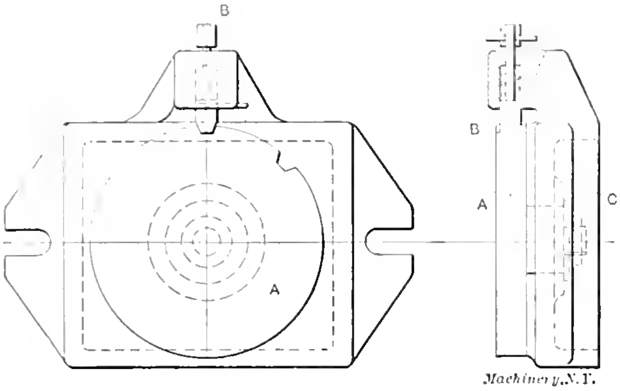

Fig. 186. Another Type of Indexing Fixture.

It is always of advantage to try to locate work in fixtures in the same manner as it is located on the machine where it is to be used.

Indexing Fixtures.

A number of fixtures for performing various operations are fitted with indexing devices, so that accurate machining at predetermined places in the work may be carried out in the shortest possible time. A simple indexing fixture is shown in Fig. 184. The work is mounted on a disk *A*, which turns in the bearing hole *B* bored out in the knee or angle iron *C*, which is located and fastened on the machine table. The disk *A* is indexed, and held in the right position by a pin *D*, which fits into a finished hole in the angle iron and also into one of the holes in the disk. The disk *A* is clamped against the knee *C* by a screw and washer *E* while taking the cut. When the main parts of this fixture are made of cast iron it is sometimes the practice to put lining bushings of tool steel in the indexing holes to prevent them from being worn out too rapidly by the continuous removal and insertion of plug *D*. This is a very simple indexing fixture, but a great deal of work can be finished with no more elaborate arrangements. By adding a plate *F*, screwed to the top of the knee, and fitted with a drill bushing as indicated, drilling operations may be performed in the same device.

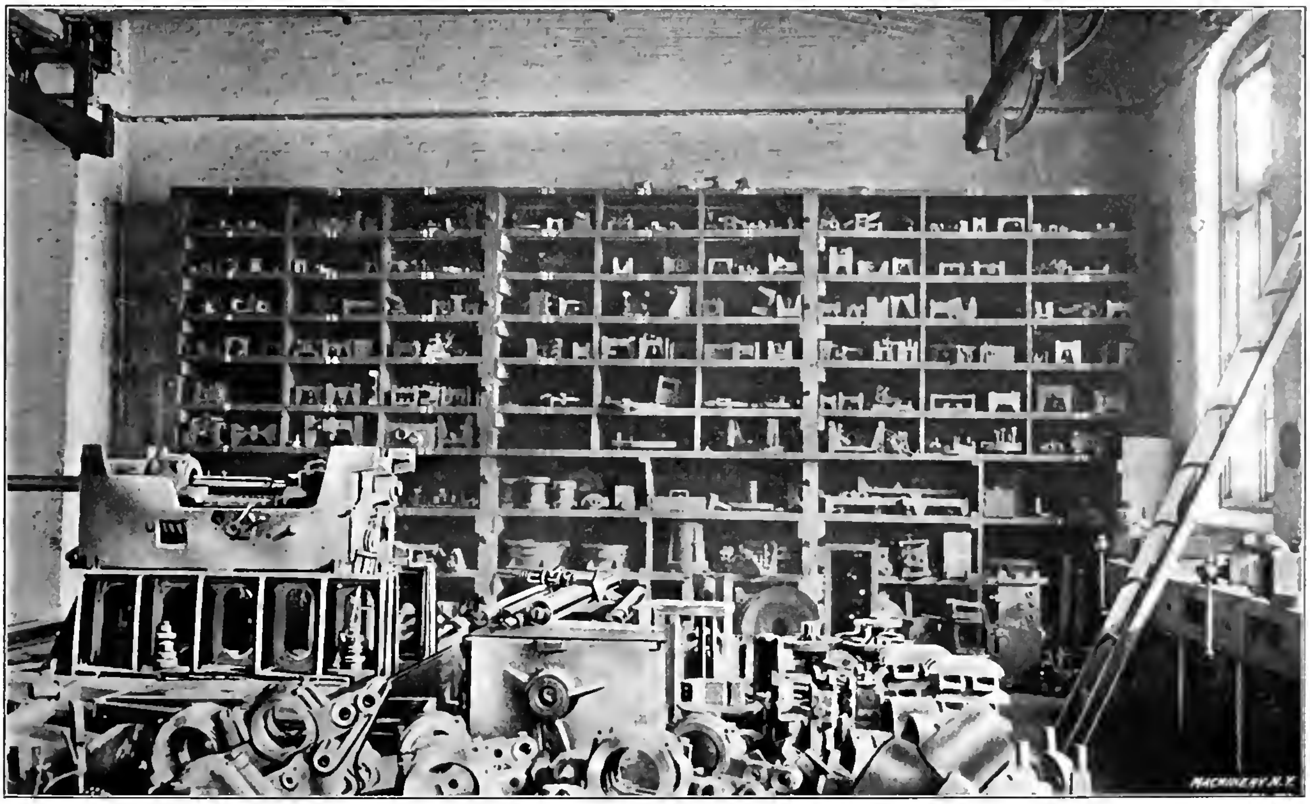

Fig. 188. An Example of Neatly and Conveniently Stored Jigs and Fixtures.

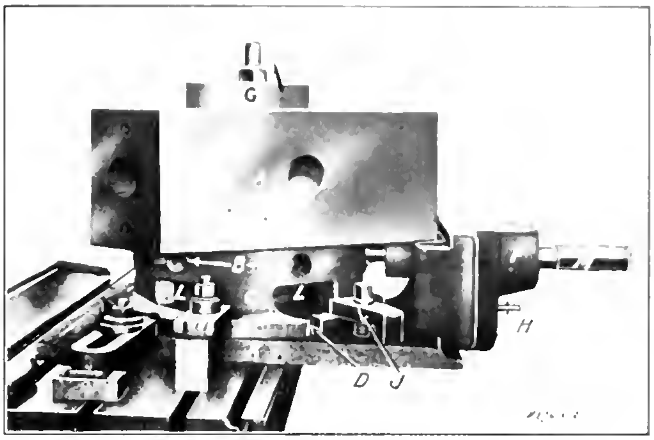

Fig. 187. A Combination Boring, Planing and Milling Fixture

In Fig. 186 is shown a similar indexing fixture somewhat modified. The work is located and held on the rotating disk *A*, which is fitted in place in the bracket or body *C*, so as to have no play. The round plunger *B* is beveled on the end, and fits the slots in the circumference of the disk. A spiral spring pushes the plunger into place. The plunger is guided by a pin in an oblong slot, so as not to turn around. Sometimes the plunger may be made square or with a rectangular section, and fit a slot which may be shaped to this form. This latter method is more expensive and does not give better satisfaction than the plunger with the round body.

A large variation of methods for indexing are in use, employing pawls, levers, springs and safety locking devices, which sometimes may be necessary. Indexing fixtures, however, designed according to the simple principles laid down above, will give as good service as many complicated arrangements. These indexing devices are used in cases where the standard indexing heads would not be suitable, and for many classes of work are equally efficient.

In Fig. 18[illegible], is shown a fixture which serves several purposes. The work, a turret A, has holes B bored out, the sides planed and the T-slots milled on the sides, all operations being performed by using the same fixture. When boring out the holes, the turret is mounted on the circular way of the revolving part C of the fixture. The work is located in right relation to the indexing notches D by a taper gib placed in the cut-out portion of the upper part of lug F; this gib locates the side of the turret square to the bushing hole passing through the lug. This taper gib is removed after the turret is clamped down securely by the strap G on the top of it, to allow indexing by the pawl H which fits into the notches D. As will be seen in the illustration, straps J hold the rotating part C securely to the face-plate K to prevent vibration during the boring operation. The lug F which holds the guiding bushings for the boring bars and also the indexing pawl, is cast in one piece with the face-plate. The casting is cored out at L for the purpose of removing the chips as well as making the indexing plate lighter without weakening it too much. When the fixture is used for planing or milling the turret, a special plug M is used, which fits the guiding bushings and the finished holes in the turret to insure perfect alignment.

Conclusion.

In a large shop with a great number of jigs and fixtures, it is quite difficult to keep them in proper order, and to have them so indexed and classified as to be able to find the required fixture at a moment's notice. It is unquestionably the best way to permit each department to have a storing place for all its own jigs and fixtures, more especially so if there is a store-room for other tools in each department. The jigs or fixtures are given out to the operators in exchange for checks, and before they are returned they should be carefully cleaned and the finished surfaces greased to prevent rusting. Before returning the check to the workman, the tool-room clerk should look over the fixture to see that no loose parts are missing, and no parts broken, and also that all loose pieces are tied together and attached to the jig body. An excellent method for storing jigs and fixtures is shown in Fig. 188. The tools are placed on shelves partitioned off and numbered and an index is kept showing at a glance the location of the tools for different operations. A copy of the index should be in the possession of the foreman, and also of the tool-room clerk, and should give the piece number of the work to be done in the jig, the number of the jig itself, and its place in the racks.

It will be seen from the half-tone that the lighter jigs are placed on the top shelves and the heavier further down. This not only permits a lighter construction of the storing shelves, but also makes it more convenient for the attendant to put the jigs and fixtures in place. If possible, jigs used for the same machine, or the same type of machines, should be in the same section of the rack, as this, to a certain extent, facilitates the getting out of jigs for the same work. When a jig or fixture needs repairing, it should be sent at once to the tool-making department, even if it is not to be used immediately.

In some trade journals there has been a great deal of paper wasted discussing what position a tool and jig designer really occupies; whether he should be considered a designer with a designer's salary, or simply a draftsman; and of other topics of similar nature. The fact remains, however, that a progressive manufacturing plant, in order to have suitable and efficient tools devised, requires a man who possesses in the first place good shop experience, in the second place sound practical judgment, and in the third place, a fundamental knowledge of theoretical mechanical principles.

* * *

The first aeronautical exhibition of any real importance has just been held in Paris. All the French models of aeroplanes were shown, including the new Santos Dumont flying machine, which is of rather interesting construction, and of particularly small dimensions. It is proposed to hold a large aeronautical exhibition in Frankfort a. M., Germany, next year.

PUNCH AND DIE FOR CORRUGATING THIN COPPER SHEETS.

A. L. MONRAD.*

The accompanying illustrations show a punch and die designed for forming copper corrugations from 0.010-inch copper sheets. The corrugations are bent in on the sides, and when completed present an appearance as shown in Fig. 1. They are then cut apart in suitable lengths and placed on top of each other, soldered together, and used for automobile cylinder cooling arrangements. These corrugations are formed by passing a copper sheet 3¾ inches wide between the punch and the die, shown in Fig. 2, feeding the strip of copper sheet along one step or corrugation for each stroke of the press. It will be noticed from the end view in Fig. 2 that it takes five strokes to complete the operations on one corrugation, although, as five operations are really performed simultaneously, one corrugation is completed for each stroke. The first stroke "breaks down" the metal, forming a half-circular corrugation. At the second stroke the section of the corrugation is formed to perfect shape, and at the same time small tools provided cut the metal at the corners of the corrugation in order to permit the edges to be bent down later on, as shown in Fig. 1. In the third operation the ends or sides are bent over to a 45-degree angle. In the fourth operation they are bent to a 90-degree angle, a small bevel of 45 degrees, however, still being left at the inside of the bent-over end. Finally, in the fifth operation, the sides are bent up to a sharp corner. Between each of these steps the metal must be released or stripped from the punch and die and fed along one step. The stripping is accomplished by means of compressed air acting on small plungers K, which strip the metal from the punch and the die at the same moment, as soon as the punch begins to ascend. The feed is accomplished by an automatic arrangement actuated by a cam, as shown in Figs. 3 and 4. This mechanism is put in action by the descent of the ram, and locates the copper strip in an exact and perfect position. The details of the stripper and feed arrangements will be explained more thoroughly later on.

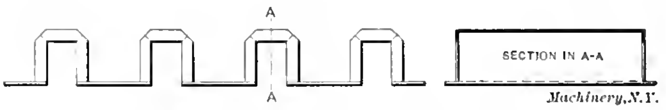

Fig. 1. Copper Corrugation to be made.

In order to prevent the punch and die from changing in hardening, it was deemed advisable to make those portions which are active in shaping the copper strips in separate parts. The manner in which these parts are inserted in the punch and die blocks is plainly shown in the end view in Fig. 2. The blocks or holders are left soft, and the hardened formers can be replaced when worn or broken, simply by driving them in place. On account of the great number of copper corrugations required, the chief feature sought in the design of the tool illustrated was to minimize the handling of the parts made, and eliminate separate operations, and for this reason an expensive tool was permissible, if efficient.

Construction of Forming and Shaping Mechanism.

In Fig. 2 is shown the front and end view of the punch and die, together with the mechanism for bending up the sides of the copper sheet, and the pneumatic stripper. The copper was ordered of the required width, and in rolls containing 200 feet of metal. These rolls were provided with large washers on each side to guide the metal, and the roll was placed in a bracket, fastened to the floor, with a steel rod through the hole in the center, on which the roll would revolve, as the copper was fed through the die. After the metal has passed through the die, it slides on a bench located at the back of the press. Gage marks are provided in the bench, and a stationary lever shear is located with its cutting surface level with the bench. The corrugated strip passes over the cutting edge of the shear, and the operator cuts off the metal to the required lengths, according to the gage marks.

The press is running continuously the whole day, at a rate of 100 strokes per minute, without any attention, the only

---

* Address: 72 Thompson St., New Haven, Conn.

thing required of the operator being to place a new copper roll on the shaft in the bracket as soon as the previous roll is used up. The metal has to be fed in by hand when starting a new roll, until a few corrugations have passed through the press. After that, the automatic feed will take care of the feeding along of the stock. While in the drawing, Fig. 2, the punch is shown considerably above the die in order to be able to show each of the parts clearly, when in actual operation the punch raises only high enough to permit the corrugated metal to pass between the punch and the die, thus guiding it on the bottom and top, while side plates guide it on the sides.

The construction of the punch and die parts are as follows: The plate *A* is of cast iron, planed on top and bottom, and fastened with four screws to the top of the platen of the press. On the top of this plate *A* is located the die block *B* fastened with four screws and two dowel pins. The die and punch blocks are made of tool steel, but not hardened. Four dove-tail slots are milled on the top of the die block for the hardened corrugating pieces *C*, which latter are ground all over and drawn to a dark straw color. In the center of the die block a ⅞-inch hole is bored to fit the shaft *D*, which operates the side pieces *L*, which, in turn, bend over the sides of the corrugations to the shape indicated in Fig. 1. This hole in the die block through which the shaft *D* passes is counterbored to a 1⅛-inch diameter at each end. In this counterbored recess helical springs *E* are placed. These springs force the side-plates *L* outward and hold them in this open position until the punch has entered the die, and the side-plates are operated by the mechanism shown to the left in Fig. 2. The action of this mechanism is as follows: A long bushing *P* is screwed into the left side-plate *L*. This bushing is supported at its outer end by a bracket *Q*. Inside of the bushing is located the driving shaft *D* already referred to, which is prevented from rotating in the sleeve by the set-screw *R*, but is permitted to slide back and forth for a limited distance, as indicated. On the extreme end of the bushing *P* a dove-tail groove is provided, into which is driven a hardened tool steel wedge *S*. On the end of the driving shaft *D* is mounted a circular disk *T*, to which is fastened a sprocket wheel *V*, held by four screws. The disk *T* turns freely on the shaft *D*, and is provided with a wedge *X* which is hardened and ground on the face. Two check nuts *W* hold the disk and sprocket in position. The sprocket wheel is driven by a chain from a sprocket placed on the press shaft, on which also is placed the cam operating the feed motion, as shown at *W* in Fig. 4. The running of the sprocket wheel is so timed that the wedges *X* and *S* will commence to operate against one another, and thereby pull in the side-plates, when the punch is about to bottom in the die. This pulling in of the side plates bends the edges of the copper sheet. The copper metal extends 1/16 inch on each side of the die. The side-plates are recessed on the side opposite the first and second corrugation in the punch, so as not to operate on the copper plate while these corrugations are formed. Opposite the second corrugation in the die four three-cornered knives *M* are placed, which split the sides of the copper sheet in the four corners of the corrugation at the second stroke as already mentioned, in order to permit the sides to be bent over. Opposite the third, fourth and fifth corrugations, the side plates *L* are shaped in a manner so as to bend the copper sheet first to a 45-degree angle, and then to a sharp corner, as has, also, been previously explained.

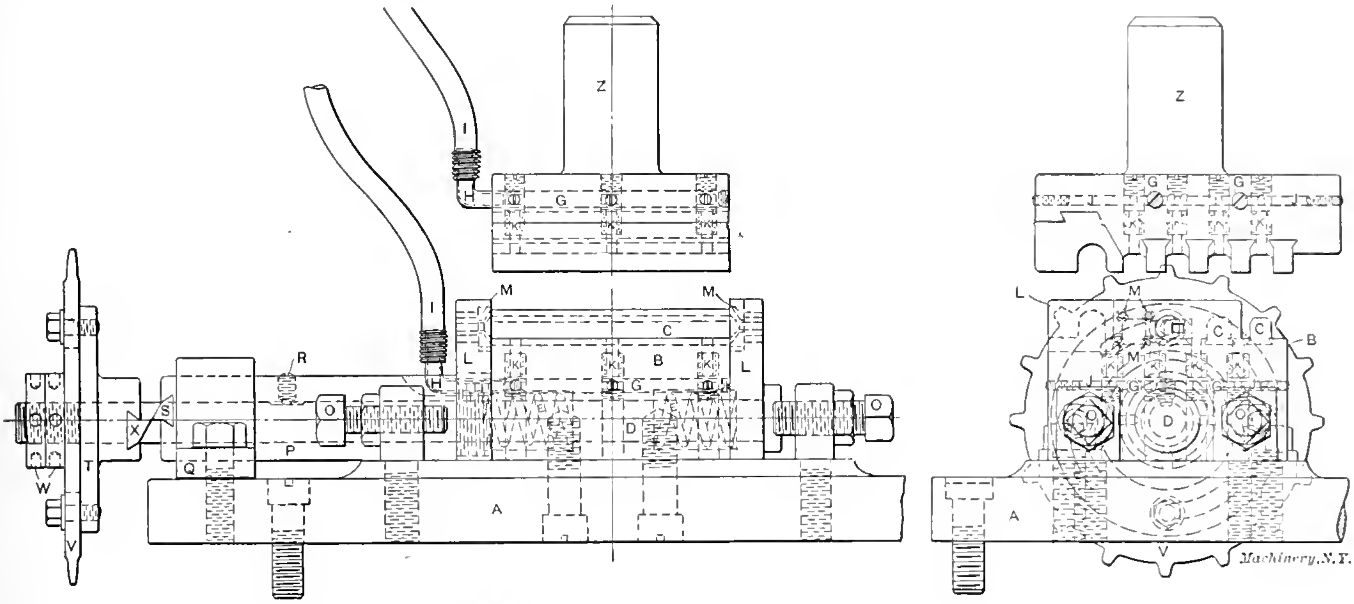

Fig. 2. Front and End View of Punch and Die.

Two stop screws *O* are placed on the outside of each side-plate in order to prevent the plates from opening any more than necessary to pass the metal through; thereby the side-plates are also enabled to guide the metal while feeding. On each side of the holes for shaft *D* in the die block *B*, ¼-inch air holes *G* are drilled the entire length of the block. One end of these air holes is plugged up with a screw, and a brass tube *H* is soldered to the other end. This tube is bent to a right angle, and a rubber hose *I* for the air supply is fastened to the outside with a brass wire. Air holes *J* are then drilled into the main channels *G*. These holes are also plugged on each end with a short screw. In the center of these holes, again, other holes are drilled, counterbored, and tapped, from the bottom of the die block for the plungers *K*, which are held down below the surface of the die by means of small helical springs. The stop screws at the bottom of the plungers are adjusted so that the latter will be flush with the top of the die. The air supply is connected with the machine, so that when the punch is ascending, air of 50 pounds pressure will be supplied below the plungers, thereby stripping the metal. The same arrangement is provided in the punch part of the tool. The copper sheet used is so thin that no mechanical device can be used for strippers excepting pneumatic plungers. Any spring-actuated device would remain open after having stripped the metal, and would have to be pressed down with the copper sheet. In so doing, the metal would be marked to such an extent that it might leak under the water pressure when the cooler is assembled.

Construction of Automatic Feed Mechanism.

The same press must be used at all times for this work on account of the fact that the details of the automatic feed mechanism must be fitted directly to the press, and while in operation become an integral part of it. In Fig. 3 is shown a front view, and in Fig. 4 an end view, of the automatic feed. In long dotted lines are shown the die plate, die block, sprocket and chain, in their position. The principle of the feed mechanism is that the guide hand *F* enters into the corrugation and holds it in place while the ram is descending, while, when the ram is ascending, by means of a combination of levers, the fingers *J* feed the copper strip along one corrugation. This mechanism is actuated through the cam *W* and the long lever *Q* shown in both Figs. 3 and 4.

On each side of the die are placed brackets *A*, held to the cast-iron plate *B* with two screws. On top of these brackets, on each side, are fastened guide plates *C*, which guide the copper strip. A U-shaped steel bracket *D* is fastened to the back of the ram. It is provided with a quarter-inch hole in each end, through which is passed the guide hand screw *E*, provided with two check nuts, acting as a stop when the screw comes to its downward position. The end of this screw is slotted to receive the guide hand *F* and a pin is passed through both so that the guide hand will move with the screw. The left-hand end of the guide hand *F* is connected to the end of a rod *G*. When the punch descends, the guide hand *F* follows and drops in a corrugation and locates the copper strip exactly in the correct position for the next stroke of the press. Back of the rod *G* is another stud *H*, having a link or plate attached to it with a free end. At the lower end of this link hangs a brass casting *I*. The opposite end of this brass casting is slotted, permitting the guide hand *F* to drop in. On the side of the casting *I* hang pawls or fingers *J*, being free to move around their fastening screws. When the casting *I* moves forward, being actuated through the lever *Q* one end of which rests against cam *W*, these pawls slip over the corrugation and drop into the next groove. When the casting *I* moves back again to the original position, the pawls hang down and catch against the side of the corrugation and feed the copper metal along.

To each side of the cast-iron plate *B* is fastened a steel block *K*, Fig. 3. To these blocks is fitted the cam lever shaft *L*, to which, in turn, are fitted the two feed arms *N*. These are located in position after the whole die and feed mechanism are assembled, a groove being turned in the shaft for the set-screws holding the feed arms *N* in position. On the other end of these feed arms two side plates *O* are attached. Between these plates a bushing is placed, a taper pin being driven through the bushing and the two plates. On the extreme left-hand end of shaft *L* the connecting link *P* is fastened, the other end of this link being connected to the cam lever *Q*, which is attached to the left side of the press by a screw *R*, holding it to the bracket *S* which in turn is attached to the press. The other end of the cam lever is bent to an angle of 45 degrees with the horizontal, and works against the cam *W* which is fastened on the press shaft together with the sprocket wheel which drives the sprocket wheel for the shaft *D* in Fig. 2. A long spiral spring *T* is attached to the end of the lever *Q*, and is connected on the other end to a rod *V*, which is fastened to the extreme end of the side of the press. A stop is provided for the cam lever by placing a bent steel plate *Y* on the left side of the press in the front as shown. The stop screw is provided with a head, against which the lever *Q* will stop. The other end of the screw is provided with a check nut to hold it in place. This arrangement has proved very satisfactory for carrying out the work for which it was intended. It looks rather complicated on the drawings, but in reality it is simple, and contains no superfluous parts.

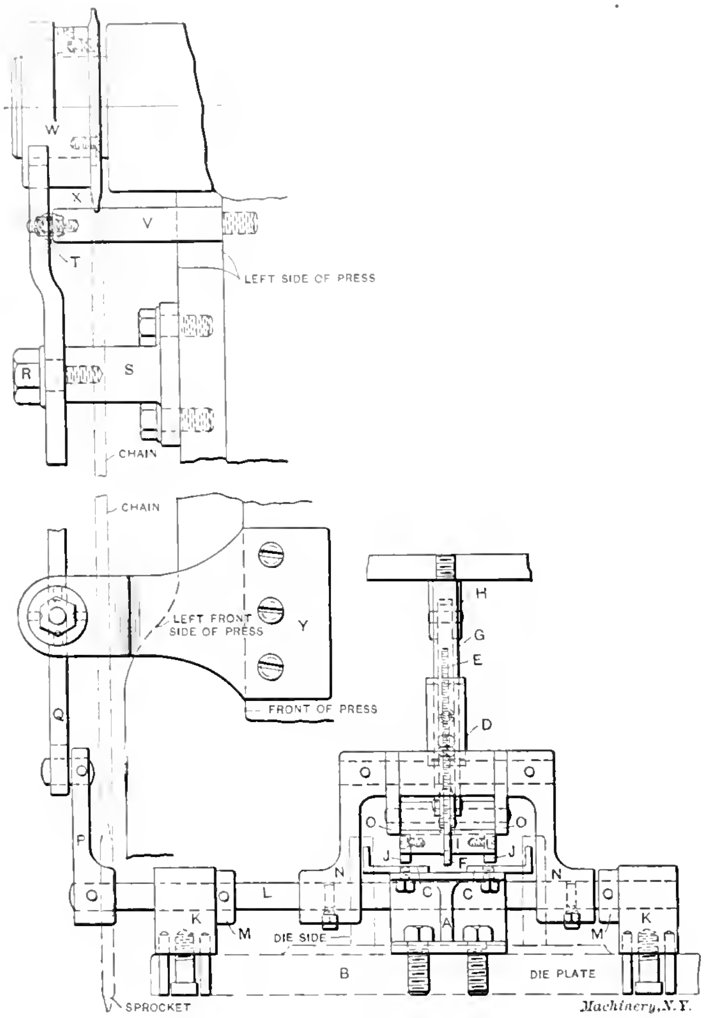

Fig. 3. Front View of Automatic Feed Mechanism.

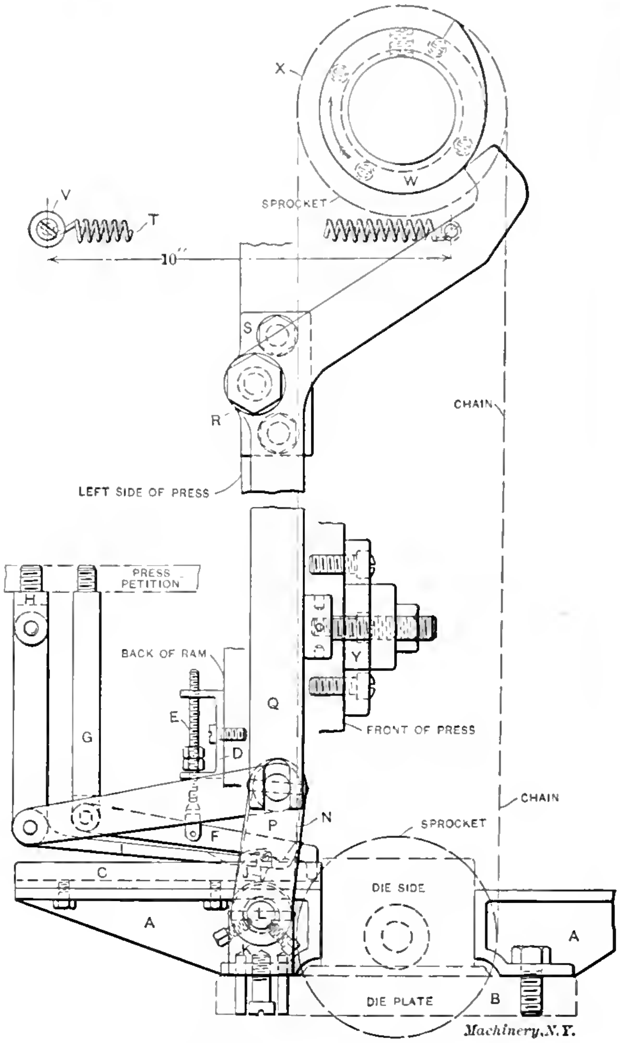

Fig. 4. End View of Automatic Feed Mechanism.

* * *

The police department of New York City is said to be considerably excited by the moving pictures shows which illustrate how safes are dynamited and robbed by safe-crackers. The pictures illustrate vividly and true to life how a safe is covered with blankets to deaden the sound of the explosion, and the robbers looting it when the door has been blown off. The vividness of the illustration and accuracy to detail make the process so plain that the tyros in crime need no further instruction to become safe robbers. No doubt the suggestiveness of these illustrations is powerful and dangerous. In the March issue we spoke of the effectiveness of the moving-picture machine in education, and in the January issue suggested that it could be used very profitably in teaching a trade. If the machine can be made a powerful incentive to crime, it surely can be made equally powerful as an incentive to industry by illustrating processes and manipulations that honest young men are eager to learn and understand.

THE FORGING OF HOOKS AND CHAINS.*

JAMES CRAN †

Most of the available information relative to hooks and chains is of a technical nature, and is better suited to meet the needs of the designer and draftsman than the blacksmith. There are given numerous tables of dimensions, and sizes, angles, etc., for finished hooks, but no information or rule seems to have been published whereby the blacksmith may arrive at a definite conclusion as to the diameter and length of material to use for hooks of different capacities. This condition has been responsible not only for a great deal of guess work, but also for the existence of poorly-constructed and very unsatisfactory hooks, which generally have required more time and material to make than necessary. When hooks of either of the types shown at *B* and *C*, Fig. 1, are to be forged, stock of the diameter *A* of the hook should be used. If a hook is made in proportion to a chain to which it is to be attached, the easiest and simplest method of determining the right diameter of material to use is to multiply the diameter of the material of which the chain is made by 2½. For obtaining the length of the material for the hook, multiply the diameter by 7. Take for example a chain of standard pattern made from material ½ inch in diameter, which is generally recognized as the correct size for a working load of 1½ ton; then ½ inch × 2½ = 1¼ inch; 1¼ inch × 7 = 8¾ inches; therefore 8¾ inches of material 1¼ inch in diameter is the right amount of stock to use for a hook that will take a working load of 1½ ton. If properly forged, a hook made from this material will be in accordance with the tables of dimensions generally given for crane hooks.

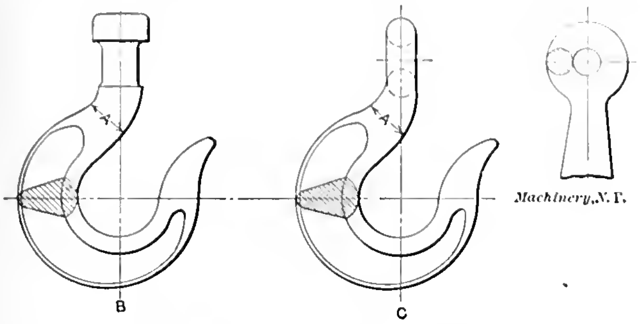

Fig. 1. Two Common Types of Crane Hooks.

Swivel hooks up to 3,000 pounds capacity are made from the end of a bar which ought to be cut the right length to permit the making of a certain number without waste. The first operation is to taper the end of the bar for the point of the hook as shown in Fig. 2. Where there is a power or steam hammer this is done by means of spring swages made with a taper impression as shown in Fig. 4. A sufficient length of the stock for one hook is then heated and bent to about two-thirds of a circle by using a bending device similar to, but heavier than, that shown in Figs. 7 and 8 in an article entitled "Tools for Increasing Production in Blacksmith Shops," in MACHINERY, November, 1908. After the hook is bent, it is removed from the bending device and is tapered or "fished" on the back at the same heat, by using tapering tools made on the same principle as spring swages, and shown in Fig. 5. The faces are slightly convex lengthwise, and the edges well rounded off to prevent leaving marks on the work. As the back of the hook is tapered, it is drawn a little on the outside; this closes it sufficiently, so that but very little finishing or truing up by hand is necessary. It is now ready to be separated from the bar. Material for heavier swivel hooks, and all sizes of hooks to be made with eyes, should be cut in lengths that will each make one hook. The reason for this is that swivel hooks over 3,000 pounds capacity would be too stiff and heavy to be bent by a hand bending device, and hooks with eyes must be tapered at both the neck and the point.

Fig. 2. Tapering the End of the Bar for the Point of the Hook.

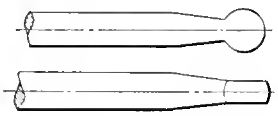

Fig. 3. Tapering and Shaping the Upper End of an Eye-hook.

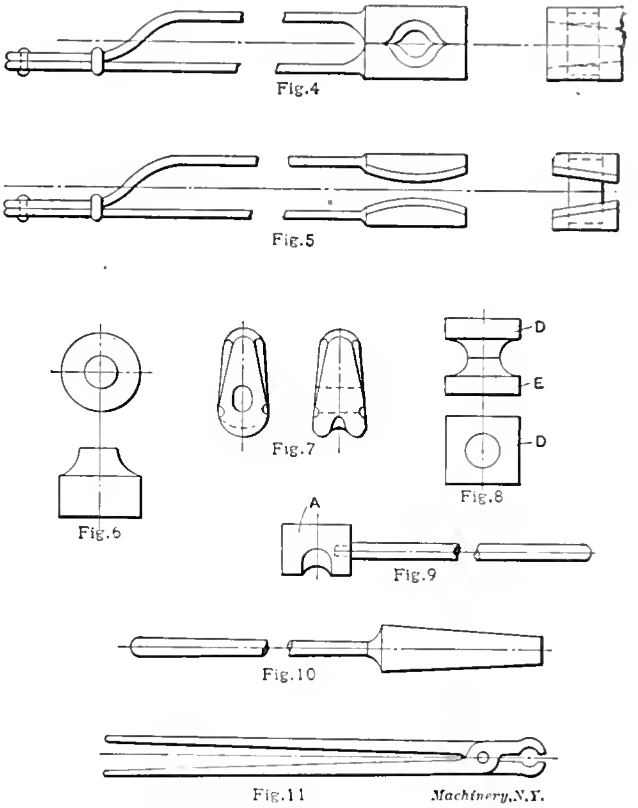
Eye hooks can be tapered at both neck and point with the same swages as are used for tapering the points of swivel hooks. The first operation in making eye hooks is to taper the neck, after which the portion for the eye should be flattened down to about half the thickness of the material used, and roughly rounded as shown in Fig. 3. The hole for the eye is then punched, the blacksmith removing as little stock as possible and drifting until the hole is large enough to admit of tools of the style shown in Fig. 6 being used to finish the inside to a half circular section. These tools are used in pairs; one tool is placed upon the lower die of the steam hammer, the eye of the hook fitted over it, and the other tool is inverted and placed on the upper side of the eye. Two or three blows of the hammer practically finishes the inside of the eye.

The outside is finished at the anvil by using another tool of exactly the same shape as that shown in Fig. 6, but provided with a shank to fit the square hole in the anvil. A short swage, the face of which is radial and having a circular impression well backed off at the edges, as shown in Fig. 7, is used to smooth the outside as the eye rests on the tool in the anvil. When this is done, the point is tapered and the hook is ready for bending, which on the smaller sizes may be done at the anvil without special tools; but large sizes of both types can be more easily and quickly bent at the steam hammer by using the former shown in Fig. 12 to start the bend. The body of the former is of cast iron, with a steel wedge or binder. Hooks to be bent are heated all over; the portion for the shank of swivel hooks is placed between two V-blocks *C* which are made to fit between the lugs of the former, and are held firmly in place by wedge *B*. A steel block *A*, Figs. 9 and 12, the face of which is made on an arc to conform with the radius of the former, and having a circular impression the entire length of the face, is placed on the upper side of the hook, and the bend is started either by gradually admitting steam to the cylinder of the hammer and pressing the hook down as far as the former will admit, or by a series of light blows. The hook is removed



Figs. 4 to 11. Tools used in Forging Hooks and Chains.

---

* For dimensions of hooks and chains, see MACHINERY'S Data Sheet No. 33, June, 1904, and also the Supplement with the current issue of the engineering edition.

† Address: 916 West Third St., Plainfield, N. J.

from the former, and the bending is continued until the hook is bent to about two-thirds of a circle, by placing it between the dies of the steam hammer as shown in Fig. 13. The back is tapered in the same manner as are smaller sizes, and the inside is trued up on the taper mandrel, Fig. 10. The advantage of having the mandrel tapered is that it can be used to true up different sizes. Large eye hooks are bent and finished in exactly the same manner except that instead of using V blocks to hold them on the former, two pieces of steel made to fit the eye of the hook and the lugs of the former as shown at *D* and *E*, Fig. 8, are used.

The Forging of Chains.

It is very seldom that chains are forged by the ordinary blacksmith, apart from making a link to repair an old chain, joining two pieces together, or attaching them to hooks or rings. Most of the chains used are made by chain makers who seldom do anything else. They are generally such experts in this kind of work that they can turn out chains in less than half the time it would take the men who only make a link occasionally. Nearly all blacksmiths, however, have to do more or less chain repairing, and it is well for them to be posted on this particular class of work. In making chains, the following dimensions will prove satisfactory for general purposes. For notation, refer to Fig. 14.

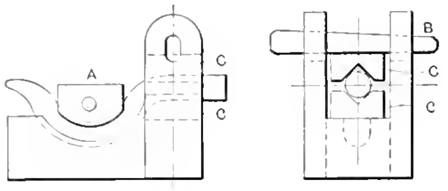


Fig. 12. Device for Starting the Bend in a Crane Hook

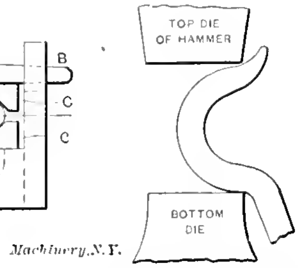

Fig. 13. Completing the Bend of the Hook.

B = width of link inside = $1\frac{1}{4}A$,

C = length of link outside = $5A$,

D = length of link inside = $3A$,

E = width of link outside = $3\frac{1}{4}A$.

Large sizes of standard pattern chains are a trifle shorter than the dimensions given above, but for all practical purposes, the formulas given can be followed. The length of chain links inside being only three times the diameter of the material of which they are made makes it rather difficult to join two pieces of chain together with a link the same length as the rest of the chain. One link of each of the pieces to be joined being placed inside the connecting link before it can be welded, leaves but very little space for holding the connecting link with tongs, and but small room for its being placed on the horn of the anvil for finishing up the end after welding. The easiest way to do work of this kind is to bend the link and scarf it as shown at *F*, Fig. 14; then bend the scarfed ends around and close them together as at *G*. After this the link should be heated all over and twisted at the lower end, as shown at *H*, until the scarfed ends come far enough apart to allow the end links of the pieces to be joined to pass over the ends. The ends are now twisted back to their first position and the link is ready for welding as shown at *K*. The link being already hot, and the end links of the chain cold, it comes to a welding temperature when placed in the fire, before the rest of the chain is affected by the heat. The tongs shown in Fig. 11 are the best kind to use either for chain making or repairing, as they take a good hold upon the work and do not cover enough of it to be in the way.

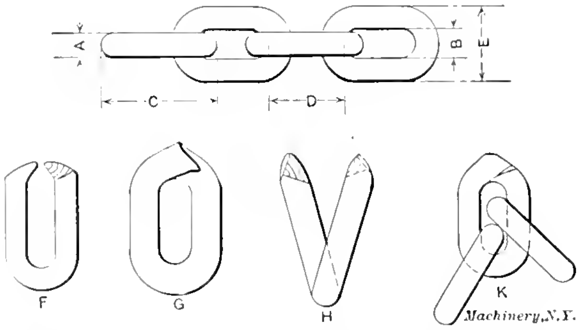

Fig. 14. Notation for Chain Dimensions, and Successive Stages in the Welding of a Chain Link connecting Two Pieces of Chain.

Chains used in connection with cranes or hoists for lifting heavy pieces are generally made with a hook at one end and a ring at the other; sometimes the chains are single, but quite often two, three or four chains and hooks may be attached to the same ring, according to the shape of the pieces they are intended to support. In places where a number of this kind of chains are used it will be found a good plan to give each chain or set of chains a number which should be marked upon them, together with their lifting capacity, in some place where it will be easily seen. A good way to do this is to use a large flat link made from the solid between the ring and the chain as shown in Fig. 15. The holes in the ends are punched and nicely rounded, the same as eyes for hooks. The flat space between the holes is used for the number, working capacity, or any other marks that may be necessary. Lifting chains should be annealed occasionally; by having them numbered or other ways marked it is easy to keep a record of each chain, when and how it has been repaired, when annealed, etc.

Crane hooks are often used for purposes which make it impossible to get the load in the center of the hook. The point then takes the greater part of the strain, and hooks for such service ought to be made from very heavy bar at least three times the diameter of the chain.

No definite information can be given for the rings, as the size of material to use depends entirely upon the diameter of the ring; the larger the ring the heavier the material should be. It is safest and best to make rings just as small in diameter as can be conveniently used; the material should in no case be less than one and one-half times the diameter of the chain to which the rings are to be attached. Links used for the purpose of connecting chain and hook should be made as short as possible, from material slightly heavier than that of which the chain is made; 9/16 inch is about right for ½-inch chains, larger and smaller chains to have the links for attaching the hooks or rings in corresponding proportion.

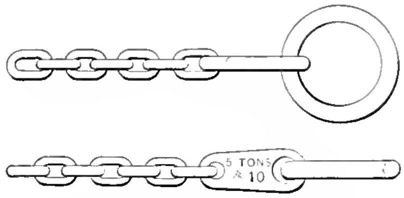

Fig. 15. Marking Chains on Special Marking Link.

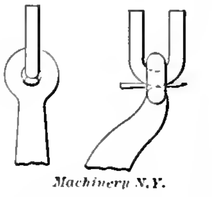

Fig. 16. A Kink when Welding Link connecting Hook and Chain.

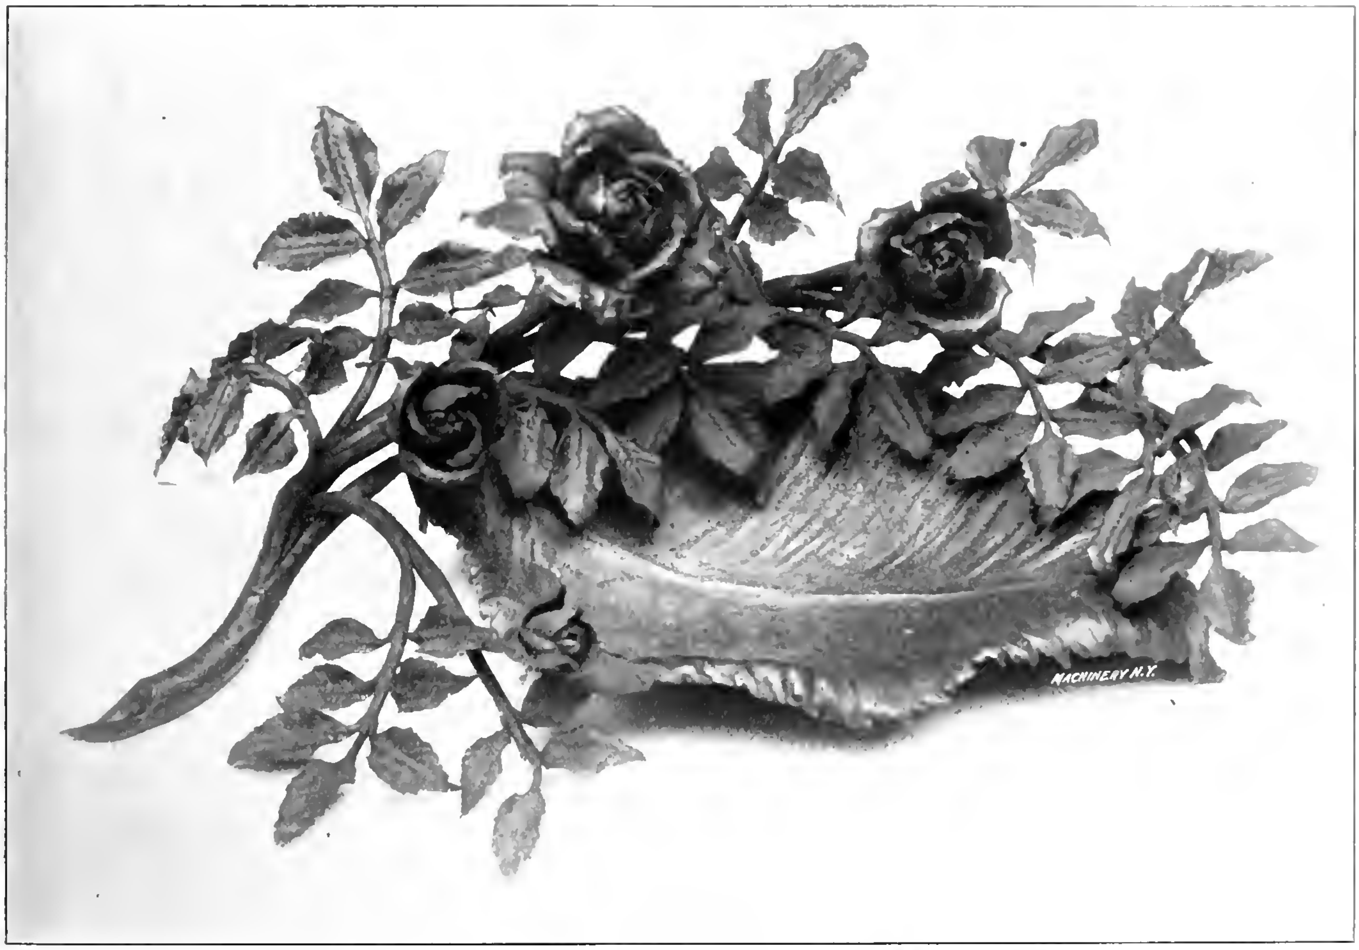
Anyone who has ever attached hooks or rings to chains knows what awkward work it is, especially if the chains are of heavy dimensions; either the hook will come in the way when welding the link next to it, or the chain will keep moving around the sides of the ring. This difficulty can be overcome to a certain extent when attaching hooks by placing the link used for the purpose in the eye of the hook and driving a wedge behind it as shown in Fig. 16. This holds the link firmly in position while the hook is held in tongs. In attaching chains to a ring, when plain links are used for the purpose, these should be left open enough at one end for the ring. Rings should be prepared for welding in the same manner as shown at *F*, *G*, *H*, and *K*, Fig. 14. In cases where more than one chain is to be connected with one ring, the different pieces of chain should be bound together with wire to prevent their moving around the sides of the ring while it is being heated and welded.

In repairing old and worn chains, material heavier than the original size of the chain should never be used, as the new link then will act as a wedge, and will put a breaking strain on the link. It is always preferable to repair with material the same size as the chain, or, where the links are

very much worn, material slightly smaller than the chain will give better satisfaction, as it will readily find a bearing in the worn ends of the links without bringing any additional strain upon them. The new links will be just as strong as the rest of the chain. It is by no means uncommon to see chains that have been repaired with links here and there throughout their length of material considerably heavier than the original size of the chain, which is a mistaken idea of making a strong job, for "chains are never stronger than their weakest link."

The best material to use for chains, hooks and rings is a good grade of wrought iron, such as Swedish or Lowmoor iron, either of which is freer from silicon, phosphorus sulphur, or other impurities than the more common brands.



Tray for Letters, Cards, etc., representing a Rose Branch Hammered out of Swedish Iron, by Mr. James Cran.

The tensile strength of the best grades of wrought iron does not exceed 23 tons to the square inch, while mild steel of about 0.15 per cent carbon will have a tensile strength nearly double this; but the ductility and toughness of wrought iron, which is greater than for any grade of steel, is in its favor for making appliances that are to be subjected to heavy strains and loads, as it will always give warning by bending or stretching before it fractures or snaps off.

* * *

TESTS OF STANDARD CAST IRON FITTINGS.

The Crane Co., Chicago, Ill., recently made a test of standard cast iron fittings, including its own make and fittings made by seven other leading manufacturers. The fittings tested were one-inch cast iron ells, and three separate tests were made. The accompanying table shows the lowest and highest pressures at which the fittings burst, together with the average of the three tests. The tests show that the weakest fittings are amply strong enough to stand any pressure to which a cast iron fitting would ordinarily be subjected. It is unthinkable that an ordinary cast iron one-inch ell would be used in service that would require a pressure of even one thousand pounds per square inch, and the weakest fitting in the lot broke at an average of 2,500 pounds to the square inch. Cast iron fittings must be made with a great excess of strength, however, not to withstand internal stress merely, but also the blows and twisting to which they are subjected in erection and use. A valuable characteristic of

Lowest Pressure at which Castings Burst	Highest Pressure at which Castings Burst	Average of Three Tests
7,300 lbs	8,000 lbs.	7,666 lbs
7,000 "	7,500 "	7,333 "
6,400 "	7,500 "	7,066 "
5,000 "	8,400 "	7,133 "
6,000 "	8,200 "	7,166 "
5,800 "	7,900 "	6,733 "
4,400 "	8,200 "	6,533
2,500 "	5,800 "	3,866

cast iron fittings is that when they are a long time erected and it becomes necessary to remove a section of a pipe line, it is not necessary to begin at the starting point and unscrew length by length; a cast iron fitting can be easily broken with a hammer and the desired section removed and replaced by the use of a simple right and left coupling or a union.

MORE ARTISTIC BLACKSMITHING.

The illustration shows a piece of remarkable blacksmithing done by our contributor, Mr. James Cran, foreman blacksmith of the Pond Machine Tool Co., Plainfield, N. J. The piece illustrated is of the same general character as that appearing as Fig. 1 in the January, 1909, number of MACHINERY, but is much larger. Its length is 15½ inches, breadth 12 inches and weight 61 ounces. It represents a rose branch with three full blooming roses and two buds; and a large leaf forms a receptacle for letters, cards, etc. The forging is characterized by extreme delicacy of work and wonderful fidelity to form.

Mr. Cran's ability as an artist in this line seems the more remarkable because he had done comparatively little work of an artistic nature until within the last few months. The greater part of his experience was acquired on heavy machine blacksmithing where clean welds and plenty of stock to clean up to the required shape have been the principal considerations. We understand that Mr. Cran will establish a small shop where he will do artistic blacksmithing to order in his spare time.

Entered at the Post Office in New York City as Second Class Mail Matter.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

APRIL, 1909.

PAID CIRCULATION FOR MARCH, 1909, 20,989 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

SIZES OF ILLUSTRATIONS.

The illustration of a machine or tool should show as clearly as possible the details of construction that are of general interest to the reader. If a machine is large, but simple in construction, it obviously does not require a large illustration to make its purpose and form apparent. On the other hand, a small machine that is not larger than a typewriter, may be so complicated and contain so much mechanism that it requires a larger illustration to show its design clearly than a massive planer weighing a thousand times as much. There really should be no comparison made of the actual sizes of illustrations, as it is the detail of each machine itself that determines in the editor's mind what size the illustration shall be.

We speak of this because of the supposed incongruity of illustration sizes that is found in these pages, particularly in the department "New Machinery and Tools" where a massive planer or milling machine is often shown on a comparatively small scale, while a screw tap or other small tool is shown much nearer its size. It is obvious to even the inexperienced that it would be impossible to show the two devices in their actual relative proportions: for if the tap illustration were made so small as to be barely distinguishable, the planer engraving would still be larger than could be spread on two pages. This fact is so simple and obvious that it is surprising that some of our friends have occasionally expressed dissatisfaction because the illustrations of their products were not as large as, in their opinion, the importance of the machine merited. We cannot be governed by considerations of mere size, but rather by the details of each case, and this is the rule by which all illustrations appearing in MACHINERY are made.

* * *

ETHICS OF ENGINEERING PAPERS.

Considerable trouble has been made in the American Society of Mechanical Engineers by the presentation of papers in which the author has quoted results of tests of his company's machines and competitive machines, to the discredit of the latter. Naturally the concerns whose machines have been put in an unfavorable light have taken exception to these papers. The situation is a very difficult one for the management of the society. It is absolutely necessary that papers on live commercial subjects be presented if the society is to live and prosper, and unless papers can be presented recording the results of tests made by mechanical engineers to determine relative economies, one of the best fields for papers will be shut off.

The society is not so situated that it can undertake on its own initiative extensive tests of various mechanical apparatus for the purpose of determining relative efficiencies and defects that should be corrected. It of necessity depends on the individual initiative of various manufacturers and the willingness of these manufacturers' mechanical engineers to report to the society the result of investigations.

A suggestion that has been made which seems worthy of consideration, is that whenever tests of competitive apparatus are to be undertaken by any concern, it should in courtesy invite representatives of the competing concerns to be present, and one or more disinterested engineers to act as referees. A report of the tests made under such conditions could consistently be presented before the society without unfairness to one concern. We hope that we shall not lose the benefit of such investigations made by engineers, and that reports can be made under substantially the conditions set forth. This would be to the material advantage of the society and the engineering profession as a whole.

* * *

NEW HIGH-SPEED STEEL.

The steel makers of Sheffield are reported to be greatly exercised over the published announcement of the "discovery" of a new high-speed water-hardening steel having from three to eight times the capacity of the high-speed steels now in common use. Knowledge of the wonderful new steel appears to have been common among the leading steel makers of Sheffield, and it seems that there was a tacit understanding to keep its existence secret until the existing stores of high-speed steel were used up. The steel makers of Sheffield in effect rebuked Prof. Arnold of the Sheffield University for his address delivered before the Royal Institution in which he announced the steel; and in a published protest they pointed out that the statement has caused the countermanding of orders for the old quality of high-speed steel, and serious losses of business have resulted.

The discovery of a water-hardening steel of even fifty per cent greater capacity than the old high-speed steels would represent a great advance, but what shall we accomplish with a steel from three hundred to eight hundred per cent higher capacity? We infer from the gossips of agents in this country that the increase of capacity is in the lasting qualities rather than in the feed and speed. A lathe tool that would stand up for, say, one hour and thirty minutes' heavy work when made of the older form of steel, will last a day or a day and a half in the same service when made of the new steel. The saving of time in grinding lathe tools is not of great importance, perhaps, but for classes of tools that require to hold a given size for long service, as in the case with reamers, boring tools, drills, automatic screw machine cutters, etc., the value of a high-speed steel of such lasting quality can scarcely be overestimated. It is probable that the new steel also has greater feed and speed capacity than the older steels.

The increased durability of the new steel is due, of course, to its ability to stand up under a higher temperature than the ordinary high-speed steel. The characteristic of "red hardness" is strongly pronounced at a temperature that would destroy other high-speed steels when cutting heavy chips. This characteristic enables a tool to be ground with a sharper angle, and the sharper angle reduces power consumption, generation of heat, and stress on machines. It is possible that the actual superiority of the new steel as regards the red hardness characteristic, is not much greater than of the other steels, but a slight increase which enables a sharper angle to be employed materially reduces heating and vibration, and these advantages being cumulative make a great increase of efficiency and durability.

The question that occurs to everyone concerned with the manufacture and design of machine tools is: "What next?" What will be the effect on machine design and shop organization? We have by no means yet realized the full capacity of the Taylor-White steels, and the discovery of a new steel of far greater capacity still further widens the gap between the steel maker and the machine shop organizer and tool designer. It is not too much to say that the discovery of high-speed steel was one of the greatest of modern times; and to have the value of the discovery more than quadrupled at one stroke, opens a vista of mechanical possibilities that causes past mechanical achievements to appear almost insignificant. It means so much for the advancement of manufactures, arts and science that the mind cannot grasp it.

* * *

THE APPRENTICESHIP PROBLEM.

The following letter, written by a well-known machine tool builder, describes the difficulties of training apprentices under present conditions and the typical methods followed in many American works (excepting the three-year contract feature) to train workmen. It is an old and well-known story, and our reason for publishing the letter is that it concretely illustrates a phase of our manufacturing development that has been wonderfully successful in production at low cost, but which, in the opinion of many, is a menace to our manufacturing supremacy, especially in the machine tool building business. If this industry cannot educate the force that will direct its future work, it will fall behind because of the lack of men trained to be resourceful and inventive, and comprehensive of the business in all its phases:

"In reply to your letter of a recent date with reference to instruction of apprentices, would say that we do not have any apprentices in our works, having discontinued this branch of our help some two or three years ago for the following reasons:

"First, our experience has been that there are only about 40 per cent of the boys that we had in hand that ever completed their course, the majority of them leaving about the beginning or during the second year. The principal reason for this was the inducements offered by other shops, many of them paying full wages to apprentices who had worked two years and over in our works.

"Second, our term of apprenticeship was four years, and in order to satisfy these boys we found that it was necessary to change them about at least once in six months; in actual practice their services were little more than a kindergarten, because no sooner had they become sufficiently accurate and practical to turn out work on the machine which they were operating, and oftentimes before they were competent, they were dissatisfied if not transferred to another machine of the same type or one of different type.

"Third, we find in our business that it is much more practical to procure the services of intelligent laboring men from twenty to thirty-five years of age. They enter our services on a three-year contract. The first year we pay them practically what they would be able to earn at common labor, advancing them each year until their term is completed. These contracts call for continual service on one line of machines or work; that is, if a man is started in at lathe work he is advanced from one class of lathe work to another as rapidly as his ability will permit; the same with planer work, etc.

"With this system we are able to keep our machines in constant operation and usually we get practical reliable help. You will understand that in machine-tool building much greater accuracy is required than is the general practice in the ordinary lines of engineering work, and the average apprentice does not attain sufficient accuracy and experience, nor has he ability to turn out work in paying quantities, when his experience is limited to six months, when changed from one machine or one class of work to another; consequently, he cannot turn out work in paying quantities to permit him to have the use of a high-priced machine to get his experience on."

* * *

An important case in commercial law was recently decided in New York State which concerns the builders of machine tools, and especially machines of a multiplex nature. It was decided that under New York statutes, a customer, who, for example, bought a twelve-spindle drill, could not claim the difference in cost between it and a nine-spindle drill when he had received the nine-spindle drill and accepted it. The use of the nine-spindle drill was held by the court to be a virtual acceptance of the drill ordered, notwithstanding the fact that it had three spindles less than the twelve-spindle drill desired.

ELEMENTS OF MACHINE MANUFACTURE.*†

FRED J. MILLER‡

Man has been described as a tool-using animal. He has used tools from the earliest times for obtaining food, making clothing and habitations, for defending himself, and for making war. It is only in comparatively recent times that he has made tools which are also machines, and which are therefore called machine tools, to distinguish them from the simpler tools which are used in the hands. In the present state of the arts and sciences these machine tools are the very corner stone and chief support of civilization. Without machinery our present mode of existence would be utterly impossible, and without machine tools we could have little, if any, machinery of any kind, agricultural, food preparing, textile, or transportation.

Machine tools are distinguished also from all other machinery because they possess, in a sense, the power of reproducing themselves. Machine tools are made by the use of machine tools. If we did not have any, the difficulty of producing the first machine tool would be enormous; but with a lathe, a milling machine and a planer to start with, the world's equipment of machine tools could be reproduced. In fact, it would be quite possible to do it with the king of machine tools, the lathe, alone. In view of these facts, machine tools, their design and construction, together with the manner of their use, constituting nearly all of what we call machine-shop practice, are well worthy of the most serious attention and study.

It might be inferred that from the first the most careful attention and study of the best equipped and best educated men would have been given to the subject of machine tool design—that the science of machine tool design would be among the things that had been most thoroughly worked out. This, however, is not the case. Generally speaking, the stresses imposed upon the various parts of a machine tool cannot be known to the designer of it. Different individual users, different shops in the same section, and different sections of the country have widely different views as to what constitutes a proper cut for a machine tool. Broadly speaking, there is to-day very considerable difference between New England and the Middle West as to what would be considered a proper cut for a lathe or planer.

Strength of Machine Tools.

Generally speaking, a designer can secure only unity of design in a machine tool, *i. e.*, he can make it approach the ideal of the wonderful one-horse chaise so that all the different parts will have substantially the same strength and power to resist wear in proportion to the load that will be placed upon them; but what that load will be, neither he nor anybody else can predict in most cases; that is determined by the user in his wisdom or his ignorance. For certain important work done in locomotive repairing, for instance, a certain railroad company uses something over three hours time of a man and an expensive machine tool. Another railroad company, using a similar lathe by the same maker, accomplishes the same work in 35 minutes. Shop practice is filled with these anomalies; and instead of there being fewer of them, as time passes on they have probably increased very much within the past ten or fifteen years, because shop practice has gone forward by leaps and bounds within that time, and, when rapid progress is being made, only a few keep pace with it; the rest drag out in a long

---

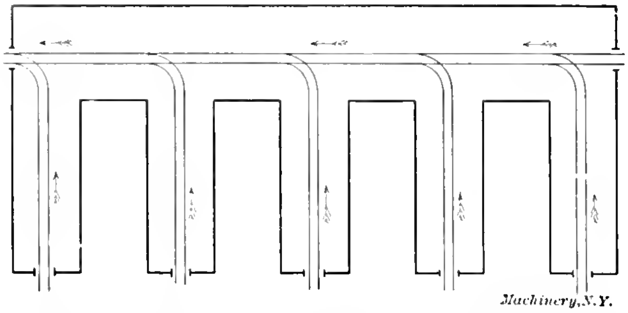
* Lecture presented before a class in mechanical engineering at the Columbia University, New York City.

† In accordance with the policy of the Department of Mechanical Engineering of Columbia University of closely associating the instruction with actual practice, engineers engaged in practical work are now giving instruction to the students in their own specialties. The regular instructor also lectures in the same series. The courses in which this plan is followed extend through the third and fourth years. A course on Principles of Machine Manufacture comprising a detailed treatment of the economic performance of standard machine tools is conducted by Mr. Fred J. Miller, vice-president A. S. M. E.; Mr. Elmer Neff, of the Brown & Sharpe Mfg. Co.; Hugh Aikman, of the J. H. Williams Co.; Mr. D. B. Bullard, of the Bullard Machine Tool Co.; Mr. C. E. Coolidge, of the Niles-Bement Co., and Mr. George Jeppson and Mr. Charles H. Norton, both of the Norton Co. Courses will also be offered in elevating and conveying machinery, pumping machinery, air machinery, and refrigerating and icemaking machinery. In the fourth year, courses conducted with the assistance of outside experts will be offered in steam turbines, manufacturing plant design, works management, and water power machinery.

‡ Address: 280 Broadway, New York.

procession the trailing end of which is out of reach and hearing, and knows not even that progress is being made.

One of the peculiarities of the branch of mechanical engineering which we are considering lies in the fact that, in designing and using machine tools the ultimate strength of a member is relatively of minor importance; because in this work, long before sufficient straining has occurred to constitute an approach to the breaking point, the deflection that takes place renders the tool useless for its purpose. Parts of machine tools that are turned, ground, scraped, or lapped true, receive this final refining treatment while under little or no stress. It is certain that every stress subsequently put upon them causes a deformation, and we must decide in each case whether or not the stresses to be imposed will produce deformation to an amount not allowable; remembering always that the allowable deformation in machine tools and machine shop fixtures is usually very small.



Machinery,N.Y.

Fig. 1. A Typical Layout of a Large Machine Manufacturing Plant.

Suppose, for example, that we bolt a casting to be planed upon the platen of a planer. Suppose that by unskilled shimming, or for some other reason, the casting does not lie solidly upon the platen at all the clamping points. Then, when the clamping bolts are tightened, the casting and the planer platen are both deflected. If the casting is much weaker than the platen it will be deflected much more than the platen; if they are of equal rigidity they will be deformed equally; if the casting is stiffer than the platen, then the platen will be most deformed. The same thing applies to the face-plates of lathes, boring mills, etc., when the work is fastened to them, and failure to realize this fact accounts for much bad work. Besides, both castings and forgings change their shape by the removal of the outer portions; usually some slight change of form continues to take place for quite a long time after such removal of the outer portions; therefore lathe beds, plug-gages and other things which must be quite accurately finished, are usually machined to very near their finished dimensions and then laid aside for a time in order that this slow change in shape resulting from the disturbance of the balance between the various contending internal stresses may be completed before the final finishing.

Baking in an oven up to about 400 degrees F., and slowly cooling, shortens the operation very much. The heat sets the molecules, or the atoms, or whatever we choose to call them, in rapid motion, and, during such motion, the forces tending to deformation produce their proportionate effect upon the final resting place of the molecules. The piece thereafter changes comparatively little.

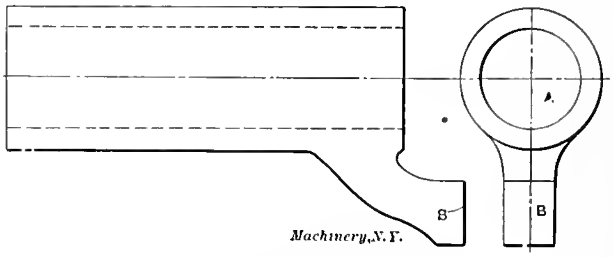
Thus we must not assume that machine tools and fixtures do not alter their shapes during constructive manipulation and use, for they certainly do to a greater or less extent. It is our business to see that they do not alter sufficiently to injuriously affect the work. The allowable deformation is, in the case of machine tools, probably less than in any other class of machinery, because accuracy of results is usually the first consideration in machine shop work.

Influence of Weight on Efficiency of Machine Tools.

Machine tools are somewhat peculiar in that mere weight seems sometimes to have an important influence upon their behavior, entirely independent of rigidity, or strength. When a machine tool has been designed to be plenty rigid enough—so that the deformation of its parts will be well within the allowable limits when subjected to legitimate stresses—one may still add more metal merely for weight, on what has been called the anvil principle. For example, a lathe taking a certain cut on work held between centers, chattered and acted badly. The small face-plate used merely to drive the work, through the medium of a dog, was removed and a large plate (as large as the lathe could swing) put upon the spindle nose in its place. Now the dog and the work were apparently driven precisely as before; neither the lathe spindle or any other portion of the lathe or work was more rigid than before; but the chattering ceased, and the cutting was steady. Whether the larger and heavier face-plate resisted torsional vibrations or lateral ones or both, I cannot say, but it seemed merely by its inertia or momentum to resist the rapid alternate accelerations and retardations which constitute vibrations. So far as I can see it added absolutely nothing except weight; but its effect was most strikingly beneficial.

This, however, does not mean that we should add chunks of pig-iron here and there for the purpose of getting sufficient weight; but it does mean that, sometimes, after patterns have been made heavy enough according to every rule and formula, they may be improved by being made still heavier, if they are for machine tools; as a prominent machine tool designer says: "In designing grinders, make them plenty heavy enough, and then as much heavier as the directors will allow."

Vibrations in machine tools seem to result in blows delivered upon the cutting edges of the tools, rapidly destroying them. In a large manufacturing establishment a great many twist drills were used which were 0.224 inch in diameter. This is an odd size and they could not be purchased at nearly as favorable prices as the standard sizes could be; and they were, therefore, made in the tool-room of the establishment in which they were used. At first a small, or No. 1 universal milling machine was employed in milling the helical grooves in these drills, but finally a larger machine by the same makers was installed for the general work of the tool-room. Occasionally both machines were employed in grooving the drills, and with the aid of special fixtures it was done rapidly.



Machinery,N.Y.

Fig. 2. The Work to be Machined.

The larger machine would have been pronounced entirely too heavy for the work, and it was used for these drills simply because it was more convenient to use both machines on the work at the same time. The cutters were made in large lots and were used indiscriminately on the two machines. The speeds were so arranged that the only practical speed on the larger machine was considerably higher than the one used on the smaller machine, but the cutters invariably held their edge and remained in service longer without grinding when used in the larger machine than when used in the smaller one. All conditions were favorable to an opposite result, except the greater weight of the larger machine. Its more massive knee and platen constituted a heavier anvil, which absorbed all vibrations. I became satisfied that if a machine were to be installed for use on that job continuously, the larger machine would have been the proper choice; although previous to that experience I would unhesitatingly have chosen the smaller as being ample for the work, as, I think, most others would have done, including the builders.

First Principles of Shop Construction.

One of the first things to be decided with regard to any shop designed for building a given machine is the general method to be pursued and the arrangement of the shop floor so as to have parts of machines progress between operations upon them in such a direction that, when finally ready for assembling, they will be near the place where they are wanted. There are two general ways of arranging for this.

In one, the castings coming from the foundry are delivered at one end of the shop, and at this end are the planers, chucking machines and boring and turning mills on which usually the first operations are performed upon castings. From here they progress from machine to machine for successive operations until, at the other end of the shop, they reach the stores or the assembling floor. About the same principle is applied in the case of forgings and it is quite common that castings and forgings enter the machine shop by the same door.

In the larger shops the alternative plan is often adopted of having a number of bays or shop floors arranged parallel to each other, either under the same roof, or separately, with open spaces between; these floor divisions all join, at one end, a floor running at right angles to them and usually devoted to assembling or erecting. Cars or trucks running on floor tracks, or overhead traveling cranes, convey materials through each of these bays, and the different classes of materials, entering at one end, progress toward the main bay; the progress of the work is analogous to the flow of water through various tributary streams until it finally reaches the larger river in which it again flows in one direction to its destination. Fig. 1 shows the direction of the movement of materials through the various sections of the shop.

In one bay there may be, for instance, the automatic and other screw machines; in another the smaller milling machines; in another the smaller lathes, planers, etc., while ordinarily there would be placed in the left-hand bay the heavier tools, floor plates, and portable tools required to deal with the heaviest castings. These when entering at the outer end of this bay, thus have the shortest possible distance to travel through the shop before reaching the general erecting floor at the left-hand end of the main bay, nearest the point of shipment.

Sometimes the main bay is higher than the others, to give head-room for the erection of large machinery, and there may be, along one side of the bay, a gallery devoted to such things as brass-working, automatic screw machines, gear cutting, etc.

The Cost Factor in Machine Manufacture.

One might suppose that, with the drawing or a sample of the machine before him, it would be possible for any one skilled in the art, by referring to data of the rates at which various operations can be performed to decide readily and almost infallibly, what methods to follow in carrying out any machine shop operation; but if one chooses a method based on the experience of a year ago, the chances are that he will deceive himself, and if he base his choice upon experience of five years ago, he will almost certainly be wrong. Besides, there are personal factors to be considered. It has been my experience that, in one first-class shop, there was a very firm belief that milling would not do at all for finishing lathe beds; that these must be planed, else time would be lost in scraping them true enough to pass inspection. In another shop all beds were milled and this was believed to be the best way of machining them. Both shops were in the front rank and both were doing the very best grade of work, of an approximately similar character, and in approximately equal quantities. It is evident that a very careful investigation would have to be made in order to decide which of these shops should be the model to follow in that matter; although it is certain that, if one could probe deep enough, one would surely find reasons for such variations in practice. One of these shops made neither planers nor millers and, presumably, had no interest in the one as against the other; while the other made both and, presumably, was as much in favor of the one as the other; so that this factor does not explain in this case such decided differences in practice.

Example of Decreased Cost Due to Interchangeable Manufacturing Methods.

In choosing a method of doing work, first, the quality of the work to be produced must be considered and then the quantity. I can perhaps best impress this by citing a case which has come within my own experience. A gray iron casting designed as the frame of a certain mechanism and shown partly in Fig. 2, was to be made. The first experimental machine had been made and tested, and four had been built precisely to the dimensions that were to be adhered to afterwards in manufacturing it, after the trial of these machines, it should be decided to take up their manufacture. The work to be done upon the castings was to bore accurately the hole *A* through the cylindrical body, face off the ends, true and square and to a definite length; and tool the surface *B* to a definite height above the squared end of the hub, true and square with it within a small limit of variation. The hole was cored in the casting, with about 3/16 inch to be removed in boring.

In the case of the first casting machined, it was held in the jaw chuck in an engine lathe, trued up by the usual process of chalk marking and adjusting, and then bored by a tool held in the tool-post in the usual way. At the same chucking the surface *B* was faced off and the adjacent end of the hub was then faced to give the right height for *B*; all this involved, of course, careful work by a skilled man. The piece was then reversed in the chuck, and by means of an indicator the bore was carefully trued up and the other end of the hub faced to give the piece proper length. For these operations it would have been put upon an arbor if the hole had been of any standard size for which an arbor had been on hand, but this was not the case. The cost of this machining was about $2.50.

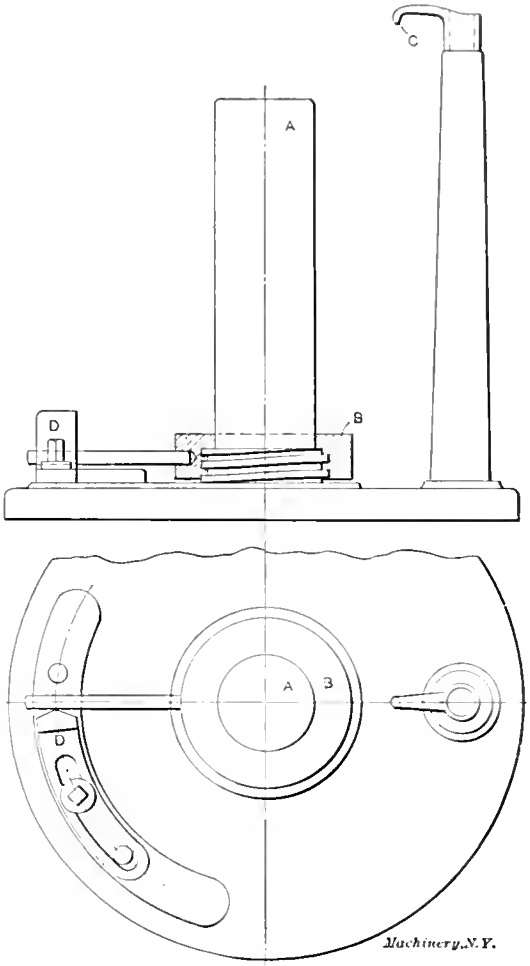


Fig. 3. The Fixture used for Facing Operations on Work in Fig 2.

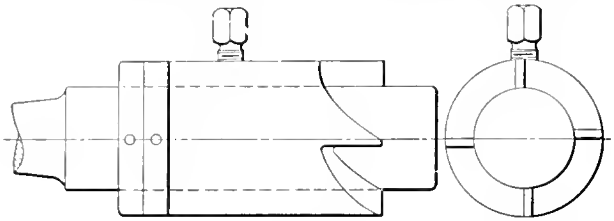
Later, ten more castings were required, and for these it was thought worth while to make a flat chucking drill to precede the lathe boring tool and an arbor on which to drive them while facing the ends and the surface *B*. This facilitated matters somewhat, and reduced the cost of machining to about $1.50 each.

It was then decided to manufacture the machine of which this formed a part, and fifty per day were to be made. The lathe was now entirely abandoned for this work, and two ordinary drill presses of good quality and with automatic feed were placed side by side and close together. A fixture was made for one of them which simply held the casting vertical, the hub resting against set-screws fitted to the frame of the fixture, with check nuts to hold them when adjusted.

A clamp held the piece against these set-screws and it was not necessary to tighten this very hard, because the lug *B* was allowed to come against a projection in the fixture and prevent rotation of the work. A hardened and ground steel bushing in the top of the fixture guided the boring tool which was what is by some called a butt-mill and by others a three-, four-, or six-fluted twist drill. It was simply a solid cylinder with a taper shank to fit the drill spindle, and having cut upon its cylindrical surface four helical grooves of such a shape that the ends of these grooves formed radial cutting lips. They were made radial, *i. e.*, they were ground to lie in or nearly in a radial plane because cored holes in castings do not, by any means, come true, and, where the core is considerably out of center, any cutting lip which is ground at an angle similar to that of an ordinary twist drill, will be crowded over by the heavier cut on one side; whereas, if the cutting lips are square; there will be no tendency to crowd off and much better results will be obtained.

The workman (not a skilled mechanic but a specially trained man) started boring and threw in the automatic feed. While the boring was thus going on, he reamed, with a hand reamer, the piece which had been previously bored, removing about 0.003 inch. He then placed this reamed piece upon the stud in the fixture shown in Fig. 3. This fixture was mounted upon the table of the second drill press with the stud *A* directly under the spindle. In the spindle was the facing tool shown in Fig. 4.



Machinery,N.Y.

Fig. 4. The Facing Tool Employed.

The work was first placed upon the stud so that the upper end, or that having the arm on it, was uppermost and the collar *B* was rotated until, by means of its internal square thread, it lowered the work upon the stud until the, as yet uncut face of *B*, Fig. 2, was at the height of the swinging gage *C*, Fig. 3. This was so made that, when the piece was adjusted to it, as described, enough metal would be left on the surface *B*, Fig. 2, to give a fair milling cut. The facing tool, Fig. 4, was then brought down and the facing continued until the end of the shank and the top of the stud *A*, Fig. 3, came together and thus stopped the cutting. The work was then reversed, *i. e.*, placed upon the stud with the opposite end uppermost, when the collar *B*, Fig. 3, was raised by rotating as before until the pin by which it was rotated came in contact with the stop *D*. The facing cutter could also be adjusted vertically upon the shank and was held in place by the threaded collars above it. All adjustments of the fixture and the grinding of the facing cutter were done by a skilled man, so that the operator had nothing to do but handle it as directed. By means of these tools, all this work was done while the boring was going on in the first drill press, and the labor cost was reduced to that necessary for the boring only. The face *B*, Fig. 2, was afterwards milled off while the piece was held in a fixture which permitted the use of a face mill.

By the plan described, the cost was reduced to about 6 cents per piece, as compared with the $2.50 and $1.50, which precisely the same work had cost by the methods previously described. Now, considered by itself, no one of these methods was necessarily any better than another. Each was adopted because believed to be the best for the conditions presented at the time. The first method, or one very similar to it, would still be the best one to follow if only one piece were to be made and if there were no assurance that there ever would be another like it.

As a first consideration the method followed in each case had to be such as to produce the results aimed at in accuracy, etc. After that it had to be adapted also to the number of pieces which were to be made, or the rate at which they were to be produced; this case has been described in detail to show that the best method of doing identically the same work usually depends very much on the quantity to be done, or the rate at which it is to be done. But it is not always possible to know how many pieces are to be made alike, and one of the most difficult problems connected with manufacturing is to decide wisely whether or not to make fixtures at a given time. A rule that is sometimes used is to make jigs and fixtures only when it is believed that their cost will be saved in one year. Some establishments charge off 20 per cent of the original cost of all fixtures at each yearly inventory, thus distributing their cost over a period of five years. One very prominent machinery building concern makes good jigs and fixtures for every machine it builds; this is done mainly because interchangeability and ability to supply parts at any time that will fit and work without question is a part of every sale or lease contract, and jigs and fixtures afford the only practical means known to them of certainly securing that object.

Rapid Development of New Tools and Methods.

Scarcely anything is as yet finally settled with regard to the details of shop practice. If to-day we are to consider the production of a new machine, the decision with respect to many things connected with its manufacture would vary between different experts; and, any decision which is reached at the present time would almost certainly differ from one that would have been reached a year ago, as well as be subject to revision a year hence.

High speed steel has exerted an important influence, enabling surplus metal to be removed from castings and forgings much more rapidly than was possible a few years ago; but this has not in the least shortened or reduced the cost of many of the most expensive operations which go into the production of machinery, *i. e.*, the careful laying out of the work, the careful measuring and gaging necessary to secure the required accuracy; the grinding, lapping, scraping, finishing and assembling. It has reduced the cost of turning, boring, drilling, milling, and planing, and, in some lines of work, these operations constitute the principal elements of cost; but in other lines they are relatively less important, and the faster rate at which these operations can now be done has affected the cost of production of such lines of machinery comparatively little.

Milling is a process which, within recent years, has undergone such changes that one who should have to decide as between milling and planing or upon the type of miller to install or the number of them needed for a certain production, would need to know the very latest attainments in that line. At first milling cutters were almost what might be called disk-shaped rotary files and were, in fact, used as substitutes for files, especially in producing forms which it was necessary to reproduce in considerable numbers with considerable accuracy—gear teeth for instance. The rate at which work was done was considered very fast, because it was so much faster than the methods which it displaced; but such a rate of doing milling would now be considered absurdly slow. Probably few milling machines used in those early days could remove more than a pound of metal per hour.

At the latest general meeting of the American Society of Mechanical Engineers a cutter was described that converts into chips and removes nearly 13.5 pounds of cast iron per minute. If capacity to remove metal were the only controlling factor, such figures would make it pretty easy to decide in most cases. But very often the amount of metal to be removed and the character of the pieces from which it is to be removed do not permit of milling at a rate anywhere near the figures given, and other factors have much to do with the choice of machines and methods.

The art of grinding has also progressed very rapidly within recent years. Grinding machines, at first used in machine shops almost exclusively for shaping or perfecting the forms of hardened steel pieces, are now quite generally used for finishing, to size and truth, spindles, piston-rods, automobile engine crank-shafts and numerous other things which are first turned roughly and considerably above the finished size; a very high finish is produced at less cost than that at which an inferior one could have been produced a few years ago.

Power for Machine Tools.

In nothing, perhaps, is the difficulty of establishing definite rules for machine shop practice more clearly shown than when we investigate the matter of the power required to drive machine tools. An old rule was to provide one horse-power for each ten men employed in a machine shop, including bench hands and all others, whether using power or not; and that rule fitted very well with former machine-shop practice. For any of the most modern machine shops, however, such an allowance would be absurdly inadequate.

As regards the practice of to-day, for example, the Westinghouse Electric and Mfg. Co., which has had a very extensive experience in equipping machine tools with electric motors, says that the conditions under which machine tools operate are so varied that it is impossible to represent even by empiric formulas the exact horse-power which should be used in all cases. They give some formulas, however, based on average practice, and assuming that ordinary carbon steel tools are used, the assumed cutting speed being 20 feet per minute. Under abnormal conditions of either machine or work the formulas will give very much smaller horse-powers than those which should be applied to the various machines.

For engine lathes: $H.P. = 0.15S - 1$ in which S is the swing of the lathe in inches. This would give, for a 10-inch swing lathe, a motor of 0.5 H.P. and for a 20-inch swing lathe 2 H.P. It may be remarked that, although the cutting speed is the same, the 20-inch lathe will have a motor four times as powerful as the 10-inch lathe, and that, if the cut taken were of the same character, the power required would be the same for both. The only way of accounting for the difference is in the fact that heavier chips are taken in the 20-inch lathes and also that more power is required to drive the lathe itself.

For lathes doing specially heavy work, such as forge lathes, the formula given is: $H.P. = 0.234S - 2$ which for a 20-inch lathe of this description would give 2.68 H.P. This is less increase of power as compared with the ordinary 20-inch lathe than might have been looked for. It will be found, however, that, as the sizes of the lathes increase, the power provided by this formula increases in a greater ratio than by the first. Thus, comparing 30-inch lathes, for example, we get 3.5 H.P. and 5 H.P., respectively, and for 40-inch lathes, 5 H.P. and 7.4 H.P., respectively.

For boring and turning mills the same authority gives: $H.P. = 0.25S - 4$ in which S = the swing in inches. This, for a 6-foot mill, gives 14 H.P. The formula for a lathe of the same swing would give us only 9 H.P.; but that formula is based upon the use of only one cutting tool; whereas boring and turning mills ordinarily use two and often more.

For drill presses the formula is: $H.P. = 0.06S$, where S = the swing of the drill press in inches; or for a heavy radial drill press: $H.P. = 0.1S$.

For planers of ordinary proportion between length and width the formula is: $H.P. = 3W$, where W = width between the housings in feet. For heavy planers for forge work: $H.P. = 4.92W$. These formulas provide for two tools cutting simultaneously; for a return speed of 3 to 1, and also for the overload at the moment of reversal. The increase in power required at the moment of reversal is considerable, and the motor must be of sufficient capacity to avoid that degree of momentary overload which, if the planer were to be used always at full stroke, might well be borne, but which becomes too much for the motor when the stroke is so shortened as to keep the planer for a very large proportion of the time in the act of reversing, and thus gives the motor practically a continuous overload.

The formula given for slab milling machines is: $H.P. = 0.3W$, in which W = distance between the housings in inches. This is for carbon steel cutters running at 20 feet per minute cutting speed; for a machine having 42 inches between housings the formula gives 12.6 H.P.

In a paper by Messrs. Wilfred Lewis and Wm. H. Taylor, presented at the annual meeting of the American Society of Mechanical Engineers December, 1908, some experiments with a milling cutter provided with helical, inserted blades of high-speed steel were described, with which cutting was done in a miller 42 inches between housings, and milling steel at a cutting rate of 88 feet per minute. As the power required to drive a milling cutter is proportional to the speed of the cutter, our formula would give 55.4 H.P.; but the power actually used in the experiment was 92.7 H.P., or, nearly 70 per cent more than the formula gives. This is a striking example of the fact, clearly recognized by the Westinghouse Company, that "the above formulas may be useful in approximating the horse-power required under given conditions, but it has been found that it is impossible to derive any formula which will take account of all the operative conditions and the results given by the formulas must be invariably tempered by judgment, based upon the character of the work, personnel and numerous other factors."

Much the same thing applies throughout the field of productive engineering. This, however, is no reason for becoming discouraged at the prospect of ever mastering it, for it is for this very reason that it is perhaps the field which, above all others, gives the widest scope for individuality and noteworthy achievement.

* * *

THE FIRST LATHE MADE IN INDIA.

The accompanying illustration shows a machine of considerable general interest because of its makers, and the fact that it is the first lathe constructed in India. It is a copy of a Barnes No. 13 engine lathe manufactured by the W. F. & John Barnes Co., Rockford, Ill., and was constructed almost entirely by native Indian boys in the Methodist Episcopal Industrial School at Nadiad, India. Mr. H. F. Bishop, who is at the head of the school, says that very little machinery is built in India, and that what is made is mostly confined to railway work, cotton mill machinery and fittings, and structural steel fabrication. The Mission Industrial School is endeavoring to start manufacturing along the lines of small machinery, tools, etc., which will give employment to the natives and lift the industries of the country out of the primitive state in which they generally exist. Mr. Bishop writes that the lathe built by these Indian boys, who but a few years ago were ignorant famine waifs, works as satisfactorily as the original lathe. Of course the castings are somewhat rough and the illustration shows it because no filling or painting was done to improve the surfaces.

The First Lathe made in India, and its Makers

* * *

Some of the native Australian woods have a very high tensile strength. The *Practical Engineer* states that the blue gum of Tasmania has an ultimate strength of 29,800 pounds per square inch, and weight for weight has 2.3 times the strength of nickel steel. The modulus of elasticity is 3,500,000. The swamp gum, red gum and salmon gum wood, also Australian native woods, have a tensile strength of about 20,000 pounds per square inch. Weight for weight, the swamp gum wood has double the strength of high-grade structural steel. While the tensile strength of these woods is high, the shearing strength is low as compared with steel as it does not exceed 2,000 pounds per square inch for any of the woods mentioned.

THE SQUARING OF THE CIRCLE.

ANTONIO LLANO *

The quadrature of the circle is a problem that everybody has heard of, but of which many persons have but a very vague idea. It has engaged the attention of mathematicians from the dawn of civilization to our own time, and been the source of many great discoveries; nor has its fascinating power failed to engage and wreck the scanty intellects of uncultured men that, having been destined by nature to dig the soil or guide the tilling plow, have lost what little reason they had in vain endeavors to solve a problem that some of them could not even state. The following brief exposition of the true nature of this problem, as well as of the simpler problems on which its solution depends, may be of interest to those that are not familiar with the subject; while the approximate graphic solutions given may prove useful to the draftsman.

"Nor has its fascinating power failed to engage and wreck the scanty intellects of uncultured men."

The simplest way of stating the problem is this: *Given a circle, to construct a square that shall have the same area as the circle.*

It should be noted that the required square is to be *constructed;* and this means that the side of the square is to be determined graphically with no other instruments than a straightedge or ruler and a pair of compasses. It is not necessarily required that the length of the side of the square should be computed; what is required is that a line should be drawn, whether its length can be calculated or not, that shall fulfil the conditions of the problem. An illustration will make clear the difference between solving a problem by computation and solving it by geometrical construction. The two methods are called, respectively, the *analytic* and the *graphic* method.

Suppose that a rectangle R, Fig. 1, is given, and that it is required to find another rectangle that shall have the same area but a different base c.

In the analytic method, the lengths of the base b and altitude h of the rectangle R, and of the base c of the required rectangle, are either given or determined by actual measurement. Suppose $b = 12$, $h = 3$, and $c = 9$, and denote by x the altitude of the required rectangle. Then, since the two rectangles are to have the same area, we must have

$$9 \times x = 12 \times 3 = 36,$$

whence $x = 36 \div 9 = 4$.

In the graphic method, it is immaterial what the lengths of b, h and c are provided these lines are given on paper; that is, provided they are already drawn. Draw AB, Fig. 2, equal to b. From A, lay off $AC = c$. From C, draw $CH = h$ in any direction other than the direction of AB. Draw AH, and produce it. From B, draw BX parallel to CH, intersecting AH produced in X. Then BX is the altitude of the required rectangle. For the similar triangles ACH and ABX give

$$AC : CH = AB : BX;$$

that is,

$$c : h = b : BX,$$

whence $c \times BX = b \times h$, as required.

When the object of a geometrical probem is to draw a line satisfying certain conditions, the line can always be drawn if its exact length can be computed; that is, a geometric construction can always be accomplished if an *exact* analytic solution can be found. Thus, in the preceding example, the rectangle can be constructed after its altitude x has been calculated. The converse proposition, however, is not true: a problem may have an exact graphic solution, and yet not have an exact analytic solution. Suppose, for example, that it is required to find the hypotenuse of a right-angled triangle whose sides are 5 and 3. We may draw a right angle, and lay off from its vertex, to any convenient scale, the lengths 3 and 5 of the sides; the line joining their extremities is the required hypotenuse. Yet, we cannot exactly determine this hypotenuse by computation, since its length is $\sqrt{9+25}$, or $\sqrt{34}$; and, although we can express $\sqrt{34}$ to any desired degree of approximation, we cannot determine its exact value.

The following additional illustration of the principle just explained has a direct bearing on the problem of squaring the circle. Let it be required to determine the side of a square having the same area as a triangle whose base and altitude are b and h, respectively. If the side of the square is denoted by x, the analytic statement of the problem is

$$x^2 = bh \div 2$$

and the analytic solution is

$$x = \sqrt{bh \div 2}$$

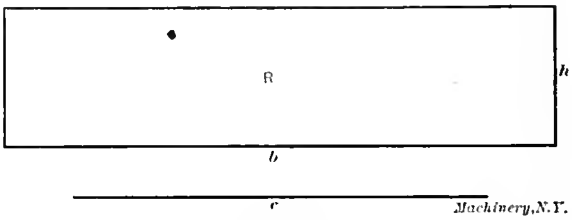


Fig. 1.

If $\frac{1}{2}bh$ is a perfect square, the value of x can be determined exactly, and the square readily constructed. Thus, if $b = 24$ and $h = 3$, $bh \div 2 = 36$, and $x = \sqrt{36} = 6$. If $bh \div 2$ is not a perfect square, there is no exact analytic solution. The exact geometric solution, however, is always possible, and is accomplished thus:

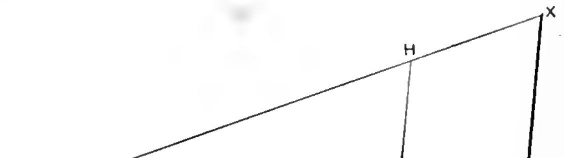

Fig. 2.

On an indefinite line AP, Fig. 3, lay off $AB = b \div 2$, and $BH = h$. Bisect AH at O, and, with center O and radius OA, describe a semicircle AQH. At B, erect a perpendicular to AH, intersecting the semicircle in X. Then BX is the side x of the required square. This follows from the fact that, the angles of the triangle ABX being equal to those of the triangle XBH, the two triangles are similar, and, therefore,

$$AB : BX = BX : BH, \text{ or } AB : BX = BX : BH,$$

whence

$$BX^2 = AB \times BH = (b \div 2) \times h = bh \div 2$$

Here, then, we have another case in which the graphic solution of the problem is always possible, whether the analytic solution is possible or not.

We may now return to the squaring of the circle; or, as mathematicians call it, the *quadrature* of the circle. If the area of a circle of given diameter could be exactly calculated,

---

* Address: International Correspondence Schools, Scranton, Pa.

the construction of the equivalent square would offer no difficulty. Suppose, for example, that the exact area of a circle is 15.75 square inches. This area may be expressed as the area of a triangle having a base of (2 × 15.75) inches and an altitude of 1 inch, and the equivalent square can be constructed in the manner already explained.

It is, then, natural to try first to find an expression, or formula, for the area of the circle in terms of the diameter or of the radius. The investigation leads to the conclusion that the area of a circle is equal to the area of a triangle whose base is the length of the circumference and whose altitude is the radius of the circle; so that, if the length of the circumference can be either computed or constructed, the area of the circle and the side of the equivalent square can be readily determined.

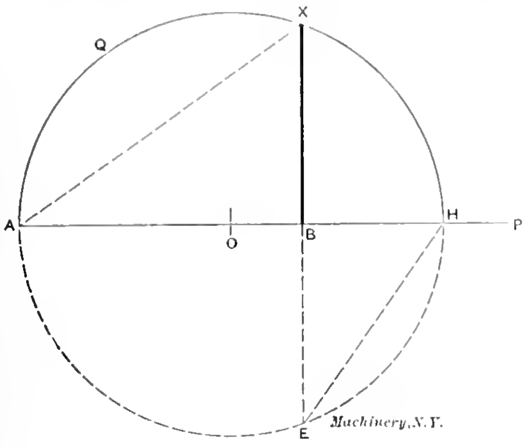

Fig. 3.

Algebraically, the relation between the area A, the radius R and the circumference C is thus expressed:

$$A = R\,C \div 2$$

Since all circles have the same form, any two circles of different diameters may be regarded as being the same circle drawn to two different scales; and so their circumferences must be proportional to their diameters or to their radii. If, for instance, the diameter of a circle is three times the diameter of another circle, the circumference of the former circle must be three times the circumference of the latter. Let R, D and C be, respectively, the radius, diameter and circumference of a circle, and R_1, D_1, C_1 the radius, diameter and circumference of another circle. Then, the principle stated above may be expressed algebraically as follows:

$$\frac{C}{C_1} = \frac{R}{R_1}, \text{ or } \frac{C}{C_1} = \frac{D}{D_1}$$

From the second of these two equations is derived the important relation

$$\frac{C}{D} = \frac{C_1}{D_1}$$

We thus see that the ratio of a circumference to its diameter is the same as the ratio of any other circumference to its diameter; that is to say, that the number obtained by dividing the length of any circumference by the length of its diameter is *constant*, or fixed, or always the same. This fixed number is usually denoted by the Greek letter π (called *pi*). From the equation $\frac{C}{D} = \pi$ follows

$$C = \pi D = 2\,\pi R.$$

If we knew the exact value of π, the circumference C, and therefore the area A, and the side of the equivalent square, could be determined, as already explained. The squaring of the circle, then, finally reduces to the determination of the number π. The French geometer Legendre proved, over 100 years ago, that π is an incommensurable quantity; that is, a quantity that, like $\sqrt{2}$, $\sqrt[3]{12}$, cannot be expressed exactly by any number, either integral or fractional. This disposed of the analytical solution of the problem, showing that it was impossible. The graphic solution, however, still remained a possibility, until the German mathematician Lindeman proved, in 1882, that this solution, also, is impossible.

But, although no exact solution of the problem is possible, approximate solutions, both analytical and graphical, have been found that meet all the requirements of practical computation and drafting. Various methods and formulas have been devised by which the value of π can be obtained to any required degree of approximation, and some astoundingly patient calculators have computed this mysterious number to more than seven hundred decimal places. For very accurate work, the approximate value 3.1415927 is used; but for nearly all practical purposes, 3.1416 is considered close enough. One-fourth of the latter value, or .7854, serves to calculate the area of a circle in terms of the diameter, according to the formula

$$A = \frac{R}{2} \times C = \frac{D}{4} \times \pi D = \frac{\pi D^2}{4}.$$

The value of π to twenty decimals is

3.14159265358979323846.

This value, as well as closer values, is obtained by means of series. Elementary geometry, however, affords some methods that, although exceedingly laborious, were for a long time the only ones used for the determination of π. The simplest method consists in computing the perimeters of the inscribed and circumscribed square in a circle of diameter 1; from these, the perimeters of the inscribed and circumscribed polygons of 8 sides; from these, the perimeters of the polygons of 16 sides, and so on. Since the length of the circumference lies between any two corresponding perimeters, the figures that these two perimeters have in common are figures of the number expressing the approximate length of the circumference, and, therefore, the approximate value of π, for in this case $C = \pi \times 1 = \pi$. It is found by this method that the perimeters of the inscribed and circumscribed polygons of 8,192 sides are, respectively, 3.1415926 and 3.1415928, nearly; whence it follows that the value of π, to six decimals, is 3.141593.

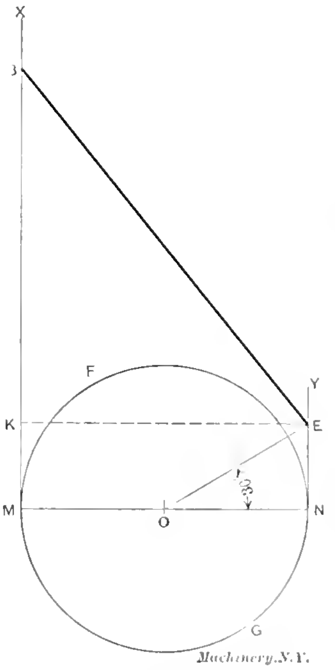

Fig. 4.

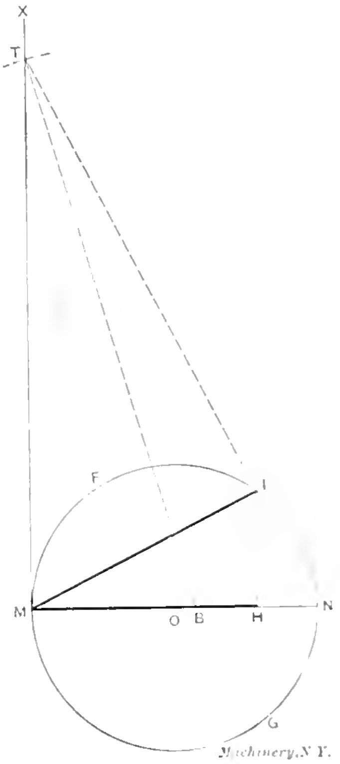

Fig. 5.

The value $\frac{22}{7}$, or 3.143, is convenient for rough calculations and estimates. A much closer value is that determined by Peter Metius in the sixteenth century; namely, $\frac{355}{113} =$ 3.1415929. The common fraction expressing this value is often used for slide-rule computations; it can be easily remem-

[illegible] applying the following rule: Write twice [illegible] first three odd numbers, thus: 113355; divide [illegible] group of figures into two groups of three figures [illegible] group, 113, is the denominator of the fraction; [illegible] group, 355, is the numerator. Since π is greater [illegible] easy to tell which of the two groups is the [illegible] and which is the denominator.

[illegible] the approximate graphic solutions, one of the simplest [illegible] in adding to 3 times the diameter one-fifth the side of the square inscribed in the circle; the result is the approximate length of the circumference. This method is equivalent to taking $\pi = 3.14142$.

A construction that gives a closer approximation than the preceding is as follows: Let *F G*, Fig. 4, be the given circle, *O* its center, and *M N* any diameter. Draw the tangents *M X* and *N Y*. On *M X*, lay off *M B* equal to 3 times the radius. Draw *O E* making an angle of 30 degrees with *O N* (which can be very readily done with a drawing triangle). The line *B E* will then be, approximately, equal to one-half the circumference. This method is equivalent to taking π equal to 3.14153, which differs but little from the usual value 3.1416.

The following construction is due to the French geometer H. Sonnet: Draw the diameter *M N* and the tangent *M X*, Fig. 5. From the center *O*, lay off *O B* equal to one-sixth the radius; from *B*, with a radius equal to twice the diameter, describe an arc cutting *M X* in *T*. Draw *T N*, intersecting the circumference in *I*. Then, the chord *M I* is, approximately, equal to the side of the equivalent square. Draw *I H* perpendicular to *M N*. Then, *M H* is, approximately, equal to the length of a quadrant, or one-quarter of the circumference. This method is equivalent to taking $\pi = 3.14158$—a very close approximation.

In practice, when the numerical value of the diameter, expressed in units of length, is known, the simplest way to lay off the length of the circumference on a straight line is to multiply the diameter by 3.1416, or, if a slide-rule is used, by $\frac{355}{113}$, and lay off the result to scale. When, however, a circle is simply given on paper (on a drawing), its exact diameter not being known, the graphic solutions are usually more convenient.

* * *

FORMULAS AND TABLES FOR HORSE-POWER OF GASOLINE ENGINES.*

MORRIS A. HALL.†

The horse-power of a gasoline engine can, of course, be figured easily enough from the well-known formula

$$\frac{P L A N}{2 \times 33{,}000}$$

in which

P = the mean effective pressure,

L = the stroke in feet,

A = the area of the piston or cylinder bore in square inches,

N = the number of revolutions per minute.

In order, however, to save calculations a table can be prepared, giving at a glance the horse-power of gasoline engines, when the bore and the stroke are known. Such a table is presented in the accompanying Supplement in Table I. This table shows the indicated horse-power or ideal power. To obtain the actual horse-power from the indicated horse-power given in the table, the figures stated must be multiplied by a factor based on the mechanical efficiency of the mechanism, which may vary from 94 to 70 per cent, and in some cases even less. As a fair average, however, 80 per cent may be used in the calculations. In the table presented in the Supplement the bore is given in the left-hand vertical column, while the stroke is given in a horizontal line at the top; beginning with a stroke which is equal to the bore, which is found in the column headed bore + zero, the stroke increases in each successive column by ¼ inch up to the final column, which is 2 inches longer than the diameter of the bore. Thus the powers given are for engines varying from 2-inch diameter by 2-inch stroke, up to 6½-inch diameter by 7-inch stroke. The figures given are, of course, for a single cylinder, and for multi-cylinder engines all that is required is to multiply by the number of cylinders. In figuring the table, the formula stated at the beginning of this article was used, the mean effective pressure being taken as 90 pounds per square inch, and the number of revolutions as 1,000 per minute. Ninety pounds mean effective pressure corresponds to a compression pressure of 68½ pounds. This may be verified by using Grover's well-known formula:

$$P = 2C - 0.01C^2,$$

where C is the compression.

This compression of 68½ pounds is taken as an average figure, but the compression may in reality vary all the way from 60 to 100 pounds, and racing automobiles have been built using a compression of 120 pounds.

As cars using 60 pounds compression, we may mention the Franklin and Covert cars; the Thomas and Meline cars use 65 pounds, while the Columbia cars use 100, and the Acme, 102. For these cases, the power corresponding may be found from the table by multiplying the figures there given by the following factors:

For 60 pounds compression, multiply by 0.933
" 70 " " " " 1.011
" 80 " " " " 1.066
" 90 " " " " 1.160
" 100 " " " " 1.111

As an example taken at random, illustrating the use of the table, let us find the power for a 5½-inch bore, 6-inch stroke, 4-cylinder engine. In the line of 5½-inch bore and in the column headed bore + ½ inch, we find the value 16.2, which, multiplied by 4, gives 64.8, as the indicated horse-power. Assuming a mechanical efficiency of 80 per cent, we get 51.8 H. P. as the actual horse-power. In Table II is given the direct or actual horse-power of gasoline engines, as figured from the empirical formula

$$\frac{D^2}{2.5} = \text{horse-power}$$

which was recently adopted by the Association of Licensed Automobile Manufacturers. This formula is based on a piston speed of 1,000 feet per minute, which gives 2,000 R. P. M. for a 3-inch stroke, 1,500 R. P. M. for a 4-inch stroke, 1,200 R. P. M. for a 5-inch stroke, and 1,000 R. P. M. for a 6-inch stroke. This table would then compare with Table I only on the basis of 1,000 R. P. M., which would give a uniform stroke of 6 inches for all engines regardless of diameter. As an example, take the same engine as above, 5½ inch diameter by 6-inch stroke, having 4 cylinders. In the table we find the horse-power given as 12.10. This, multiplied by 4 gives us 48.4, which is reasonably near the figure 51.8 for the horsepower, previously found, to indicate that the empirical formula given above is approximately correct.

* * *

Consul-General Frank H. Mason writes from Paris that some of the noticeable features at this year's exposition of automobiles in Paris was the evidence of the low-priced car, and the general attempt to reduce the price of standard automobiles, without reducing their comfort or usefulness. This reduction in price has been partly achieved by elminating unessential features, and also by improved construction tending towards simplification. Larger and more comfortable bodies have been placed on moderate sized frames; the cylinders are cast uniformly in one piece, and the motor is placed further forward on the chassis, with the radiator behind it. The gear boxes are shorter and smaller, and the cardan shaft and live axle drive are almost universally used on vehicles below 25 horse-power. Forced feed-lubrication is used on the high grade types. The high tension magneto is replacing the low tension type. Self-starting devices are common, even on medium priced cars, and the honey-combed radiators are losing ground.

* * *

The very best formal training for a young man is that of an engineer, no matter what pursuit he may follow. It establishes the true value of efficiency, the habit of orderly thinking.

CUTTING HELICAL GEARS ON THE BROWN & SHARPE AUTOMATIC SCREW MACHINE.

The ribbon spools of a certain typewriter are rotated by a system of shafts and gearing, which includes a pair of small spiral gears—or helical gears, rather, to be exact. These, until recently, were cut on small hand-operated gear-cutting machines of special design, which performed the operation in the same way that helical gears are cut in a milling machine; that is to say, the blank was fed forward and rotated at the same time under a revolving formed cutter. It was then returned to the starting position again, indexed and fed forward for a second cut—and so on until all the teeth were formed. Having had some previous experience in cutting triple worms for gas meters in the automatic screw machine, the Brown & Sharpe Mfg. Co. undertook to cut these helical gears in the same way. The tools and operations employed for this work are herewith illustrated and described. The effectiveness, rapidity, and comparative simplicity of the mechanism employed, will at once appeal to the mechanical mind; and the job, as a whole, is a first-rate piece of evidence of the versatility of the automatic screw machine.

Helical Gear Generating Tool for the Screw Machine.

The machine is shown rigged up for producing helical gears in Fig. 1. Figs. 2 and 3 show front and rear views of the tooth-generating tool, and Fig. 4 shows details of its construction. The principle of its operation will best be understood from the latter engraving.

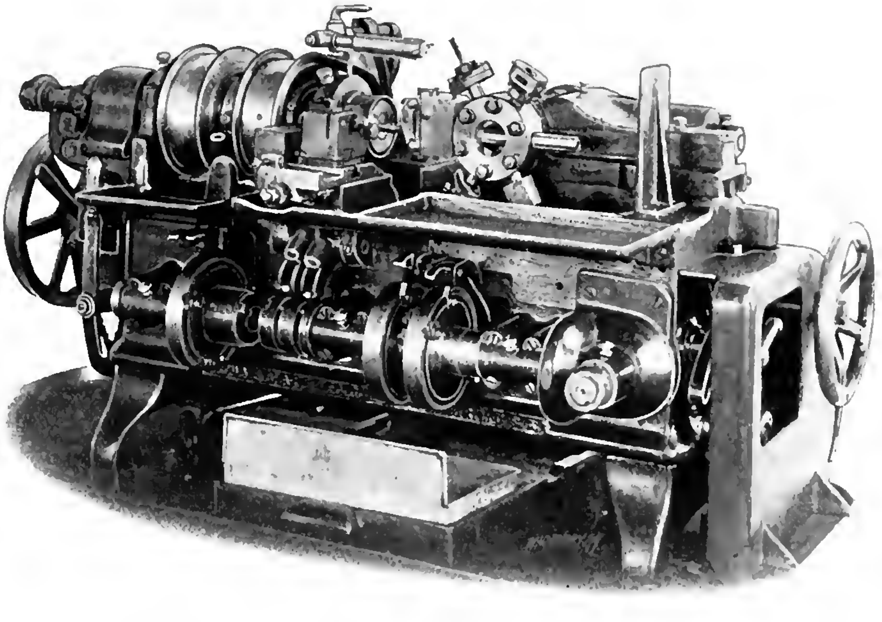

Fig. 1. An Automatic Screw Machine, arranged for Gear Cutting.

When this tool comes into action, the blank has been formed in the machine to the condition shown at *D* in Fig. 5. The hole has been drilled and reamed and the outside diameter formed to the required dimensions. When the tool is brought up to the work the three-cornered driving center *G* enters the drilled hole, and is thereby caused to revolve with the blank. As it is screwed firmly into the long driving gear *H*, this latter is also set in motion in unison with the spindle of the machine. Gear *H* has helical teeth cut on it engaging mating teeth in helical gear *J*, which is mounted on a short horizontal shaft having spur gear *K* keyed to it at the rear end. This gear, through a large idler *L*, drives gear *M*, which is keyed to the cutter spindle *S*. Cutter *N* mounted on the spindle has the form of a helical gear properly cut to mesh with the gear to be formed. It is made of hardened tool steel and is ground on one face, which face is set as shown in the end view, so that it is in the plane of the axis of the work. By means of the train of gearing just described, it will be seen that cutter *N* may be caused to revolve in unison with the work as though it were in mesh with the latter after the teeth have been cut.

Driving center G and the front bearing of gear H are supported in a sliding bushing O seated in the body P of the tool. A plunger Q in the shank of the tool is pressed by a long and stiff spring against the end of the bearing of H. This serves to keep G pressed into the hole in the work. As the tool advances over the work, G and H are forced back with relation to the holder, remaining stationary so far as endwise movement is concerned with relation to the work. The thrust between *Q* and the end of *H* is taken by a hardened ball pivot bearing as shown, so that the friction is inappreciable. The extended lip on the bushing *O* is simply for the purpose of providing the long keyway shown, which engages a pin in the body *P* to prevent *O* from turning. When the tool is not in contact with the work, screw *R* limits the outward movement of *G*, *H*, and *O* produced by spring plunger *Q*.

The Operation of Cutting the Teeth.

Consider now that we have a gear blank in the machine with the teeth all cut but not yet severed from the bar, and suppose the cutter *N* to be meshed with it as shown at *D* in Fig. 5. Suppose further that the spindle of the machine has been stopped. If now the turret slide be moved forward or back from the position shown, so that tool *P* is pushing forward or back over the work, center *G* and gear *H* remain stationary with reference to the work, but move back and forth with relation to the tool-holder. This axial movement of gear *H* will evidently rotate helical gear *J*, which, through the train of spur gears *K*, *L* and *M* will in turn rotate the cutter *N*. The ratio of this train of gearing is such that the rotary movement given to *N* by the longitudinal movement of the tool-holder in either direction keeps it exactly in step with the teeth of the work. Thus the movement of the turret slide rolls the cutter on the work just as if the latter were mounted perfectly free on its axis and were rolled by the teeth of the work itself, instead of through the train of gearing described.

Consider further, with the cutter and work set in the relation shown in Fig. 5, that the turret slide of the machine is fixed in position, but that the spindle and the work is rotated. The rotation of the gear revolves the three-cornered driving center *G*, which, in turn, transmits its motion to gear *H*, and thence to gears *J*, *K*, *L*, *M*, and cutter *N*. The ratio of this train of gearing is again such that the rotary movement thus given the cutter is in the proper ratio to keep the latter in step with the teeth cut in the work, so that the work and cutter revolve together as if they were a pair of helical gears driving each other, with no connection through the train of gearing.

It has thus been shown that the cutter will be kept in step with the work if the tool is moved axially back and forth over the work while the latter is stationary. It has also been shown that the cutter will keep in mesh with the work, while the latter is revolving and the turret slide and the tool are stationary. Since the cutter and work are kept in step under these two conditions separately, they are still in step when the two movements are combined. This tool and its arrangement of gearing can thus be moved back and forth over the revolving work without throwing the teeth in the cutter and the teeth in the work out of step with each other. This always supposes, of course, that the tool is not moved back so far that driving center G loses its contact with the work, as the proper meshing of the cutter depends on the driving connection between G and the blank. If G is ever moved back out of contact with the blank, this con-

nection is broken and when the cutter is again moved forward onto the work, it will probably be found out of step.

The action of cutter *N* will be readily understood now that the method of driving it has been explained. The face, which is in the plane *x—x* of the axis of the work, as shown in the end view of Fig. 4, is the cutting edge. As the tool is forced onto the work, this revolving cutting edge, having the exact shape of the helical gear which is to engage with the work, cuts teeth of that exact shape on the blank as it is gradually forced over it. In other words, the operation is an example of the molding-generating principle, the cutter *M* molding the proper surface to mesh with its own teeth.

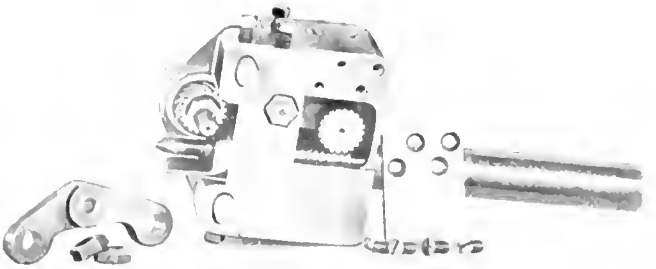

Fig. 2. Front View of the Helical Tooth Generating Tool.

Details of Construction of Generating Tool.

The various adjustments of the tool may be understood by reference to Figures 2, 3 and 4. The shank of the tool is made very long, as may be seen also in Fig. 1. This permits the use of a spring for plunger *Q* long enough so that its pressure will not be materially greater when the cutter is pushed clear over the work at the completion of the cut, than when center *G* first enters the hole in the work. If the pressure should materially increase, there would be danger that *G* might be pressed further into the edge of the hole, thus disturbing the axial relation of *G* and the blank, and consequently throwing the cutter and the work out of step with each other by that amount. The use of the long spring avoids the possibility of trouble on this score.

The cutter spindle *S* is mounted in bronze bushed bearings in front and back plates *T* and *U*, which are clamped together and to the body *P* of the tool by studs and nuts *V*. These studs, as is most plainly shown in the sectional view in Fig. 4, pass through elongated slots in the body so that the cutter spindle may be adjusted for a larger or smaller diameter of work by means of set-screws *W*, the adjustment being locked by nuts *V*. This adjustment would, of course, disturb somewhat the correct meshing of gears *L* and *M*.

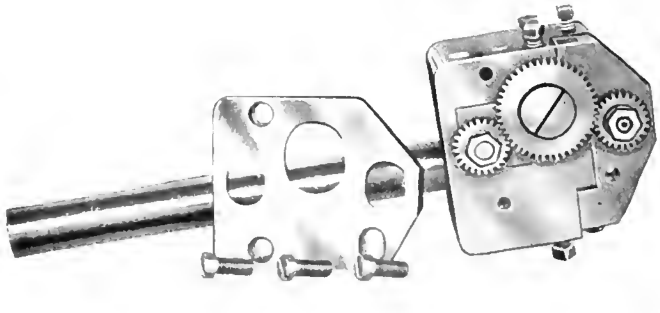

Fig. 3. Rear View of Generating Tool with Gear Guard Removed.

Gear *L* is therefore mounted on a stud *X* which floats in an enlarged hole in the body, and so may be adjusted by means of suitable set-screws which bring it into proper mesh with both *M* and *K*. The shaft on which the latter is mounted is also carried in a sliding block *Y*, by means of which gears *J* and *H* can be moved into closer or freer mesh. After the cutter has been set to the proper diameter for the work, the whole system of gearing may thus be adjusted to mesh without discoverable back lash and without binding. It is advisable to have as little back lash as possible between the cutter and the driving center to prevent the former from jumping or chattering when first commencing the cut. When there is much back lash the ends of the teeth where the cut commences are not formed to quite the proper shape. While there is no great harm in this in the case of a helical gear, in which the contact takes place in the center of the face, it gives a poor appearance to the work, and so should be avoided.

The thrust of the revolving work, pressing down on the cutter when the tool is in action, is taken by a ball bearing at *Z*. This is the only point where there would be any great danger of excessive friction so that the probability of *G* slipping in the work, due to too great a resistance in the mechanism it has to drive, is obviated. As was explained earlier, for the desired action, the cutting edge of the cutter must be in the plane of the center line of work. In the tool shown, no special provision is made for maintaining this condition. As the face of the cutter is sharpened it is necessary to pack it out with filling washers. In later designs, adjustments are provided for bringing the cutting point on a line with the center.

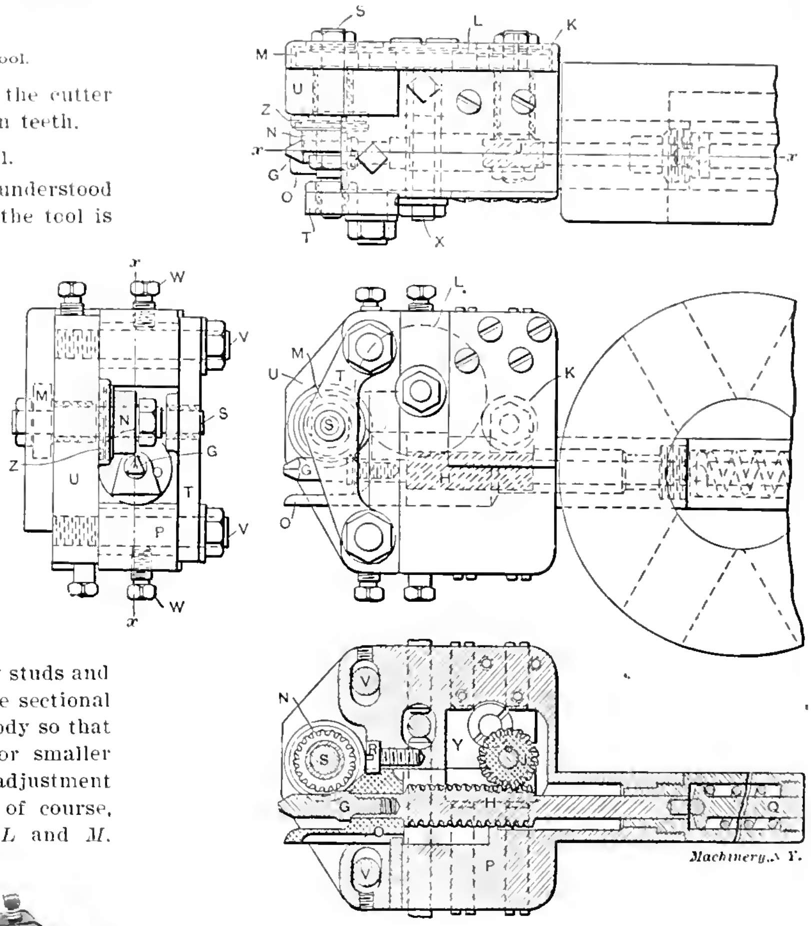

Fig. 4. Details of Construction of Generating Tool.

Order of Operations in making the Completed Gears.

The order of operations followed is shown in Fig. 5. The part to be made is shown with dimensions at the bottom of the engraving. The first operation after feeding the stock is centering and facing, as shown at *A*. This is done with a tool held in the turret, and shown pointing upward to the right in Fig. 1. The turret is next revolved two holes, and the drill is brought into action. Then the turret is revolved again and the hole is reamed. The reamer is mounted in a "floating holder" seen pointing downward to the left in Fig. 1 (the turret revolves in a counter clock-wise direction). This form of holder enables the reamer to be centered accurately, so that it will cut to size and take off an equal amount with all of its teeth. While the drilling and reaming are going on, the blank is being formed by a circular form tool mounted in the front cross slide, as shown at *B* and *C*. The operation of cutting the teeth at *D* has already been sufficiently described. At *E* the hole is being

counter-bored. This counter-boring incidentally removes the marks made by the sharp corners of driving center *G*. At *F* the completed piece is being severed from the bar. While the counter-boring is in progress, and during the first part of the cutting-off operation, the front form tool as shown at *E* and *F* is again brought down to clean off the burrs produced by the gear cutting tool.

Fig. 5. The Order of Operations and Rates of Feed.

A pair of finished brass gears made by this process and mounted in a little angle plate is shown, as an initial piece at the beginning of this article. A few of these were made up to exhibit the work of this machine and the set of tools provided for it. The writer, who has one on his desk, can swear to its being a very attractive plaything. The little gears mesh smoothly with each other, and appear to be finished, on the whole, rather better than would be the case had they been shaped by a formed cutter as usual. There appears to be almost no limit to the possibilities of the automatic screw machine in the hands of a resourceful designer, and this little exhibition set of gears serves very well as a reminder of that fact. R. E. F.

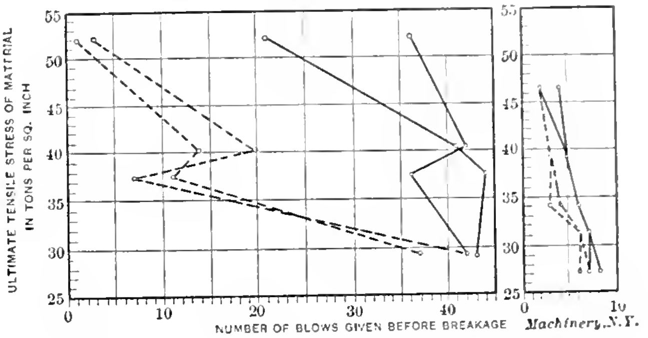
COMPARISON OF STRENGTH OF THE U. S. AND THE WHITWORTH STANDARD THREADS.*

Strength is a very important feature of screw threads, and many experiments have been made with regard to it. There appears to be little doubt that bolts provided with the Whitworth thread are stronger than those provided with other standard screw threads. Experiments have been carried out in connection with the work of the Engineering Standards Committee of Great Britain, which indicate the difference in strength of the Whitworth and the U. S. or Sellers forms of screw threads. The tests were shock tests, and must be considered as conclusive, because in every case the Whitworth thread sustained a greater number of blows before fracture than the U. S. thread. The experiments were carried out by dropping a 400-pound weight through a distance of three inches, and also through a distance of twelve inches, and then recording the number of drops required before fracture occurred. In order to make the tests as authentic as possible, each set of screws compared were made from the same bar.

In the accompanying diagram, Fig. 1, are shown the results of the three-inch drop tests. The graduations on the base line show the number of blows given to the specimen before fracture occurred. On the scale to the left is given the ultimate tensile stress of the material from which the screws were made, in tons per square inch. It is interesting to note that the strength of the U. S. thread more nearly approaches the strength of the Whitworth thread when only mild steel is concerned; the higher the ultimate breaking stress, the greater advantage does the Whitworth form show over the U. S. form of thread. In Fig. 2 are shown the results obtained in the twelve-inch drop test. It will be noticed that in this case the difference, as a rule, is smaller, but the Whitworth thread maintains its advantages in strength, although not in so marked a degree as in the shorter drop tests.



Figs. 1 and 2. Shock Tests on Bolts with U. S. and Whitworth Standard Threads.

In the diagrams, the results obtained in the tests of specimens threaded with U. S. standard thread are shown by dotted lines, and the results of the tests of specimens threaded with Whitworth thread, in full lines. The two lines shown for each indicate results of two sets of tests on eight bolts each. The results of the individual tests are shown by the small circles, and these have been connected by the lines merely to show at a glance which circles refer to the same set of experiments.

* * *

The headings of one of the twin tubes under the Hudson River, connecting New York (Hudson Terminal) and Jersey City, were joined January 27, and the event was celebrated by an official inspection trip. The approximate distance between the terminal in Jersey City and the Hudson Terminal at the foot of Cortlandt St., New York City, is 6,000 feet. It is expected that both tubes will be completed and the system in operation about July 1, 1909. The headings of the second tube were joined March 11.

* From an article by Mr. H. F. Donaldson in *Engineering*, February, 1909.

MACHINE SHOP PRACTICE.*

CYLINDRICAL GRINDING 1.

The grinding machine is one of the most useful tools found in a modern shop, for with this tool it is possible to finish a considerable variety of work in less time than is required when a lathe is used, and, in addition, the quality of finish and degree of precision attained are such as to make the production of interchangeable parts comparatively easy. The grinder is not only a tool for finishing hardened work and work requiring great accuracy, as it is widely used for finishing general machine details which have been previously roughed out in the lathe.

Cylindrical grinding machines, like milling machines, are divided into two general classes, known as plain and universal grinders. The first type is used for grinding work in large quantities, which varies comparatively little in form, which means that it is essentially a machine for manufacturing purposes. The general construction of the universal grinder is similar to that of the plain grinder, but it differs from the latter in having certain special features and auxiliary attachments which adapt it to a more general or universal class of work. Such a machine, as built by the Landis Tool Co., is illustrated in Fig. 1. With this particular type of machine, the platen *A* remains stationary, while the revolving wheel *B* is traversed past the work, which is mounted between the centers of the head- and tail-stock *C* and *D*. The length of the stroke of the wheel carriage is regulated for work of different lengths by varying the position of the dogs *E*, which are mounted on the dog-wheel *F*. On the periphery of this wheel worm-teeth are cut, and the dogs are held in any desired position by worms *G*, which may be lifted out of engagement with the wheel when the dogs are to be moved a considerable distance. The tappet *H* against which these dogs strike, thus reversing the movement of the carriage, can be swung out of the way when it is desired to let the dogs pass, so that the work being ground may be inspected or measured. The amount that the wheel carriage moves longitudinally per revolution of the work is regulated by changing the position of the lever *I*. The lever *J* is used for reversing the carriage at any point, by hand, while the traverse is started or stopped by lever *K*. When it is desired to move the carriage longitudinally by hand, the wheel *L* is used. The platen *A* may be swiveled about a central stud when grinding taper work between the centers, unless the taper be too great, when the lower wheel slide is set to the required angle. There are two sets of graduations on the end *M* of the platen, one giving degrees and the other the taper (by eighths) in inches per foot. It might be mentioned that the graduations on grinding machines are only intended to give an approximate setting, gages and micrometers being used to test the accuracy of both taper and straight work. When slight adjustments of the platen are found necessary, the fine adjusting screw *N* is used. It will be noticed that there are two pulleys *O* and *P* mounted on the head-stock. The first is for driving the head-stock spindle when grinding work held in a chuck (which replaces the pulley *P*) or when driving large work held between the centers; but as it is advantageous to grind most work on dead or stationary centers the loose pulley *P* is provided, which simply revolves upon the head-stock spindle, which is then locked. The object of grinding work while it revolves on stationary centers is to secure accuracy, as then any slight error which may be in the spindle bearings is not reproduced in the work. As it is often necessary to grind the sides of milling cutters, disks, etc., which must be held in the chuck, the head-stock is made to swivel and is provided at *Q* with graduations in degrees. The emery wheel is moved to or from the work by the hand-wheel *R*, which is graduated to indicate reductions of 0.001 inch in the diameter of the work. In conjunction with this hand-wheel there is a feed which is actuated at the end of each stroke and which may be set to advance the wheel at each reversal from 0.000125 to 0.0025 of an inch; the corresponding reductions in the diameter of the work are, of course, equal to twice this amount. This feed is effected by the pawl *A* (Fig. 2) which meshes with ratchet teeth in the periphery of the wheel *R*. Provision is made for automatically disengaging this feed when the wheel has ground any predetermined amount (within 0.00025) from the work. This is accomplished by a removable ring *B*, mounted on the hand-wheel, which has attached to it a knock-out cam *C*, which engages with the pin *D* on the pawl *A*. When setting this feed to grind a given amount, the wheel is first brought into contact with the work, by turning the hand-wheel *R*; the ring *B* is then moved around until the cam *C* is against the pin on the pawl *A*. As the machine makes its first stroke the pawl is disengaged from the ratchet. The wheel should then be allowed to pass over the work until it has practically ceased cutting, when the traverse should be stopped, say at the foot-stock end. The diameter of the work is next measured carefully with a micrometer. The thumb-latch *E* is then pressed against its stop four times for each 0.001 inch reduction in diameter required. As this thumb-latch has attached to it a spring pawl *F* which engages with the ratchet teeth on the wheel *R*, the ring *B*, with its knock-out cam, is moved away from the pawl, each time the latch is pressed an amount equivalent to one ratchet tooth, which means that the emery wheel will be fed in 0.000125 inch farther before the feed is automatically thrown out. Hence the latch is pressed once for each 0.00025 inch reduction in diameter required. After the feed is set to grind the required amount, the cut should be continued until the wheel has practically ceased cutting, when it should be stopped at the foot stock end as before, and the work again measured. If the wheel used is adapted to the work, and the relative speed of wheel and work are at least approximately correct, the reduction in diameter will be equivalent to that for which the feed was previously set, providing the amount of metal removed is not too great, for in that case the work will be large, owing to the wear of the wheel.

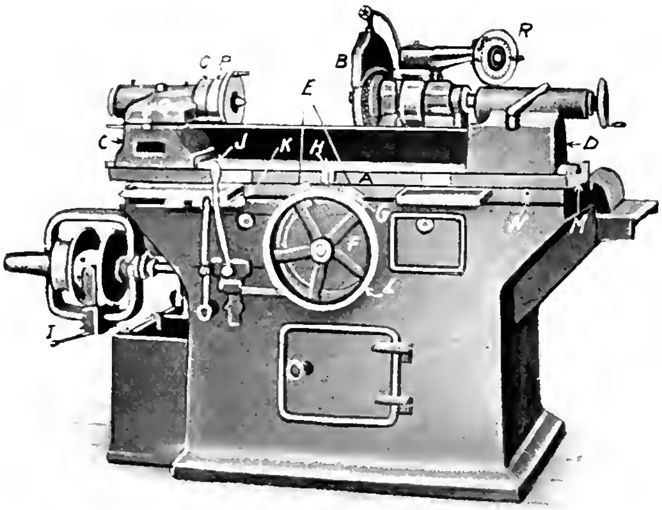

Fig. 1. A Universal Grinding Machine built by the Landis Tool Co.

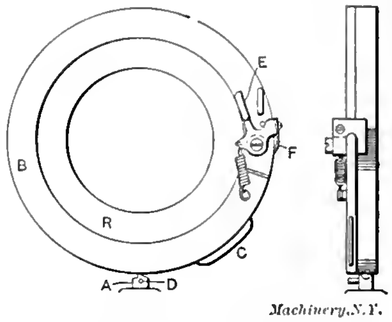

Fig. 2. Mechanism for Setting the Automatic Feed to grind any Predetermined Amount.

If satisfactory work is to be done in the grinder, it is absolutely essential that the grinding wheel be of a grade and grain which is best adapted to the material to be ground. Grinding wheels are composed of a large number of grains or kernels of some suitable abrasive material, such as alundum or corundum, which are held together by what is known as a bond. By varying the amount of this bond, wheels of different grades are obtained. The term grade does not refer to the degree of hardness of the abrasive, but to the

---

* With Shop Operation Sheet Supplement.

tenacity with which the bond holds the grit in place, and it is designated by the letters of the alphabet; *A* being extremely soft, *M* medium, etc. The grain or coarseness of a wheel is designated by numbers which indicate the number of meshes to the square-inch through which the kernels of grit will pass. The degree of hardness and the kind of material to be ground are factors which determine the grade and grain of a wheel. For example, machinery steel requires a harder wheel than does hardened tool steel. The reason for this will perhaps be better understood if we think of an emery wheel as a cutter having attached to its periphery an innumerable number of small teeth, for this is literally what the thousands of small grains of abrasive are. When the wheel is of the proper grade, these small teeth or kernels of grit are held in place by the bond until they become slightly dulled, when they are torn out of place by the increased friction. Obviously, these grains or cutters will become dulled sooner when grinding hard than when grinding soft steel; hence the harder the material the softer the wheel, and *vice versa*. When a hard wheel is used for grinding hard material the grit becomes dulled, but it is not dislodged as rapidly as it should be, with the result that the periphery of the wheel is worn smooth or glazed, so that grinding is impossible without excessive wheel pressure. Soft materials, such as brass, however, are ground with a soft wheel, which crumbles easily, thus preventing the wheel from becoming loaded or clogged with metal, as would be the case were a hard-bonded wheel used. When a wheel is used which is too soft, the wear is, of course, greatly increased, as the particles of grit are dislodged too rapidly, and consequently the wheel is always "sharp." This means that the abrasive has not done sufficient work to become even slightly dulled, and the result is a rough surface on the work.

The area of the surface which is in contact with the wheel is also a factor which should be considered when selecting the proper grade. As the contact area increases as the diameter of the work increases, the wheel should be correspondingly softer because the grit is more quickly dulled by this greater contact. The grain or degree of coarseness of the wheel is another item which should be considered in making a selection. Generally speaking, coarse wheels are better adapted to most work, as deeper cuts may be taken, and, in addition, the work is kept cooler because of their porosity. When a very fine finish is required, however, particularly on a number of duplicate pieces, fine wheels are often used to advantage for finishing, after the work has been ground to within, say 0.003 inch of the required size, with a coarse wheel. If little stock is to be removed from a hard surface, however, the coarse wheel could be dispensed with and a fine wheel used to advantage, as the wear of such a wheel is less, though the tendency to burn the work is greater, as the water (a copious supply of which should always be used) does not reach the grinding parts so easily. There is, of course, an advantage in using one wheel for both roughing and finishing, and a coarse wheel, say of 36 grain, will produce a finish fine enough for most purposes, if the work speed is reduced somewhat, and the wheel is trued with the diamond just before taking the finishing cuts.

Proper preparation of the work is another important item in connection with grinding which should be considered. The machine centers should be accurately ground to an angle of 60 degrees, but it is also essential that the centers in the work be true, to the proper angle, and clean when the work is placed in position. Parts which have been hardened (such as the mandrel illustrated in the Shop Operation Sheet accompanying this issue) prior to grinding, are occasionally so distorted by this hardening process that they cannot be finished to the required size. Straightening can then be resorted to, but this should not be done while the work is cold, as there is always a tendency for it to resume the original shape, owing to internal strains, and even if properly heated there is more or less danger of such distortion. When necessary to straighten hardened work it should always be heated, though not enough to anneal it, and then straightened in a press. By proper annealing prior to the hardening process the tendency of the work to spring out of shape is often overcome. This annealing, which releases the internal strains incident to the rolling or forging operations, should take place after the outer surface has been removed in the lathe, then if the work when tested runs practically true it may be machined to the grinding size, which, for a mandrel such as illustrated on the Shop Operation Sheet referred to, would be about 0.010 or 0.012 inch above the finish size. If, however, the test should show that the piece was badly warped, it should be heated to a cherry red, straightened, and then annealed as before.

Whenever possible, grinding should be the last operation performed so that the work will not be marred or sprung out of true. Key-ways in shafts, etc., should invariably be finished prior to grinding, as the removal of metal for the key-way from one side of the shaft will often distort the latter. The machine itself should be carefully examined frequently, as its efficiency often depends upon a little intelligent care. The bearings of the head- and tail-stock spindles, and particularly those of the wheel spindle, should be carefully adjusted to eliminate all lost motion, and the cross-slide for the wheel should also be adjusted and oiled so that there will be that perfect freedom of movement which is necessary if this part, as is often required, is to move as little as one-eighth of one-thousandth of an inch with accuracy.

A continuation of this article will appear in the May issue, which will also be accompanied by a Shop Operation Sheet giving an example of cylindrical grinding.

THE PUNCH THAT WAS "PINCHED."

C. TUELLS.

Jim was master mechanic at the old novelty shop when it was located just back of Chinatown in the dirtiest section of one of Boston's poorest streets. The novelty shop made most anything that could be made cheaply with sheet brass and punch presses, and many were the ragged youngsters who played under its windows and went through the scrap barrels for souvenirs.

"Running up the street at full speed was a ragged urchin with Jim's punch in his hand."

Although Jim was master mechanic he didn't travel around the shop with a slide rule in his hand, figuring out speeds and timing the presses, and looking for trouble in general. Jim's trouble all came to him, for all the mechanical work of the shop between the toolmaker and the presshands fell at his door; in fact Jim was the general utility man of the press room. If a punch needed grinding, Jim ground it; if a die was to be set, Jim set it; if a countershaft needed adjusting, why send for Jim, of course.

The novelty shop was a small affair, and the tool room was in proportion; one toolmaker did all the work, but when

times were [illegible] he sometimes had to turn up his sub-press pins while the shaper was running a long cut over a die blank in order to keep ahead of the job.

Well, one day Jim was setting up a new die in the punch-press, and, like every other new job, a few little things had to be done before the punchings came out satisfactory, and among these things half an inch had to be sawed off the end of the punch shank, which was, as the Irishman said, "too long on one end." It was only nine-sixteenths inch diameter, so Jim, anxious to get the job going, hustled over to his bench vise, gripped the punch and started his hack-saw going to the tune of "Yankee Doodle," one eye on his work and the other through an open window on a group of ragamuffins playing tag in the street below.

Jim was in a hurry. He thought (as we all thought once) it would be quicker to break the last quarter-inch, so holding the surplus end that he *did not want* in the vise, he hit the punch a much misjudged and mighty blow with his two-pound hammer. It broke—and the punch went sailing through the window into the middle of the street.

Jim looked out the window just in time to be too late, for running up the street at full speed was a ragged urchin with Jim's punch in his hand, and a broad grin on his face. Pursuit was useless, for before Jim could get to the street the boy was out of sight, and most of his comrades as well. The punch never came back. After trying to explain the situation to the boss, the toolmaker, much to his disgust, had to drop everything and put in the rest of the day getting out a new punch.

Jim is wondering to this day whether that punch found its way to the cupola of some iron foundry by way of the "junky," or if it still reposes among that particular youngster's treasures. Jim now holds the end of the punch that he *wants* in the vise before breaking, because—well, "there's a reason."

* * *

POWER OF INSURANCE COMPANIES TO IMPROVE LIVING CONDITIONS.

The power of the casualty insurance companies of the United States is being employed to improve the working conditions in factories and reduce the great number of accidents to life and limb that makes America an industrial slaughter house. A further development of the great work of the insurance companies in this line, of much broader scope, is proposed, which is hoped will improve living conditions and materially increase human longevity. It has been shown by the work of Col. Gorgas in Havana, Cuba, that the improvement in sanitation tremendously decreased the death rate. The death rate in Havana was cut in two, being brought down to about twenty-four deaths per thousand per year. In New York City it was materially decreased by Col. Waring's street cleaning crusade. Of course, it is to the material advantage of the casualty and life insurance companies to reduce the number of accidents in manufacturing establishments and to improve general sanitary conditions throughout the country, and this work of enormous scope, if undertaken, would be undertaken on the basis of good business policy alone. The life companies may aim to stamp out the great scourges, typhoid fever and tuberculosis, both preventable, one being caused almost entirely by infected drinking water and the other by bad housing. The reduction of accidents and increase in length of life would reduce the amount of claims and increase profits, but all true philanthropy has practically the same result. The improvement of living of the poorer classes reacts favorably on general conditions and increases common prosperity.

* * *

A novelty which has come into use in a number of British drafting-rooms is the employment of "cross-section" tracing cloth for detail drawings. The tracing cloth is ruled with vertical and horizontal lines one-eighth of an inch apart, in the same manner as ordinary cross-section sketching paper. It is claimed that the use of this kind of tracing cloth is the source of considerable saving in time, as it is easier to terminate lines at correct points and it makes it possible to draw simple details directly on the tracing cloth.

IMPROVEMENTS IN HIGH-SPEED STEEL.

Recent advances in the manufacture of high-speed steel have enabled the Firth-Sterling Steel Co., of McKeesport, Pa., to obtain results with their "Blue Chip" steel in every-day machine shop work, which are believed by the makers to mark a definite advance in machine shop practice. These improvements have resulted in a steel that is less affected by the heat of the cutting action, and so is capable of increased cutting speed and longer life. For finishing cuts on fine-grained metals, it is hardened in air or in oil, though for roughing work, or cuts in coarse-grained metals in general such as cast iron, it can be quenched in water the same as old-fashioned tool steel. For hardening, it is heated to the extremely high temperature required by all high speed steels.

To bring the advantages of this new product to the attention of manufacturers, Wheelock, Lovejoy & Co., of Boston, Mass., and New York City, agents for the Firth-Sterling Steel Co., have been giving exhibitions of its work in Worcester and Springfield, Mass., and Providence, R. I. The three half-tone engravings shown herewith were made from photographs taken in the plant of the Baush Machine Tool Co., where the Springfield exhibition was held. In Figs. 1 and 2 is shown the "Lo-swing" lathe (built by the Fitchburg Machine Works, Fitchburg, Mass.) engaged in rough turning spindles for a large size of the Baush multiple spindle drill. These spindles are of 45-point carbon steel and have the dimensions shown in the sketch in Fig. 3. The "Lo-swing" lathe, as is well known, is particularly adapted to the rapid turning of bar stock, being arranged to use as many tools for this work as may be required by the number of diameters and shoulders to be turned. In the case shown two chips are taken, the first reducing from 2¾ inches to 1¾ inch, and the second making a further reduction to 1½ inch for a short distance, as shown in Fig. 3. The rear of the lathe, in Fig. 1, shows the work just before the second tool comes into action, while Fig. 2, taken from the front of the machine, shows the conditions at the completion of the cut. The figures given for this cut in 45-point carbon steel are: 165 revolutions per minute, giving a surface speed of about 120 feet per minute; feed, 75 revolutions per inch; length of time required for taking cut, about 4 minutes and 50 seconds. These feeds and speeds on this metal are claimed by the makers of the steel and the builders of the lathe to be obtainable in common, every-day practice. Results much more spectacular than these could be and have been obtained for exhibition work, but they are not considered practicable for recommendation as standard shop practice.

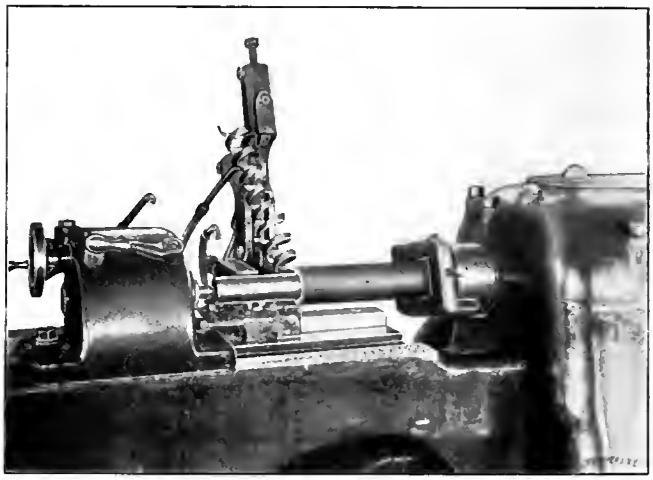

Fig. 1. Taking a Stiff Chip on the "Lo-Swing" Lathe with "Blue Chip" Steel.

The steel makers state that the "Lo-swing" lathe was selected for this test because it is capable of putting a lathe tool to more severe service than any other machine that had been met in their experience in selling tool steels. They, in common with other steel makers, had been previously unable to furnish cutting tools which came up to the possibilities of this machine. The way in which the work and the tool are tied together, and the rigid support for both, make the action one of pure cutting only, so the size of chip taken is

limited purely by the heat resisting qualities of the metal and the strength of the work, instead of by the breaking of the cutting edge from chattering and vibration, as is common in the standard lathe. Of course, cuts comparable with that here described have been taken from heavy forgings on lathes of great size and weight, but the size of the machine employed should be taken into account in making comparisons.

An improvement in a tool steel which increases its capacity of resistance to heat gives it a greater advantage than is indicated by this fact alone. A tool deteriorates, so far as heating is concerned, from the fact that it is unable to carry the heat away fast enough through the blade and shank to prevent the cutting edge from reaching a dangerous temperature. This heat-carrying capacity may be increased by using a blunt cutting edge, which furnishes a larger body of conducting material for the blade. Owing to the heat-resisting qualities of the improved steel, this cutting angle can be greatly reduced, making the action more knife-like. This, in turn, reduces the heat generated per cubic inch of metal removed, since less work is done in shearing the metal, the action being more nearly the ideal one of slicing it off. This advantage of the sharper cutting angle gives the further advantage of less power consumption per cubic inch of metal removed per hour, so that there is a gain in every direction. In the particular lathe shown, also, it should be considered that the design is such as to permit the use of more acute cutting angles with any steel than is ordinarily possible with the standard lathe.

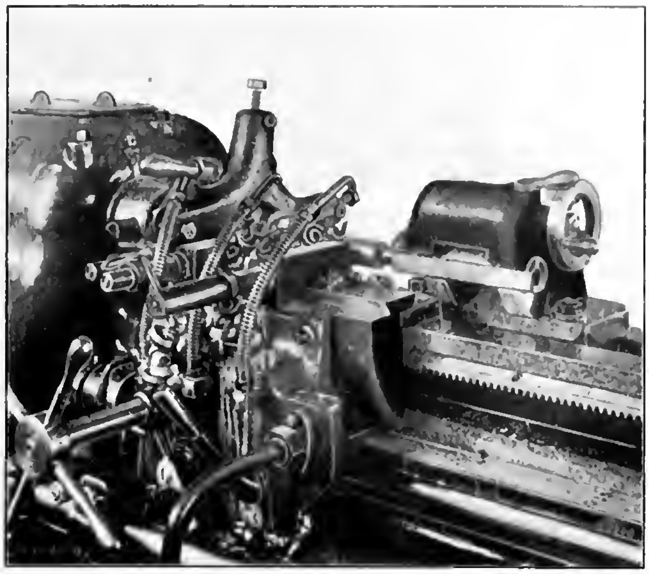

Fig. 2. Front View of Lathe at Conclusion of Cut.

An interesting point as to the use of water or other cooling compounds for turning, was mentioned by Mr. Juthe, who had charge of the exhibition. This relates to the most effective point to apply the cooling liquid. Mr. Fred W. Taylor advises that it be directed on top of the chip, over the top face of the tool. In work of the kind here illustrated, however, it has been found that the important point is to keep the work itself cool. If the tool is cutting in cold metal, its action is satisfactory and the edge is durable. If, however, it is cutting in metal already highly heated, it has been found impossible to cool it properly by directing the stream against the already severed chip. That the plentiful supply of cooling liquid furnished in the machine shown is effectual in cooling the work is evidenced by the fact that it is not found necessary to readjust the tail-center during the course of a high-speed cut in which much heat is generated

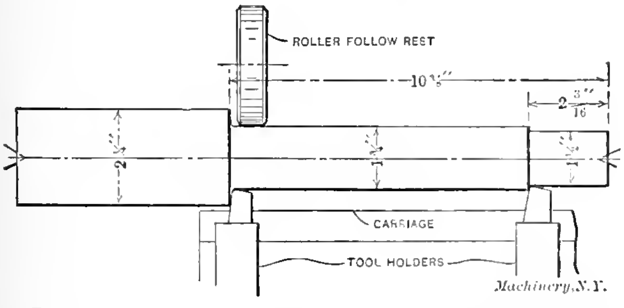

Fig. 3. Dimension of Work and Arrangement of Tools in Fig. 2.

Fig. 4 shows an unusually interesting planer, which was also used at this same exhibition. This planer is built by the Powell Tool Co., of Worcester, Mass., and employs the ingenious principle of an accelerated speed *on the cutting stroke*. So far as we know, this is the first planer built employing this principle. In action, the cutting tool first enters the work at the ordinary cutting speed or slightly less, and, when well started, is accelerated to a much faster rate of travel. At the end, before running out of the metal, it is again slowed down to the medium speed just before reverse. This has the advantage of starting in a heavy cut slowly, without danger of breaking the tool, and still permitting the highest practicable speeds to be taken during the main part of the cutting action. The slowing down before the cut runs out has the advantage of preventing the breaking out at the ends which is otherwise inevitable on heavy cuts. For the occasional work in which the cut is not continuous, but passes over a succession of cuts with intervening clear spaces, the accelerated mechanism may be thrown out by the simple shifting of a lever, permitting the planer to operate in the ordinary way. The increasing of the speed during the cutting action increases the output of the planer very greatly, as compared with the increase obtained by accelerating the return stroke, to which the most attention has been given by designers of planers. The accelerating mechanism is of very simple construction and does not require an extra belt. The design appears to have been worked out in a very simple and effective manner.

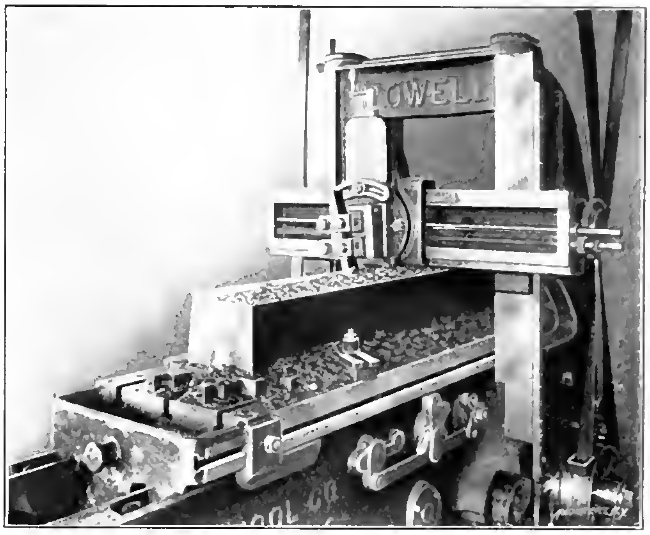

Fig. 4. The Powell Accelerating Cut Planer.

It will be interesting to compare the steel exhibited at this demonstration with the new English water-hardened tool steels, about which so much has been written lately, as soon as the latter reach the American market, and are used sufficiently to get a thorough understanding of their capabilities.

* * *

A large hydro-electric power plant will be erected by the Grand Falls Power Co. on the St. Johns River at Grand Falls, New Brunswick. The contract for the construction work has recently been placed with the Frank B. Gilbreth organization of New York. The plant will generate 100,000 H. P. electric current, which, it is stated, will be furnished to cities in New Brunswick and Maine. The work involves the construction of a number of shafts in rock excavation 130 feet deep, a power chamber 30 x 260 feet and 130 feet deep, and a tail race tunnel 28 feet in diameter and 2,400 feet long, and also a power house 350 x 260 feet. The intake shafts will be nine in number, the diameter of each being 12 feet. The total head developed at this place is 135 feet. Numerous auxiliary structures, sub-stations, and long distance transmission lines will also be erected and the total expenditure is estimated at over $5,000,000.

LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

CHART FOR THE COST OR PURCHASING DEPARTMENT.

The accompanying chart is very useful in the drafting-room, cost, or purchasing departments. When ordering stock or checking up to see if enough material is on hand, a glance from the drawing to the chart is all that is needed. The inner circle of figures is for the length in inches of the piece required; while the figures on the outside give the number of linear feet of stock necessary to make 100 pieces.

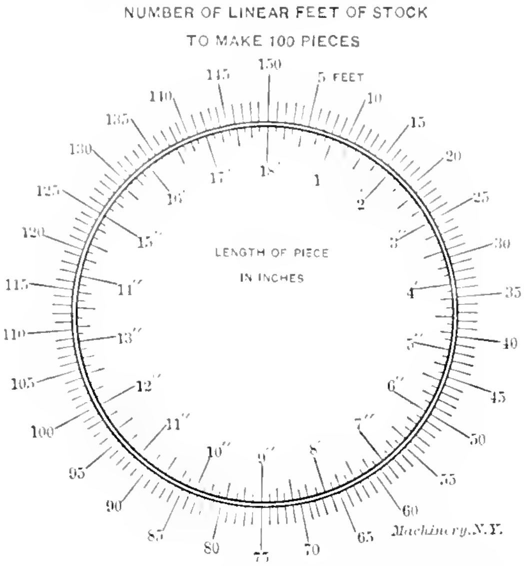

Chart by which the Number of Linear Feet of Stock required for a Number of Pieces of given Length, may be determined.

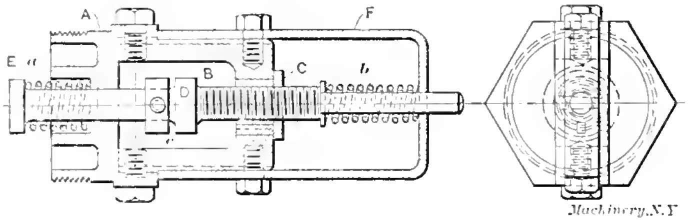
For example, if the length of a piece as per order, is 2⅞ inches, and there is an allowance for cutting off of ⅛ inch, the total length of the piece would be 3 inches. By locating the figure in the outer circle which is opposite the figure 3 in the inner circle, we find that the required number of feet for making 100 pieces is 25; having this, the amount of stock for any number of pieces may easily be determined.

Rochester, N. Y. RALPH W. DAVIS.

VALVE TIMING GAGE FOR AUTOMOBILE MOTORS.

The valve-timing gage, shown in the engraving, has been in use for some time and has been found very satisfactory. It is far superior to the old method of timing valves, with a screw driver. With this gage the exact opening and closing of the valve, relative to the fly-wheel, can readily be determined. The body *A* is made to fit the valve plug hole in the cylinder head of the motor. *B* is a guide for bushing *C* which is keyed to keep it from turning when spindle *D* is adjusted. Bushing *C* must be a slide fit in guide *B*. Spindle *E* is held in contact with the valve head by spring *a*. *F* acts as a guide for the upper part of spindle *D* and also holds spring *b* in position. The construction of the gage can readily be understood by referring to the engraving.



Gage for Obtaining the Opening and Closing Point, Relative to the Fly-wheel, of the Valves on Automobile Motors.

When the gage is to be applied to an engine it is threaded into the cylinder valve-plug hole, and the spindle *D* is adjusted until a thin piece of paper can freely move between the collar *c* and the spindle *D*. This should be done when valve to be timed is closed. The fly-wheel of the motor is then turned very slowly until the paper is held tight between *c* and *D*; but the bushing *C* should still be seated on the guide *B*. A point is then marked on the fly-wheel for the valve opening. The fly-wheel is again turned slowly in the same direction, while pulling on the paper, until the paper is released; this will indicate the closing of the valve. These points are numbered on the fly-wheel according to the number of the cylinder timed.

St. Louis, Missouri. C. T. SCHAEFER.

A THREE-SPINDLE MILLING ATTACHMENT.

A three-spindle attachment for the milling machine is shown in the accompanying drawing, where Figs. 1 and 2 represent the front and side elevations of the complete device, while Fig. 3 is a sectional view. The device is clamped to the milling machine by fastening the bracket *A* to the overhanging arm. The central or main spindle *B* is driven by the spindle of the machine to which the head is attached, by means of the taper arbor *C* which is fastened to the spindle of the attachment by a locking cap, as shown in Fig. 3. Each of the three spindles has an independent longitudinal adjustment. This adjustment is made by screwing the rear bearing in or out of the housing, as the work may require. The spindles are locked in place by the check-nuts *D*. The small spindles *H* are driven from the main spindle by the gears *E*. Figs. 1 and 2 show part of the supporting bracket cut away in order to expose the worm-wheel and worm which are used for rotating the spindles *H* about the main spindle *B*, by turning the handle *F*. The latter is provided with graduations which read to minutes, for measuring the angular adjustment of the spindles. Figs. 4 and 5 show the attachment set for cutting three T-slots, which, in one case, are close together, and in the other further apart. The rotation of the head is sufficient to obtain a considerable

Fig.6

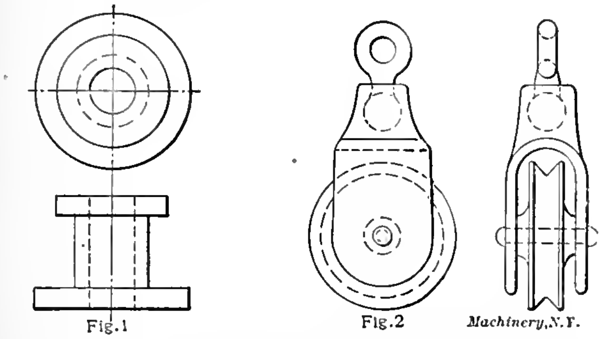
An Attachment with Spindles having an Angular Adjustment for Varying the Distance between T-slots, etc.

variation in the distance between slots. Fig. 6 shows the device as equipped for cutting dovetails, finishing the several surfaces at one cut. Various forms of dovetails, T-slots, grooves, etc., can be worked out in similar fashion. Obviously, the same cutters may be used in many cases for milling parts which are to fit together, a slight rotation of the head giving the necessary play in the finished piece. The same method can be employed for compensating for wear, or allowing for a reduction in size by grinding. The cutters for these different purposes may, of course, be of various sizes, and the one on the main spindle will differ from those on the outer spindles in that it will be cut to the opposite hand. This attachment will be found to be more useful for factory than jobbing purposes, and where any amount of such work, as illustrated in Figs. 4 to 6, is being done it will be found to greatly reduce the labor cost of production as compared with the old single spindle method.

Washington, D. C. G. ROBERT O'NEAL.

SOLUTION OF THE CASTING PUZZLE.

In MACHINERY for January, there appeared a short article descriptive of a casting puzzle. The engravings accompanying it showed a brake ratchet with a loose bushing, flanged on each side, cast in the center of the pawl. The usual method of making castings of the kind in question, is to first cast the bushing, as shown in Fig. 1, clean it, coat it with graphite, and place it in the mold in which the piece to surround it is to be cast, in the same manner as an ordinary baked sand core would be placed. The coating of graphite prevents the molten metal from adhering to its surface. A little observation shows that castings of this kind are more common than is generally supposed. Pulley blocks of the type shown in Fig. 2 are a fair example of the class of casting referred to. They are commonly used for stretching clothes lines or for similar purposes, and retail at 10 cents each.



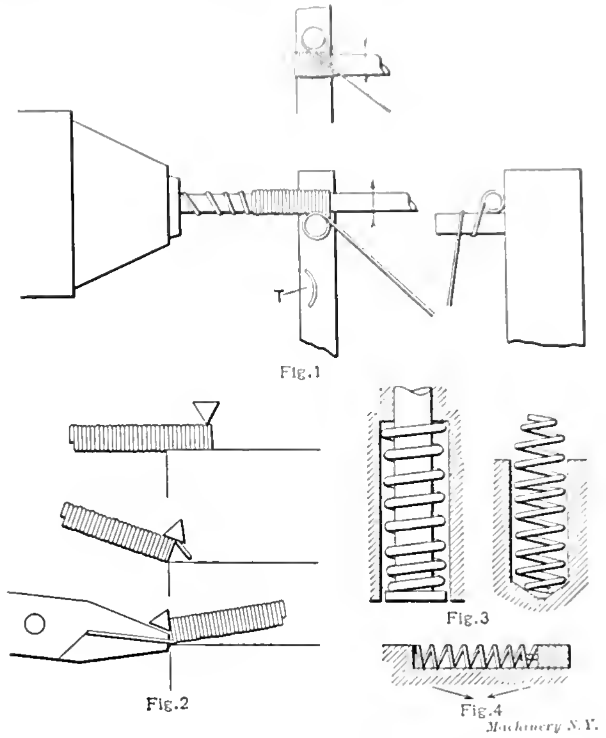
Figs. 1 and 2. Bushing around which Pawl is cast, and Sheave and Block which are cast together.

JAMES CRAN.

Plainfield, N. J.

WINDING SPRINGS.

I have used, for some time past, a tool for winding springs with initial tension which is not only effective, but is much simpler and more convenient than the one described by Mr. Viall in the February issue. With this tool, springs can be wound without any gearing up or bother other than to put a drill chuck in the spindle and clamp a tool in the tool-post. I keep a piece of steel with my lathe tools of the same size as the tools, and use it principally as a rest for the hand tools and polishing sticks, when working out punch and die contours, and for several other purposes. This tool has several holes in it in various positions, some of them tapped and others blank. One of these holes serves to hold a quarter-inch pin that is used when winding springs. Fig. 1 shows this tool in use, and it should be noticed, in particular, that it is set at such a height and in such a position that the spring mandrel is well supported. With this tool, right- or left-hand springs can be coiled and the lathe may be run forward or backward. As before stated, it is not necessary to gear the lathe, but if this were done, the lead should not be a few thousandths more or less than the size of the wire, but theoretically just that size; as it would not come out just right anyway on a long spring. My method is to throw in the nearest carriage feed, set the compound rest parallel to the ways, and with it take up the difference between the wire lead and the feed of the carriage. It makes little difference whether the wire leads off the pin exactly in line with the last coil, a little ahead of it, or three or four coils behind; and if the spindle speed is not too high it is easy to make the necessary adjustment with the compound rest. At *T* is illustrated the set given to the wire in rounding the post, which gives it the initial tension—it is really a spring coiled against itself.



Figs. 1 to 4. Methods of Winding and Fitting Springs.

There are several other things about coiled springs that come to my mind which may be of interest. Eyes for the springs may be formed over the sharp edge of a vise or plate with a three-cornered scraper or file ground smooth. This work, which is done in three stages, as illustrated in Fig. 2, is accomplished quickly, and a very neat and square eye is the result. When a number of springs are to be made alike, I count the coils by drawing the edge of the scraper along the length of the spring, allowing one coil for the eye, and then press the scraper down, as illustrated. By keeping the eye already formed on the end in the proper position, all the springs will come out with a full eye and all eyes will bear the proper relation to one another, all being alike or half-quartered one way and half the other, as desired. When springs are always wrong there is usually a good reason. The spring *A* in Fig. 5 will lie flat and stay on its pins. Spring *B* is adapted to pins in different planes, but if used instead of *A* it will probably be necessary to make another soon for want of the original. Sometimes a spring should act both torsionally and in tension; then one like *C* will answer if given sufficient twist before it is pinned in place. Compression springs are more often used in this way. When fitting a compression spring over a stem and in a hole, close the end that thrusts against the stem until it is a tight fit and is fairly central, and open the end that bears in the hole until it also is a good and a central fit, as indicated in Fig. 3. If the spring is heavy grind the ends about square. When

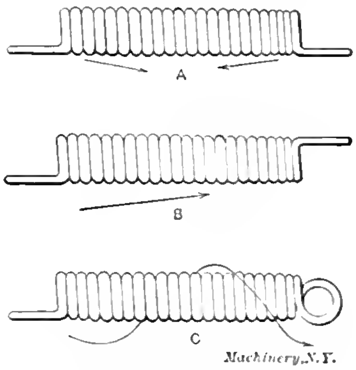


Fig. 5. Springs having Eyes located with Reference to the Retaining Pins.

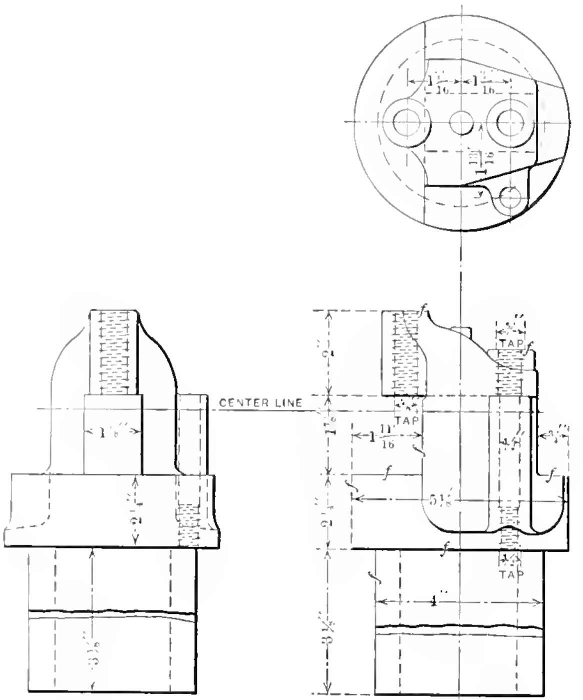
springs are fitted in this way the stem is not chewed in half, and dust from the holes does not clog other working parts. In fact, the spring is just as good and works as freely at the end of a year as when new. Fig. 4 shows a spring that was used continuously and had to be replaced often and quickly. Many schemes were tried in order to keep it in place and at the same time have it accessible. By cutting the ends so that they both bore on top and placing the spring as shown, the thrust kept it in place and the spring was easily removed and replaced when necessary. When grinding heavy springs to square them, do not quench them when they are red hot, or you may have trouble in getting out those same ends after they have broken and done some damage.

SIRIUS.

ELEVATING TOOL-POST DESIGN.

In the February number of MACHINERY under the title "Changing Old Lathe to Increase Cutting Value" an article appears which lays particular stress on the so-called "new" design of tool-post. The tool-post, as outlined, almost to the identical dimensions, was first used by us in 1883, under patent rights purchased from Mr. Lipe. We continued its use under the patent, exclusively, until about 1897-8, when the patent expired. Blue-print of our shop drawing No. 23, March 15, 1883, (reproduced herewith) will show that the designs of the two tool-posts are practically identical.



Elevating Tool-post used by the Bullard Machine Tool Co.

S. H. BULLARD, Vice-President

Bridgeport, Conn. Bullard Machine Tool Co.

[The contributor of the article in question did not claim that the design was new, and the title to the illustration, Fig. 2, was unfortunately worded. Its meaning is that the illustration shows the *new* tool-post that was substituted for the old one, and not that it is of new *design*.—EDITOR.]

USE OF BOW-DRILL IN THE MANUFACTURE OF KNIVES.

That a curiosity like the hour glass finds a place in modern manufacturing, as cited in the January issue of MACHINERY, is an instance of how the mechanical world in its ceaseless striving for the improved, will turn to the records of the past and take from them and adapt to present-day use some primitive mechanism long since discarded and forgotten. A parallel case is found in the employment of the prehistoric bow-drill, of the North American Indians, in certain knife factories. Probably few of us ever give a second thought to the initial plate inserted in the handles of our pocket knives. In cutting the recess for these the bow-drill works with a neatness and dispatch that surprises one. More intricate shapes demand a more laborious process, but the simpler ones, such as ovals, round-ended oblongs, and other forms not requiring sharp corners, are mortised out with the bow-drill. The spindle carries in its lower end a chuck in which is held a tool made of two prongs of steel much like a tuning fork but sharpened and pointed so as to fly outward with the centrifugal force generated by the revolution. A metal templet having a hole the size and shape of the recess to be cut, is placed over the wooden handle which is gripped in a special vise *A*. Then the operator, usually a boy, grasps the bow-drill in both hands, gives the bow a couple of vigorous pulls, meanwhile imparting a slight longitudinal swinging motion in the direction of greatest length, and produces almost instantaneously a hole which is the counterpart of that in the templet. The cutters *B* are made from a piece of rectangular stock turned the full length, except that part which fits in the slot of the chuck or socket. After the pivot pin holes *C* have been drilled, the piece is split in two and it is then ready for tempering. Cutting edges are formed on the lower ends by grinding the inside, as shown at *D*. But a small part of this sharp end touches the templet, so that the wear of the templet and cutters is hardly more than would occur between two unbroken hardened surfaces running at the same rate. To cause the points to spread more readily, a spring acting in the same manner as a caliper spring is slipped over the upper ends, as shown at *E*. Except for the purpose mentioned above, the bow-drill is, for the most part, merely a museum curiosity, yet for this mortising of knife handles it holds its own and gives complete satisfaction.

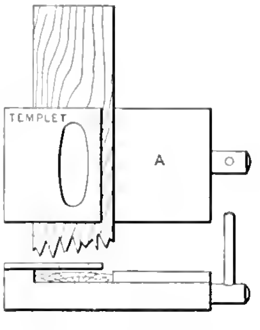


Fig. 1. Vise and Templet with Handle in Position.

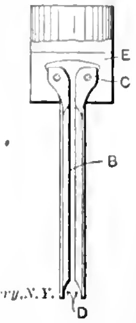

Fig. 2. Centrifugal Cutter which is controlled by the Templet.

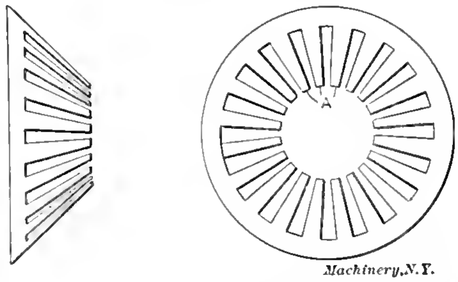
Middletown, N. Y. DONALD A. HAMPSON.

TO KEEP AN ANGULAR REAMER FROM CHATTERING.

We have a 45-degree reamer which is used for reaming valve seats in our cut-out valves. This work was formerly done in the lathe, and when the reamer was so used, it did very satisfactory work; but in order to lessen the cost of production the drill press was tried. At first, the reamer chattered so that the drill press had to be abandoned; but this chattering was finally overcome by the use of a leather washer, such as here illustrated, under the reamer. The leather strips *A*, which are a little thicker than the depth of the teeth, are placed between the latter. When making the washer a block of hard wood was fastened to the drill press table with the grain vertical, and an impression made in the wood by running the reamer into the end. A piece of leather of suitable size was then soaked in warm water until it was perfectly pliable. At night, when the shop shut



Leather Washer which fits between the Reamer Teeth and prevents Chattering.

down, the leather was laid over the impression in the wooden block and the reamer forced into it by the hand feed. The leather was left in this position over night, and in the morning it was dry, and formed perfectly to the tool. All that remained to be done was to cut spaces for the reamer teeth.

Geneva, N. Y. Roy B. Deming.

UNIVERSAL CAMERA BRACKET.

In the February, 1908, issue of Machinery, the writer described a simple camera holder to be used when photographing tools or other objects laid on the floor. However, the writer has since then seen another camera bracket which is even better and which combines the features of being universal, rigid, and cheap. It is far superior to the ordinary ball and socket joint universal camera holder, where the camera is liable to fall over in any direction when the thumb nut is loosened.

Fig. 1. Universal Camera Bracket of Simple Design.

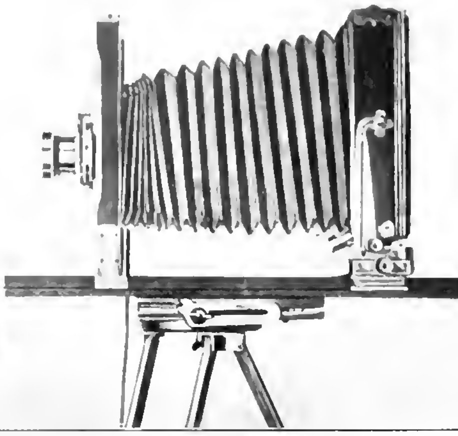


Fig. 2. Camera mounted in Horizontal Position in Bracket.

Fig. 3. Camera mounted in an Inclined Position.

The accompanying illustration, Fig. 1, shows very plainly the general construction of the bracket, and the illustrations, Figs. 2, 3, and 4, show the camera in different positions, mounted on the tripod. The detail dimensions given below are for brackets used with a 5 by 7 inch camera. The top and bottom boards, which are each made of three layers of wood glued together, are 5¼ inches wide, 7½ inches long, and ⅜ inch thick. The top of the tripod, on which the bracket is mounted, is 5 inches in diameter, and the boards were made 5¼ inches wide, in order to make the side clamping pieces clear the top of the tripod. The two boards were made by a trunk maker for 35 cents. The two hinges are common 1¼-inch brass hinges which will cost 5 cents. The two thumb nuts and the thumb screw required may be bought for another nickel. The adjusting slides are cut and filed out of 1/16-inch spring brass, the slot in them being 2¾ inches long, and just wide enough to admit a 3/16-inch bolt. This bolt is made like an ordinary stud bolt, except that it is provided with wood-screw threads on one end. The end provided with standard threads has a screw driver slot cut into it. A brass nut is set into the lower board, 2½ inches from the edge on which the hinges are fastened. The regular tripod thumb screw is screwed into this nut. The thumb screw which fastens down the camera is set into the upper board 3½ inches back from where the tripod thumb screw comes through the lower board. A hole, 1⅝ inch in diameter, is cut into the lower board, for the head of the thumb screw in the upper board, so that two boards may be folded together. The object of placing the thumb screw holding the camera so far back, is to provide means for getting at both thumb screws at the same time, no matter what the position of the camera. A piece of cotton flannel cloth is glued to the top of the upper board to avoid scratching the camera base, and to prevent slipping. The bracket is easily carried fastened to the tripod, and provides the cheapest and most useful camera bracket the writer has ever seen. Ethan Viall.

Decatur, Ill.

SQUARES ON THE ENDS OF TAPS AND REAMERS.

It is to be regretted, in these days of standardization, that our tap manufacturers cannot all get into line regarding the sizes of the squares on the ends of taps. Owing to the bruised and twisted squares on the ends of taps in a shop I recently worked in I had to help in systematizing the whole matter of squares on the ends of taps and reamers. It was found that the taps as made by the makers did not have the same size squares; they were thus often very loose fits for our tap wrenches, so it was decided to ask six of the best-known tap manufacturers to submit the sizes of squares adopted by them for their taps, and from these details to determine a standard.

Table I shows the different makers' practice, which, as can be seen, varies very much, and as experience has shown that even these sizes are only used approximately, it was decided to adopt the standard as shown by the last column, to use solid tap wrenches with square holes of these standard sizes, and to grind down the squares of all taps in use to a few thousandths below these sizes. By comparing the last column with the other sizes, it will be found that it is now possible to buy taps from any of these six makers with the assurance that the square can be made to suit our standard tap wrenches. All new taps bought must, of course, be carefully examined regarding the squares, and, where necessary, be at once ground down to the standard.

While the above only discusses the question of squares, I should like also to say that there seems to be a difference of opinion among manufacturers as to the amount to leave on the diameter of new taps so as to ensure a reasonably long life and yet, at the same time, make them conform to standardized screw gages. For instance, one maker sends out his ¼-inch taps 0.0025 inch above nominal diameter, while another sends them 0.01 inch above. Why this difference? It cannot all be accounted for by distortion in hardening; it therefore raises the question of what are the practical limits. If 0.0025 inch is sufficient, then 0.01 is too much, and *vice versa*. This point, therefore, should receive some special consideration from tap manufacturers so that one set of limits might be adopted and adhered to by all manufacturers of taps.

TABLE I SIZES OF SQUARES ON TAPS

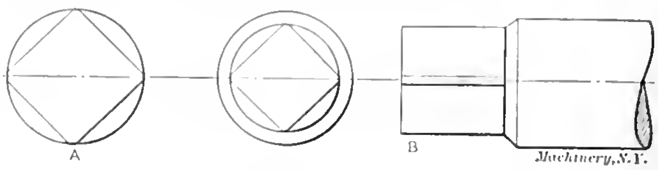
Diameter of Tap.	Maker No. 1.	Maker No. 2	Maker No. 3.	Maker No. 4	Maker No. 5.	Maker No. 6.	Adopted Squares.
1/8"	5/32"	7/64"	1/8"	0.145"	3/16"	5/32"	3/32"
5/32	5/32	9/64	1/8	0.145	3/16	5/32	1/8
3/16	5/32	5/32	1/8	1/8	3/16	5/32	1/8
7/32	5/32	11/64	3/16	11/64	3/16	5/32	5/32
1/4	3/16	3/16	3/16	13/64	3/16	3/16	3/16
5/16	3/16	1/4	7/32	1/4	1/4	13/64	3/16
3/8	7/32	1/4	7/32	7/32	1/4	15/64	7/32
7/16	1/4	9/32	1/4	7/32	1/4	7/32	7/32
1/2	5/16	5/16	1/4	17/64	9/32	5/16	1/4
9/16	11/32	11/32	5/16	5/16	5/16	11/32	5/16
5/8	3/8	13/32	11/32	11/32	3/8	25/64	11/32
3/4	7/16	15/32	7/16	27/64	7/16	15/32	13/32
7/8	9/16	9/16	1/2	1/2	9/16	35/64	1/2
1	5/8	21/32	19/32	9/16	5/8	5/8	9/16

The squares on the shanks of reamers are in the same unstandardized state. Table II gives sizes of squares adopted by two of the most prominent American makers of hand reamers. Each maker has a standard of his own, which is different from his neighbors', and is also different from that adopted by the tap manufacturers, so that it would be required to buy a great many wrenches to cover the requirements unless some such plan of standardization as outlined above is adopted. Of course, adjustable tap wrenches might be used, but solid tap wrenches are preferable if a number of taps and reamers are in daily use, because there are no parts to get out of order; they are, as a rule, lighter and are thus easier to handle, giving the operator more command over the tap or reamer; they are cheaper, and therefore a fuller equipment can be had with the same investment of capital; and a much closer working fit can be maintained between square and square hole, thus obviating the unsightly twisting off of the squares. "MECHANIKOS."

TABLE II. SQUARES OF HAND REAMERS.

Reamer Sizes.	Maker No. 1.	Maker No. 2.	Reamer Sizes.	Maker No. 1.	Maker No. 2.
1/2"	3/8"	3/8"	1 3/16"	11/16"	11/16"
9/16	3/8	3/8	1 1/4	7/8	7/8
5/8	7/16	3/8	1 5/16	15/16	7/8
11/16	15/32	3/8	1 3/8	15/16	7/8
3/4	15/32	9/16	1 7/16	15/16	7/8
13/16	17/32	9/16	1 1/2	15/16	1
7/8	9/16	9/16	1 5/8	1	1
15/16	5/8	9/16	1 3/4	1	1 1/4
1	5/8	11/16	1 7/8	1	1 1/4
1 1/16	11/16	11/16	2	1	1 3/8
1 1/8	[illegible]	11/16	2 1/4	1	1 3/8

[The question of uniformity in the size of squares on taps and reamers is certainly one that ought to receive proper attention. In the case of the squares on taps as indicated by the last column in Table I. it will be seen that when the square is made small enough to be below the size of that used by all the makers of taps, sharp corners are produced when the squares are ground down to this size. Square corners on a tap or reamer square are rather objectionable; not only does it make the tool unpleasant to handle, but the appearance and finish of the tool is greatly impaired. The proper square for any size of shank is to make the size of the square equal to ¾ of the diameter of the shank. This will leave small rounded portions at the corners of the square, as shown at *A*, in the accompanying engraving. In the case of hand reamers, however, the squares should not be milled directly on the shank as is the case with taps, because the shank on hand reamers is of nearly the same diameter as the reamer itself, and is supposed to be able to pass clear through a reamed hole. If the square is milled directly on the full diameter of the shank, burrs will be thrown up by the wrench, and these are liable to mar the reamed hole. The end of the shank of a reamer should therefore always be made as indicated in the engraving at *B*. The shank should be turned down a sufficient amount below its full diameter for the length of the square, and then a square equal to ¾ of the diameter of this turned-down portion should be used. Some makers do not turn down the end of the shank, but simply mill the square small enough so that the edges of the square come below the outside diameter of the shank, but this, of course, produces sharp corners, gives an unsightly appearance to the reamer, and makes it unpleasant to handle.—EDITOR.]



Squares on Taps and Reamers.

HOW MANY GASHES SHOULD A HOB HAVE?

In the article with the above title published in the engineering edition of the January, 1909, issue of MACHINERY, the author, after mentioning the well-known relation between the number of flutes in the hob and the number of threads in the worm, says, "this is one requirement, but there seem to be other factors that enter into the decision as well." He then proceeds to explain the relations existing between the number of teeth in the worm-wheel and the number of threads in the worm.

In a letter in the *American Machinist* for October 11, 1906, the writer uses the following language: "Another point learned in the work of Messrs. Brown & Sharpe, is that a hob will sometimes cut rough teeth if the number of teeth in the wheel is a multiple of the number of threads in the hob, even though the hob is fluted in accordance with what I have pointed out in this letter." I have written in regard to this matter, thinking you might like to call attention to the fact that the principle discovered was known in the Brown & Sharpe Works some little time ago.

The outlines of the wheel teeth can sometimes be cut somewhat more accurately and smoothly by shifting the thread of the hob into different tooth spaces, but I should not care to recommend this scheme as coming from the Brown & Sharpe Mfg. Co. OSCAR J. BEALE.

Providence, R. I.

A BEVEL GEAR PROBLEM.

In cases where a bevel gear drive with a shaft at an angle to the face of the frame, and also at an angle to the vertical center line of the machine, producing what might be called a double diagonal shaft, cannot be avoided, the following formulas and illustrations will be of great value in figuring the actual angle between the shafts, as well as the two angles to which the bearings for the double diagonal shaft must be bored.

Fig. 1 shows three views of the drive, and indicates clearly how it is arranged. Fig. 4 is a front view showing the angle x between the shafts in a vertical plane. Fig. 3 is the development of the plane AB, showing the actual length AB_1 between the apices of the bevel gears, and also the actual distance BB_1, to which the upper apex is offset from the lower, and the actual angle between the center lines of the upper gears.

Fig. 2 is a development of the oblique plan AB_1C on which the gear apices A and B_1 are located, showing the actual

length AB_1 between the apices, and the actual angle z between the center lines of the lower gears, for which these gears must be figured. Fig. 5 is a side view showing the shortest distance CB_1 between the center line of the lower shaft and the upper gear apex.

The angle x, the vertical height BC (Fig. 4), and the horizontal distance BB_1, are considered as given. From these we can easily get angle y.

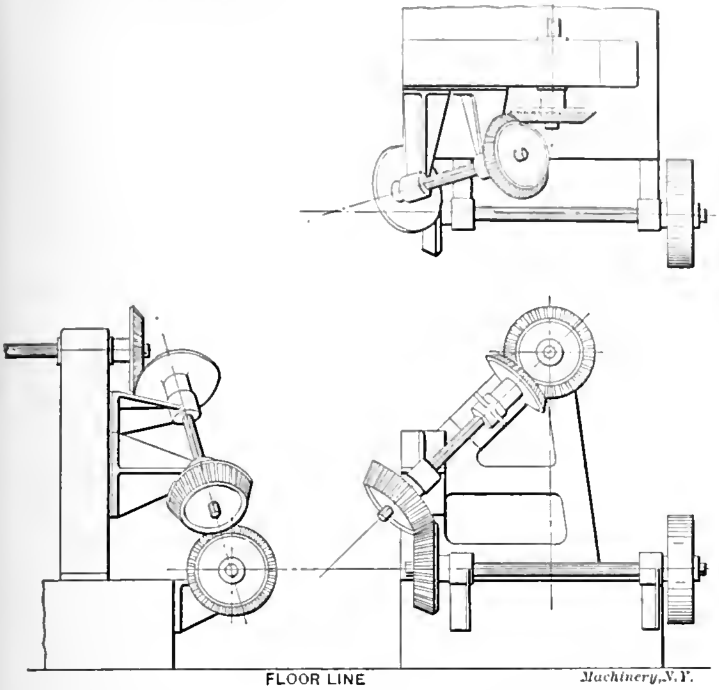


Fig. 1. Arrangement of Bevel Gearing with a "Double" Diagonal Shaft.

The formula for figuring the angle y is deduced as follows: In Fig. 4, let $BC = a$; and angle $= x$; then

$$AC = \frac{a}{\tan x}; \text{ and } AB = \frac{a}{\sin x}.$$

In Fig. 3, $AB = \dfrac{a}{\sin x}$; angle $= y$; then

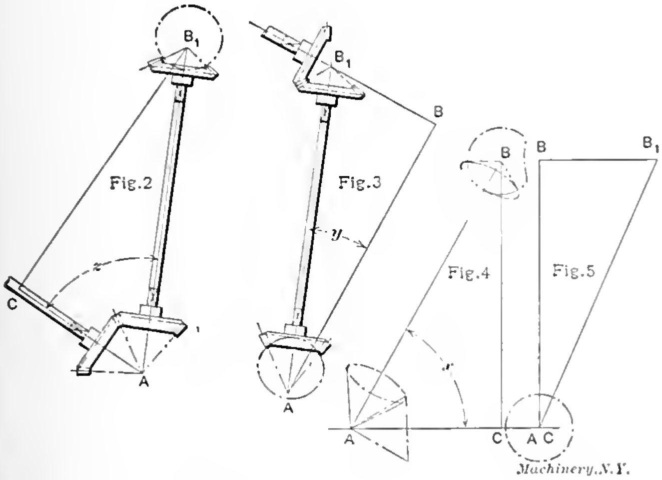

Fig. 2. Diagrams for Solution of Problem shown in Fig. 1.

$$AB_1 = \frac{\dfrac{a}{\sin x}}{\cos y} = \frac{a}{\sin x \cos y}.$$

In Fig. 2, $AC = \dfrac{a}{\tan x}$; $AB_1 = \dfrac{a}{\sin x \cos y}$; angle $= z$; then

$$\cos z = \frac{\dfrac{a}{\tan x}}{\dfrac{a}{\sin x \cos y}} = \frac{a}{\tan x} \times \frac{\sin x \cos y}{a} = \frac{\sin x \cos y}{\tan x};$$

But since $\tan x = \dfrac{\sin x}{\cos x}$

$$\cos z = \frac{\sin x \cos y}{\dfrac{\sin x}{\cos x}} = \cos y \cos x.$$

$$\cos z = \cos y \cos x \qquad (1)$$

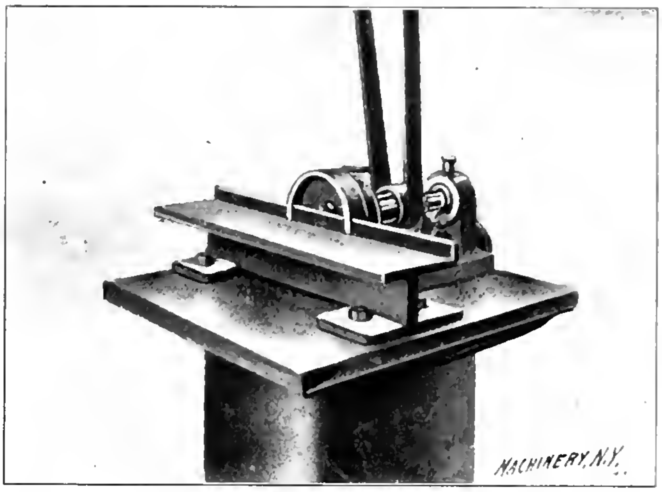
$$\cos x = \frac{\cos z}{\cos y} \qquad (2)$$

$$\cos y = \frac{\cos z}{\cos x}. \qquad (3)$$

Brooklyn, N. Y. EDW. PERSON

SPECIAL GRINDER.

The half-tone engraving below shows a grinder on which work is done much in the same manner as on a buzz planer. A large number of drawn steel strips of various lengths are found to be slightly convex on the sides, the difference being about 0.001 inch in thickness for a width of 5/8 inch. It was required that these strips be of exactly the same thickness for the full length, and for the purpose of making them uniform the grinder illustrated was built. The table is provided with a rib, which is slotted in two places, and the cylindrical part of the cup wheel passes through these slots as shown The table itself is set at a very slight angle to the plane of the face of the wheel, so that only one side of the wheel (that which is running in the downward direction) extends beyond the rib. This side of the wheel projects through the rib about 0.001 inch. By means of this device the operator is enabled to quickly remove the superfluous stock from the steel strips, and to do it accurately.



Special Grinder for Accurate Grinding.

Middletown, N. Y. DONALD A. HAMPSON.

THE EXPERIENCE OF A CUSTOMER.

After reading your editorial entitled "The Experience of Purchasing Agents" I was led to compare the experience of the founding firm mentioned with the treatment handed me by a like firm which, by a queer circumstance, happens to make just such a device as mentioned in the editorial. In my case I was not the seller but an inquiring buyer, with ready cash to pay for what I wanted, out looking for someone to make an article at the best price. The matter I made inquiry about was not of much account, I acknowledge, but it was not the only work I was likely to have to offer such a concern. I went to this company and asked them to cast two sets of parts and to give me an estimate of their charge for finishing a lot of the pieces. The castings were to be ready in two days and at that time I was also to have the figures of their estimate. When the time came I got the castings, for which they charged just seventy-five per cent more than I could get them made for at another place, as I found out later. As for the estimate—well, the official that took my order was out of town and no one else seemed to know about it. "He will be back tomorrow," I was told, so to be decent I went again the next day, but he had not re-

turned I was taken up to see the superintendent whom I found busy with another official painting a box. After waiting about three minutes I was finally approached by the superintendent, but he knew nothing of the estimate. In reply to a query about the cost of castings and how they came to charge so much for the ones they had made, he gave the arguments that one usually hears when a price is questioned. I wanted to laugh when he suggested that when I bought a watch I had to pay for something more than metal at so much per pound. The comparison between making a watch and a simple block of cast iron seemed just a bit bright.

Now what I am writing all this for is to draw attention to the point of view of the purchaser who goes out seeking the best place to spend his money, and what effect the manner in which he is received will have on his decision to leave an order. Surely he will not be likely to waste much time on a firm that does not endeavor to give him good service, and if he goes away with a feeling of disgust he isn't coming back very soon.

If firms have difficulty in selling their wares, and what firm does not, I would like to ask why it is that some neglect to make friends of purchasers who come inquiring about goods.

Somebody will say, perhaps, that the small jobs are not worth bothering with; but everything has been begun in a small way and who can tell what is not going to develop? As in the case previously referred to, the little job might be closely connected with something more important that would be worth getting—at least in these slack times. I have considerable work that I must send out, such as castings and machine work that I can not handle. Will this firm get the work? Hardly, but they would have had it, for they are the handiest for me to go to at present. They also make drill presses and bench lathes that I might need if my present tools gave out or I needed more. How much cheaper it is to make sure of the trade that comes inquiring than that which has to be sought; this seems to me to be a matter for consideration that seldom enters into the business plan of machinery concerns.

How often have I noticed, when going to a factory to inquire about tools or some other product, how patient one has to be to get waited on. Generally one goes into a door and lands up against a rail or a partition with a hole in it, and, after waiting awhile, a small boy asks you how you dare come in, and after you have told him that you only want to spend some money, he goes off and leaves you to sit down to wait. If you do not sit down you are quite likely to get tired of waiting and walk out to some other house. After the salesman finally gets to you he has to make you forget the time and trouble it has been to be able to tell him what your business is.

If the sales agents find that inducing a purchaser to buy something they want to sell is discouraging work, let them get busy and devise some new ways of handling the customer that is trying to spend his money. "A Buyer."

HARDENING TAPS.

Some time ago a certain jobbing shop contracted to produce 100 taps which, as expected, furnished no little trouble in the hardening, before a successful *modus operandi* was worked out. The contract specified a No. 10 tap, 7 inches long, with 4 inches of thread. Threading and fluting was a simple and inexpensive matter, the only extra outlay being for master dies for the screw machine and a special support to keep the taps from springing under the milling cut. Hardening, however presented life-size difficulties. Several of the usual ways were experimented with and discarded. The taps were heated in an open fire, a pot of lead, or a gas furnace, and quenched in oil or water, but the result was always the same—the taps were warped 1/16 inch and worse. A sample submitted to the customer was promptly and emphatically rejected. Then case-hardening was tried, and with an unlooked-for degree of success. The taps were heated in the gas furnace, rolled in a mixture of powdered prussiate of potash and flour, and quenched in water. They came out perfectly true and straight, and the temper was afterward drawn with a blow torch. A subsequent duplicate order (at an advanced price) was an assurance of the satisfaction they gave in service. Just why the taps warped in one case and not in the other, is not apparent, for, with the exception of the case-hardening application, the methods were identical.

DRILL PRESS VISE WITH ADJUSTING JAW PLATES.

I noticed in the February number of Machinery an article on a drill press vise. Mr. A. J. DeLille, in describing the vise, which has several excellent features, devoted the major part of his description to one feature only, viz.: the jaws being under-cut and the jaw plates sliding down when the article to be held is gripped. The work is thus pressed firmly and uniformly down upon the surface of the vise.

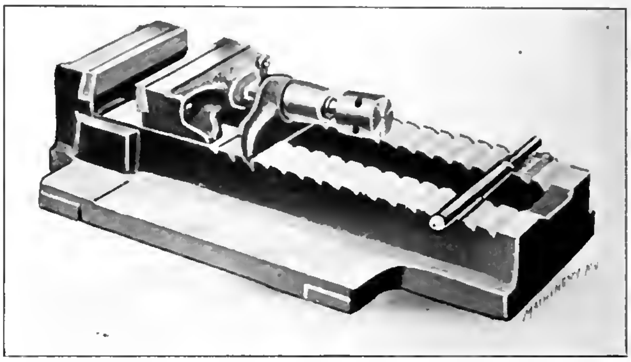

Fig. 1. Taylor's Standard Pattern Machine Vise, with Adjusting Jaw Plates.

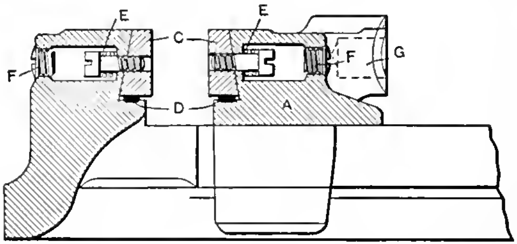
It may interest Mr. DeLille to know that I am the inventor and patentee of this vise, and I take this opportunity of expressing my surprise that it has not come into wider use in the United States. I do not see why practically every machine vise should not be made with these sliding jaw plates. My patents expired some years ago, and there are six or seven British firms, in addition to myself, making this type of vise, and on the continent, especially in Germany, it is made by thousands. Yet none of the leading United States makers show it in their list of vises. I have failed to find any adequate reason for this vise not meeting equal popularity in America. Charles Taylor.



Machinery,N.Y.

Fig. 2. Section through Vise, showing Construction of Jaws and Sliding Plates.

Birmingham, England.

[The following description is supplied by Mr. Taylor: Fig. 1 shows the Taylor standard pattern vise, and Fig. 2 is a section of part of the vise showing that the rear faces of the steel jaw plates *C* are inclined, thus causing them, when an article is gripped in the vise, to slide downward for a very short distance, carrying with them the article held, the pin holes in the jaws being slotted to allow of this motion. The jaw plates are held back against the jaw by screws and springs *E*. The jaw plates are raised again, when the article held is released, by simple springs, working in the recesses *D*, shown at the bottom of each plate. The small cap-screws *F* keep water and dirt from entering the pin holes. *G* is a piece of hardened steel fixed in the jaws to receive the pressure of the screw.—Editor.]

* * *

A rival of the Maxim muffler for firearms has been invented by Joseph C. Coulombe, a graduate of Norwich University, Northfield, Vt. The Coulombe invention differs from the Maxim silencer in that it is not an attachment to the end of the barrel, but forms part of the barrel itself.

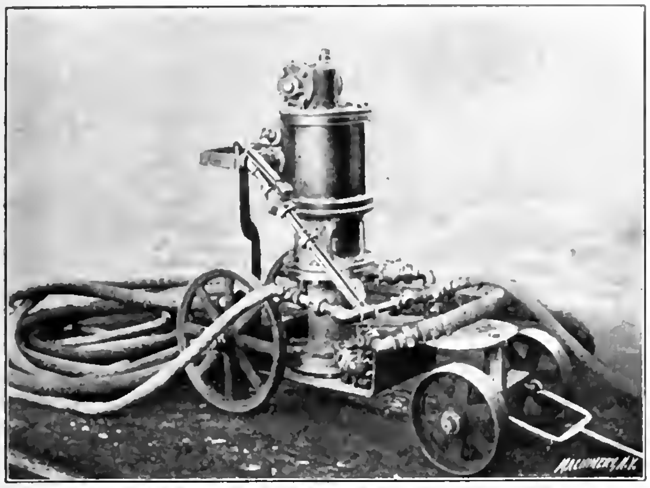
SHOP KINKS.

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A PORTABLE LOCOMOTIVE BOILER TESTER.

A very convenient apparatus for testing locomotive boilers is in use in the Fort Wayne shops of the Pennsylvania Railroad. The device consists of a powerful water pump operated by air, which is mounted on a truck as shown in the illustration. This machine, together with the necessary hose, is easily moved to wherever it is needed; the air hose is then connected with the regular shop air supply and the water suction hose with the water supply. The discharge end of the water hose is coupled to the inlet valve on the boiler. The pump is then started and the cold water pressure run up to the desired point. After the test is over, the air and water hose are coiled around the pump cylinders and the machine is moved out of the way until it is again wanted. E. V.



ADJUSTABLE V-BLOCK.

Of the thousand and one appliances such as jigs, etc., that are in use in machine shops, there are but few that are applicable to more than the one purpose for which they were designed. In the shop in which I am employed, there is a pair of V-blocks used for the purpose of holding spindles that are to be splined their entire length and which vary in diameter from 3¾ to 7 inches. It was found quite difficult to hold these spindles in ordinary V-blocks or in a slot of the planer platen with ordinary clamps and bolts. The V-blocks shown herewith not only hold the work securely, but adapt themselves to spindles of different diameters. They are cast hollow to make them light. The angles of the sides *A* and *B* are 30 and 60 degrees, respectively. The clamps are slotted, as shown, to permit adjustment and are tightened against the work by two ¾-inch collar bolts. These blocks, which have a very powerful grip, are also useful for holding large impression rolls when slots to receive a steel blade are being cut in the rolls. They can also be used to advantage on the milling machine when doing work such as here illustrated. C. E. Hale.

PARALLELS FOR VERTICAL BORING MILLS.

The parallels illustrated herewith, which are for use on the vertical boring mill, are almost invaluable for the chucking of pulleys, gear blanks, or anything that requires to be parallel with the face of the chuck. The parallel with four arms is intended to be used in conjunction with a four-jawed chuck, while the one with the three arms is for a three-jawed chuck. A cored hole should be provided in the center, as shown, which is somewhat larger than the holes being bored, to provide clearance for the boring tool. One of the most valuable features of a parallel of this type, is that it is impossible, when starting up the machine at high speed, for it to fly out and strike the operator. We have all our mills fitted with these parallels to accommodate the different sizes of work, and would dislike very much to have to do without them.

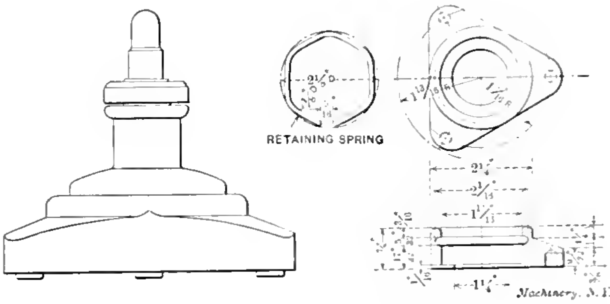
HOLDER FOR THE INK BOTTLE.

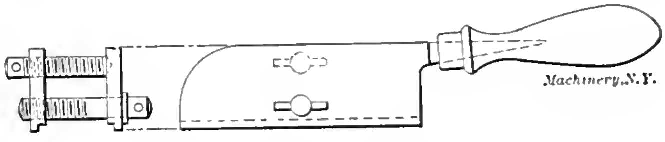
One of the draftsman's troubles is that of keeping the ink bottle right side up, and although there have been many holders for this purpose, the one shown herewith will, I think, be of interest to fellow draftsmen. The bottle is held in place in the holder by a retaining spring which fits in the recess shown in the sectional view. This spring can be made in different shapes, if necessary, so as to receive almost any size or shape of bottle which will pass through the opening. When the spring is made to the dimensions given, it will be the right size when in place for holding a Higgins ink bottle. Common lead pencil rubbers are inserted into the three holes shown in the bottom of the holder for the purpose of preventing it from sliding when it is placed on a very slanting surface. C. S. Blank.



Indianapolis, Ind.

OFFSET FILE HOLDER.

A simple form of offset file holder is shown in the engraving. The two sides are made of ¼-inch soft boiler steel, and between these the file is gripped. The lower screw shown, draws the jaws together, and the upper screw spreads them apart, thus forming a powerful clamp. The file is gripped anywhere along its body, and as the teeth sink into the soft jaws, the handle is prevented from coming loose. This device may be used with more comfort when the handle is set at an angle as shown. L. J. Sparks.



Chester, Pa.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give details and name and address. The latter are for our own convenience and will not be published.

TO OBTAIN THE SIDES OF A RECTANGULAR AREA IN THE SAME RATIO AS THE SIDES OF A GIVEN RECTANGLE.

B. W. C.—1. What is the rule for finding the dimensions of a rectangular area that shall have the same ratio between the sides as a given smaller rectangle? 2. What is the rule for finding the dimensions of a square prism whose sides shall be in the same proportion as a given smaller square prism?

A.—The rule is to divide the area of the required rectangle by the area of the given rectangle, and extract the square root of the quotient. The square root is the factor by which the dimensions of the given rectangle are to be multiplied to yield the dimensions of the required rectangle. For example, having given a rectangle 3 × 4 square feet, what are the dimensions of a rectangle having 192 square feet, with the sides of the same ratio? The area of the given rectangle is 3 × 4 = 12 square feet. 192 feet divided by 12 equals 16. The square root of 16 is 4. Multiplying both dimensions of the given rectangle by 4 yields 12 and 16. 12 × 16 = 192 square feet, the required rectangle. 2. Follow the same procedure for a solid as in the case of a rectangle, except that the cube root of the ratio of the given and required solids is found, and dimensions of the given solid are multiplied by the cube root, the result being the dimensions of the required solid. Example: A tank is 3 × 4 × 5 feet and it is desired to construct another tank containing 480 cubic feet with sides in the same ratio. What are the dimensions? Divide 480 by 60 the cubic contents of the given tank, extract the cube root of the quotient and the root is 2. Then the required tank dimensions will be 6 × 8 × 10 feet.

PROBLEM IN GRADUATING.

J. H.—The illustration shows a measuring tool which has a table in which two plugs *A* and *B* are located. The pin *a* is concentric with the plug *A* which is stationary. The plug *B* is free to turn, and pin *b* is 0.016 inch eccentric with it. The illustration is not drawn to scale in order that the problem may be made as clear as possible. The distance between the centers of the pins *a* and *b* is 11.984 inches, when *b* is in the position shown. I want to graduate the table, as shown at *C*, so as to increase the distance between the pins by thousandths of an inch. That is, so that when point *o* reaches the first graduation, the center of pin *b* will have advanced 0.001 of an inch, and so on up to 0.016 inch, when the center distance will be 12 inches.
